For integrating the sub-view solutions to obtain the collective solution for the complete view, we first *order* the sub-views. Then, we iteratively build the view-solution by *aligning* and *merging* the next sub-view solution in the given order. Let \mathbb{S} denote the input list of sub-view solutions, and *viewSol* be the final view solution that we wish to compute. Algorithm 3 describes the high-level process for constructing *viewSol* from \mathbb{S} , and its ordering, aligning and merging procedures are described in the remainder of this sub-section.

Algorithm 3: View Solution Construction

```

1  $\mathbb{S} \leftarrow \text{ORDERSUBVIEWS}(\mathbb{S});$ 
2  $\text{viewSol} \leftarrow \emptyset;$ 
3 foreach  $s \in \mathbb{S}$  do
4    $\text{viewSol}, s \leftarrow \text{ALIGN}(\text{viewSol}, s);$ 
5    $\text{viewSol} \leftarrow \text{MERGE}(\text{viewSol}, s);$ 

```

5.1.1 Sub-View Ordering. Ordering is implemented through a greedy iterative algorithm where we can start with any sub-view as the first choice. Subsequently, at iteration i , let the set of visited sub-views until now be \mathbb{S} . A sub-view s from outside this set can be chosen to be the next in the ordering only if it satisfies the following condition: On removing the common vertices between s and \mathbb{S} in the (chordal) view-graph, there should not exist any path between the remaining vertices of s and the remaining vertices of \mathbb{S} . This algorithm is described in detail in [21].

5.1.2 Aligning. After obtaining the sub-view merge order as per above, in every iteration we merge the next sub-view solution (s) in the sequence to the current view-solution (*viewSol*), after a process of alignment. The alignment algorithm is a two step exercise, as shown in the example of Figure 8:

Solution Sorting: First, the *viewSol* and s solutions are each sorted on their common set of attributes to facilitate direct

comparison of their matching ranges. For instance, the solutions A, B and A, C in Figure 8a are each sorted on the intervals enumerated in the common attribute A .

Row Splitting: Our addition of consistency constraints during the LP formulation ensured that the distribution of tuples along the common set of attributes is the same in the various sub-views. Therefore it is easy to see that the sum of NUMTUPLES values in any interval of the common attributes is the same for the sub-view solutions under alignment. For example, in Figure 8a, the total number of tuples with $A = [40, 60]$ is 30K in both the A, B and A, C solutions. Likewise, the other entries in column A also have matching total number of tuples across the solutions. The align step *splits* the rows in these solutions such that the corresponding rows in both solutions have the same number of tuples. The sub-view solutions of Figure 8a are shown in Figure 8b after undergoing the alignment process, with both solutions now having identical NUMTUPLES in the corresponding rows.

A	B	NUMTUPLES	A	C	NUMTUPLES
[60, inf)	[0, inf)	30K	[60, inf)	[0, inf)	30K
[40, 60)	[0, 5) U [15, inf)	20K	[40, 60)	[2, 3)	30K
[40, 60)	[5, 15)	10K	[20, 40)	[0, 2) U [3, inf)	20K
[20, 40)	[5, 10)	10K			
[20, 40)	[15, inf)	10K			

(a) Sub-view Solution

A	B	NUMTUPLES	A	C	NUMTUPLES
[60, inf)	[0, inf)	30K	[60, inf)	[0, inf)	30K
[40, 60)	[0, 5) U [15, inf)	20K	[40, 60)	[2, 3)	20K
[40, 60)	[5, 15)	10K	[40, 60)	[2, 3)	10K

[20, 40)	[15, inf)	[0, 2) U [3, inf)	10K

(c) Merged View Solution

Figure 8: Align and Merge Example

5.1.3 Merging. This is the last step in the construction of the view solution. Here we simply merge the two solutions obtained after alignment through a “position” based join, where the physically corresponding rows in each solution are combined, with the common attributes being represented once. For example, the aligned solutions of Figure 8b are merge-joined using the positions (or row identifiers) to deliver the final view solution of Figure 8c.

As discussed earlier, DataSynth adopted a sampling algorithm for constructing the view solutions post LP solving. In marked contrast, Hydra *deterministically* generates the view solutions, facilitating us to operate purely in the summary space. There are

two tangible benefits of this deterministic strategy: (a) elimination of the time and space overheads due to sampling, and (b) elimination of sampling-based errors in satisfying CCs.

5.2 Instantiating View Summaries

As shown in Figure 8c, each row in the view solution is comprised of a series of intervals (across various attributes) and the number of tuples in the region represented by these intervals. We now need to decide as to how these tuples are distributed *within* the attribute intervals. Our current solution is very simple: Assign the *entire* cardinality to the *left boundaries* of the intervals. For example, the third row in Figure 8c would result in generation of 10000 tuples all having $A = 40, B = 5, C = 2$ values.

Note that, in principle, we could have used a more sophisticated cardinality distribution within the intervals. However, our simple deterministic choice helps to reduce the subsequent additive errors that are incurred while ensuring referential integrity across views (described in next subsection). This is so because choosing values deterministically within a bucket minimizes the likelihood of encountering an fk value that is not present in the corresponding pk column.

5.3 Making View Summaries Consistent

Since the solution for each view is obtained independently, there could be inconsistencies across them. For example, referring back to the view schema shown in Section 3.2, R_{view} has attributes borrowed from S_{view} and T_{view} , and its solution may feature values that are not present in the corresponding attributes of these two views. To address this problem, we first carry out a *topological sort* on the “referential dependency graph”² and then iteratively make the current view consistent with its predecessors. Since a topological sort is employed, Hydra can handle dependency graphs that are DAGs unlike DataSynth which is restricted to tree traversals.

To make a pair of views V_i and V_j consistent with each other, where V_i is dependent on V_j , we iterate over the rows in the view solution of V_i and look for the value combination that each row has for the attributes borrowed from V_j . If that value combination is not present in the solution of V_j , we add a new row in its solution with the corresponding NUMTUPLES attribute set to 1. This results in an additive error in the total number of tuples in the view as compared to the original AQP at the client. But we hasten to add that the error is a fixed number of rows, determined by the nature of the constraints and the LP solution, and *not* by the data scale. Therefore, at Big Data volumes, the discrepancy can be expected to be minuscule, and our experiments empirically confirm this expectation.

The inter view consistency component is present in DataSynth as well, but since its view solutions are comprised of complete database instantiations, and not just summaries, the time and space overheads incurred for making the views consistent can be large. Moreover, the additive error in DataSynth is amplified due to its inherent sampling errors. Our experiments also capture this distinction between the errors incurred due to referential constraints in Hydra and DataSynth.

5.4 Constructing Relation Summaries

After constructing consistent solutions across all the views, we next need to obtain the corresponding relation summaries. For

²A graph where each relation is represented by a node and an edge (u, v) is added if relation u is dependent on relation v through a referential constraint.

this, we create a summarized relation schema \tilde{R}_i for each relation R_i . This schema consists of all attributes in R_i except the primary key attribute, and additionally, the NUMTUPLES value for each entry in \tilde{R}_i , as sourced from the view solutions.

For the common attributes between the summarized relation and the corresponding view solution, the value combinations and corresponding NUMTUPLES value are directly borrowed from the solution. What remains are the foreign key attributes. For filling a foreign key attribute fk, we need to first consult the view corresponding to fk’s target relation, say V_j . To fill the fk value in row r of \tilde{R}_i , we extract the value combination in row r of view solution of V_j , and then project the attributes corresponding to V_j – let this be denoted by v . Now, we iterate over the solution set of V_j and compute the cumulative sum of the cardinality entries till v is reached. This sum provides the fk value corresponding to the r th row of \tilde{R}_i , and we thus obtain \tilde{R}_i for each relation R_i .

The set of relation summaries, computed as described above, provides the entire database summary – a sample such summary was previously shown in Figure 5 (for simplicity, the figure shows the PK columns instead of the number of tuples).

Like before, DataSynth again iterates over the complete instantiated (consistent) views to construct the corresponding materialized relations. Obviously, this leads to enormous time and space overheads in contrast to our data-scale independent summary based approach.

6 TUPLE GENERATOR

The Tuple Generator component resides inside the database engine, and needs to be explicitly incorporated in the engine codebase by the vendor. As a proof of concept, we have implemented it for the PostgreSQL v9.3 engine by adding a new feature called *datagen*, which is included as a property for each relation in the database. Whenever this feature is enabled for a relation, the scan operator for that relation is replaced with the dynamic generation operator. As a result, during query execution, the executor does not fetch the data from the disk but is instead supplied by the Tuple Generator in an *on-demand* manner, using the available relation summary.

Each row in the relation summary has a value combination and an associated NUMTUPLES entry. We consider the pk values to be the row numbers of the relation. Therefore, to get the r th tuple of a relation R , the pk is chosen as r and the rest of the attributes come from the relation summary. We iterate over the rows of \tilde{R} and take the cumulative sum of the NUMTUPLES entries until the sum exceeds r . Say the summation crosses the value r in j th row of \tilde{R} . Then the rest of the values of the r th tuple are assigned to be precisely the same as those present in the j th row of \tilde{R} . For example, the 120th row of relation S in Figure 5, would be $\langle 120, 20, 15 \rangle$.

Note that this form of tuple generation is expected to be efficient since the attribute value assignments are deterministic and independent, and these expectations are confirmed in the experiments shown in the following section.

7 EXPERIMENTS

We have implemented the Hydra design, described in the previous sections, in a Java tool running to over 15K lines of code. The popular Z3 [14] solver is leveraged to compute solutions for the LP formulations. In this section, we evaluate Hydra’s empirical performance, using our implementation of DataSynth as the comparative yardstick in the analysis.

Database Environment. The TPC-DS [1] decision-support benchmark database, with a default size of 100GB, is used as the baseline in our experiments. The database is hosted on a PostgreSQL v9.3 engine [4] with the hardware platform being a vanilla HP workstation (3.2 GHz 16 core processor, 32 GB memory, 500 GB SSD hard drive) running Ubuntu Linux 16.04.3.

A complex query workload, WL_c , featuring 131 distinct queries (enumerated in [21]), was created by customizing the 99 queries of the benchmark such that only non-key filter predicates and PK-FK joins were retained, and all nested queries were separated into independent sub-queries³. The AQP’s for these queries were generated on the PostgreSQL query processor, resulting in 351 cardinality constraints. The distribution of the cardinalities for these CCs are shown in Figure 9, with the cardinalities measured on a log-scale. The figure clearly indicates that a wide range of cardinalities are present in the constraints, going from a few tuples to almost a billion.

Figure 9: Distribution of Cardinality in CCs (WL_c)

The above constraints result in a large number of geometrically overlapping regions. Hydra, due to its region-partitioning approach, comfortably handles this scenario. In marked contrast, DataSynth, due to its grid-partitioning construction, generates a very large number of LP variables (in the several billion) from the constraints, overwhelming the solver’s capabilities. We therefore also created an alternative simplified query workload, called WL_s , with 311 CCs, wherein the variables created by DataSynth were less than a million, and therefore well within the solver’s processing power.

7.1 Quality of Volumetric Similarity

We begin by investigating how closely the volumetric similarity, with regard to operator output cardinalities, is achieved between the client and vendor sites for the WL_s workload by the Hydra and DataSynth regenerators. This behavior is captured in Figure 10, which plots the percentage of CCs that are within a given relative error of volumetric similarity. From the plot it is evident that Hydra satisfies around 90 percent of the CCs with virtually no error, and the remaining CCs are also satisfied within a relative error of less than 10%. This is in contrast to DataSynth, which accurately satisfies around 80 percent of the CCs, but then incurs as much as 60% relative error to achieve complete coverage of the remaining CCs.

There are two reasons for the error-prone behavior of DataSynth: (1) the probabilistic sampling technique, and (2) the maintenance of referential integrity. While Hydra also is forced to

³Similar to DataSynth, the restriction to non-key-based filters is because the conversion from relations to views lose the key attributes. Likewise, only PK-FK joins are supported since they are inherently present in the design of views.

Figure 10: Quality of Volumetric Similarity (WL_c)

insert additional tuples to maintain referential integrity, the number is substantially smaller than those injected by DataSynth. This is because the integrity errors are *amplified* by the impact of the sampling errors. This effect is quantified in Figure 11, where the number of extra tuples inserted is plotted on a log-scale for representative TPC-DS tables. We see here that Hydra is often an *order-of-magnitude* smaller with regard to the addition of these extra tuples as compared to DataSynth. Also, recall that integrity errors in Hydra are independent of the data scale and therefore are minuscule at Big Data volumes. We also show this in [21].

Figure 11: Extra tuples for Referential Integrity (WL_c)

As a final observation, it is interesting to note that DataSynth has to contend with both *negative* (volumes less than desired) and *positive* (volume greater than desired) relative errors, due to its sampling strategy – in fact, about one-third of the CCs suffered negative relative errors. In contrast, Hydra only generates positive errors due to the inclusion of extra tuples for satisfying referential integrity. From a practical standpoint, it is perhaps preferable to have positive errors since they induce greater stress on the data processing elements in the engine.

7.2 Scalability with Workload Complexity

We now turn our attention to evaluating the complexity of the underlying LP that is formulated by Hydra and DataSynth. Since LP complexity is essentially proportional to the number of variables in the problem, we compare this number for the two techniques. Further, since LP complexity is, to the first degree of approximation, independent of the database size, we present the comparison only for the 100 GB instance.⁴ The number of LP variables for a representative set of TPC-DS relations, including the major fact and dimension tables (`catalog_sales`, `store_sales`,

⁴Of course, the database engine’s choice of query plans may change to some extent with database size, leading to a slightly different set of CCs.

item) is captured, on a log-scale, in Figure 12 for the WL_c complex workload. We observe here that the LPs formulated using the region-partitioning strategy in Hydra generate *several orders of magnitude* fewer variables than the corresponding LPs derived from the grid-partitioning in DataSynth. As a case in point, consider the catalog_sales table – the number of variables created by DataSynth was almost 5.5 million, which is reduced to as low as 1620 by Hydra. Even more dramatic is the change for item table, where the number of variables is reduced from an enormous 10^{11} to around 3700.

Figure 12: Number of variables in the LP (WL_c)

From an absolute perspective also, the large number of variables created by DataSynth is a critical problem since, as mentioned previously, the LP solver crashed in handling these cases. In marked contrast, the few thousands of LP variables generated by Hydra were easily solvable in less than a minute. Moreover, even when we switched to the simple workload, WL_s , the LP solution time for DataSynth was almost an hour, whereas Hydra completed in a few seconds as shown in Figure 13.

Complex Workload (WL_c)		Simple Workload (WL_s)	
DataSynth	Hydra	DataSynth	Hydra
crash	58 sec	50 min	13 sec

Figure 13: LP Processing Time

7.3 Scalability with Materialized Data Size

This experiment compares the data instantiation times, post LP solution, of DataSynth and Hydra on the WL_s workload. While Hydra, in principle, due to its summary-based approach, does *not* have to instantiate the data immediately, we assume in this experiment that the vendor requires complete materialization.

The experimental results are shown in Figure 14, where we also present, for comparative purposes, the performance with 10 GB and 1000 GB databases, apart from the default 100 GB database. We see here that there is a huge reduction in the materialization time of Hydra at all scales. Further, even in absolute terms, Hydra is able to output a 100 GB database in around 11 minutes, whereas DataSynth takes 42 hours to complete the same task.

The marked difference in the efficiency of the two techniques is attributed to the fact that DataSynth instantiates complete views through sampling, subsequently performs *several passes* on these instantiations to ensure referential integrity, and to derive relations from them. Hydra on the other hand, after LP-solving, constructs the database summary in just a few seconds, and then instantiates the materialized database directly from it.

Size (in GB)	DataSynth	Hydra
10	4 hours	2 min
100	42 hours	11 min
1000	> 1 week	1.6 hours

Figure 14: Data Materialization Time

7.4 Scalability to Big Data Volumes

In our next experiment, we validated the ability of Hydra, thanks to its summary-based technique, to scale to Big Data volumes. To demonstrate this feature, we modeled an exabyte-sized (10^{18} bytes) data scenario as follows: We used CODD, which is capable of modeling arbitrary metadata scenarios, to obtain the optimizer-chosen plans at the exabyte database scale for all the workload queries. To get AQPs for this database, we executed the obtained plans on the 100 GB instance and scaled the intermediate row counts with the appropriate scale factor. Hydra was able to formulate and solve the LPs (one per relation), and generate the database summary in less than **2 minutes**. Once the summary is generated, the database can begin to submit the workload queries since the data required for the execution can be produced on-the-fly by the Tuple Generator.

7.5 Dynamism in Data Generation

Our next experiment evaluates Hydra’s ability, due to the Tuple Generator and Database Summary architecture, to produce tuples *on-the-fly* instead of first materializing them, and then reading from the disk. To verify whether dynamic generation can indeed produce data at rates that are practical for supporting query execution, we compared the total time that Hydra’s tuple generator took to construct and supply tuples to the executor, while running simple aggregate queries, as compared to the standard sequential scan from the disk.

Rel. Name	Size (in GB)	Row count (in millions)	Scan time (secs)	
			Disk	Dynamic
store_returns	3	29	16	8
web_sales	10	72	43	25
inventory	19	399	107	74
catalog_sales	20	144	46	48
store_sales	34	288	168	87

Figure 15: Data Supply Times

The results of this experiment are shown in Figure 15 for the five biggest relations in the 100 GB database instance. We see here that the tuple generator is not only competitive with a materialized solution, but is in fact typically *faster*. Therefore, using dynamic generation can prove to be a good option since it can help to eliminate the large time and space overheads incurred in: (1) dumping generated data on the disk, and (2) loading the data on the engine under test.

7.6 Performance on JOB Benchmark

A legitimate concern with regard to the above encouraging results for Hydra is that they may be an artifact of the TPC-DS database, and perhaps might under-perform on other datasets. To address this concern, we consider in our final experiment, a schematically highly different database, namely the JOB benchmark [17], which is based on the IMDB real-world dataset. Here, we created a

workload of 260 queries, resulting in 523 CCs, whose cardinality distribution is again highly varied as seen in Figure 16.

Figure 16: Cardinality distribution of CCs in JOB

We found that Hydra efficiently solved this workload as well, with the number of variables in each view being typically in the few thousands, and never exceeding a hundred thousand, as shown quantitatively in Figure 17. The overall database summary was quickly generated in around 20 seconds, and produced a database of high fidelity that satisfied all the constraints with no more than 2 percent relative error.

Figure 17: Number of Variables for JOB

8 RELATED WORK

Over the past few decades, a rich corpus of literature has developed on synthetic database construction. There are two broad streams of research on the topic, one dealing with the *ab initio* generation of new databases using standard mathematical distributions (e.g. [12, 15]), and the other with *regeneration* of an arbitrary existing database. In the latter category, there are two approaches, one of which uses only schematic and statistical information from the original database (e.g. [19, 22]). The other uses both the original database and the query workload to achieve statistical fidelity during evaluation (e.g [6, 11]) – our work on Hydra falls into this class. In this section, we briefly review recent literature on this spectrum of research categories.

Ab Initio Generation. Descriptive languages for the definitions of data dependencies and column distributions were proposed in [12, 16, 20]. For example, [12] proposed a special purpose language called Data Generation Language (DGL) that is used by the tool to generate synthetic data distributions by utilizing the

concept of iterators. It supports a broad range of dependencies between relations but the construction of dependent tables always requires access to the referenced table, creating a bottleneck on the data generation speed.

In contrast to the above, MUDD [23] and PSDG [16] generate all related data at the same time. However, this approach can also be rendered inefficient if the referenced tables are large in size. MUDD proposes algorithms to parallelize the data generation process, and to efficiently generate dense-unique-pseudo-random sequences and derive nonuniform distributions. Both MUDD and PSDG decouple data generation details from data description, facilitating customization of the tool to suit user needs.

In the distributed setting, a faster way of generating references is through recomputing since it eliminates the I/O costs incurred to satisfy referential constraints across relations that are present across different nodes. PDGF [20] was designed with this goal of achieving scalability and decoupling. In PDGF, the user specifies two XML configuration files, one for the data model and one for the formatting instructions. The generation strategy is based on the exploitation of determinism in pseudo-random number generators (PRNG), which enables regeneration of the same sequences, hence eliminating the scan overheads. PDGF supports the generation of data with cyclic dependencies as well, but incurs high computation costs for generating the associated keys. Finally, PDGF comes with a set of fixed generators for different datatypes and basic distribution functions.

A similar generator is Myriad [5], which implements an efficient parallel execution strategy leveraged by extensive use of PRNGs with random access support. With these PRNGs, Myriad distributes the generation process across the compute nodes and ensures that they can run independently from each other, without imposing any restrictions on the data modeling language.

Finally, a rule-based probabilistic approach, based on an extension of Datalog, has been recently proposed in [9], which is capable of generating data characterized by parametrized classical discrete distributions – however, it is not always feasible to assign such distributions to real-world data, especially over multivariate spaces.

Database-dependent Regeneration. DBSynth[19] is an extension to PDGF, which builds data models from an existing database by extracting schema information, and using sampling to construct histograms and dictionaries of text-valued data. Further, if the textual data contains multiple words, Markov chain generators are used to analyze the word combination frequencies and probabilities. Finally, after the model construction is complete, PDGF is invoked to generate the corresponding data.

Like DBSynth, RSGen [22] takes a metadata dump, including 1-D histograms, as the input, and generates database tables along with a loading script as the output. It uses a bucket based model at its core, which is able to generate trillions of records with minimum memory footage. However, the proposed technique works well only for queries with only a single range predicate. Further, due to the inaccurate statistical models in the query optimizer, the volumetric similarity is poor for queries involving predicates on correlated attributes.

UpSizeR [24] is a graph-based tool that uses attribute correlations extracted from an existing database to generate an equivalent synthetic database. A derivative work, Rex [13] produces an extrapolated database given an integer scaling factor and the original database, while maintaining referential constraints and the distributions between the consecutive linked tables. Dscaler [26]

addresses the problem of generating a non-uniformly⁵ scaled version of a database using fine-grained, per-tuple correlations for key attributes, but such information is typically hard to come by. Moreover, all these techniques only generate the *key* attributes, whereas the non-key values are sampled from the original database using these key values. Hence, the approach becomes impractical in Big Data and security-conscious environments. Finally, Dscaler fails to retain accuracy for some common query classes.

Query-dependent Regeneration. Apart from the above techniques, another line of work [6, 10, 11, 18] is based on workload dependence (as in the case of Hydra). Here the aim is to generate a database given a workload of queries such that volumetric similarity is achieved on these queries. In particular, RQP [10] gets a query and a result as input, and returns a possible database instance that could have produced the result for that query. The idea of using cardinalities from a query plan tree was first introduced in QAGen [11]. They start by constructing a *symbolic database*⁶, and then translate the input AQPs to constraints over the symbols in the database. Subsequently, a constraint satisfaction program (CSP) is invoked to identify values for symbols that satisfy all the constraints.

On the positive side, these generators are capable of handling complex operators as they use a general CSP, but the performance cost is huge since the number of CSP calls also increases with the database size. Further, it requires operating on a symbolic database of matching size to the original database, and processing of the entire database during the algorithm execution. This makes it impractical for Big Data environments. Finally, QAGen supports only one query plan in the input. This limitation was addressed in a follow-up tool called MyBenchmark [18], which creates a symbolic database on a per query basis and at the end tries to heuristically merge the various databases into a small number of databases. Clearly, generating a database on a per query basis has enormous time and space overheads, and further, a single database is not guaranteed in the output.

DataSynth [6] identified the declarative property of cardinality constraints and its ability to specify data characteristics. Given a large number of cardinality constraints as input, the paper proposed algorithms based on the LP solver and graphical models to instantiate tables that satisfy those constraints. However, it suffers from high LP complexity, data scale dependencies, and inaccuracies with regard to volumetric similarity, as we have discussed in this paper. Hydra materially extends the DataSynth approach by adding dynamism, scale and functionality.

9 CONCLUSIONS

The ability to synthetically regenerate data that accurately conforms to the volumetric behavior on queries at client sites is of crucial importance to database vendors, and will become even more so with the advent of Big Data applications. In this paper, we have proposed Hydra, a data regeneration tool that takes a substantial step forward towards achieving this goal. Specifically, by reworking the basic LP problem formulation into a region-based variable assignment, Hydra improves on the state-of-the-art DataSynth's performance by orders of magnitude with regard to problem complexity, data materialization time, and scalability to large volumes. Secondly, by using a deterministic alignment technique for database consistency, it provides far

better accuracy in meeting volumetric constraints as compared to the probabilistic approach employed in DataSynth. Finally, its summary-based framework organically supports the dynamic regeneration of streaming data sources, an essential pre-requisite for efficiently testing contemporary deployments.

In our future work, we plan to focus on covering a richer set of query operators, such as grouping functions, within the Hydra framework. Also, we would like to investigate how to leverage additional summary information (such as value-based correlations) that the client might be willing to provide for achieving stronger fidelity with the original database.

TPStream: Low-Latency Temporal Pattern Matching on Event Streams

Michael Körber Nikolaus Glombiewski Bernhard Seeger

Database Systems Group, University of Marburg

{koerberm,glombien,seeger}@mathematik.uni-marburg.de

ABSTRACT

Complex Event Processing (CEP) has emerged as the state-of-the-art technology for continuously monitoring and analyzing streams of events in time-critical applications. The key feature in CEP is *sequential pattern matching* to detect a user-defined sequence of conditions on event streams. However, many CEP applications are not restricted to events only, but require native support for *situations* (aggregated event data lasting periods of time) and expressive temporal pattern matching among these situations. These important requirements regarding situations are not sufficiently addressed in the CEP literature so far.

In this paper we present *TPStream*, a novel event-processing operator for both deriving situations from event streams and detecting temporal patterns among situations. First, we provide a formal foundation of situations and *TPStream*. Then, we propose a low-latency algorithm for *TPStream* that delivers situations and temporal matches at the earliest possible point in time. Furthermore, we utilize a simple, yet effective cost model in order to adapt to changing workloads on the fly and with negligible cost for migrating operator states. The results of our experimental evaluation show that *TPStream* is capable of processing high-volume event streams with low latency and outperforms applicable CEP solutions from academia and industry.

1 INTRODUCTION

During the last decade, Complex Event Processing (CEP) has emerged to the technology of choice for analyzing massive streams of events in near real time. Typically, CEP systems detect composite (complex) events by combining, aggregating and filtering streams of simple or other composite events and report matches to registered event sinks. In turn, these sinks react to the detected event by triggering appropriate actions in a timely manner. CEP can be applied to a wide variety of application domains, including IT infrastructure monitoring, traffic monitoring, health care and financial applications.

Problem Statement: A noticeable fraction of currently available CEP systems is build upon point based temporal semantics. That is, each event is associated with a timestamp (e.g., the moment a measurement was made) and event streams are ordered accordingly. With only a *single* timestamp the expressible *temporal relations* between two events are limited to before/after/at the same time relationships. However, many real-world scenarios comprise the detection of complex *temporal patterns* among situations lasting for periods of time. Consider the following traffic-monitoring application:

Example: A traffic monitoring system is continuously receiving sensor data from connected cars (i.e., position, speed, acceleration). One of the systems goals is to notify drivers about potential

Figure 1: Detecting aggressive driving with situations

dangers around their locations, such as an aggressively driving car. Among others, the American Automobile Association has identified the following two actions being indicators for aggressive driving¹: “Operating the vehicle in an erratic, reckless, careless, or negligent manner or suddenly changing speeds” and “Driving too fast for conditions or in excess of posted speed limit”. From these definitions, a pattern to detect aggressive drivers could be stated as: “A sharp acceleration followed by hard braking, both accompanied by a period of speeding.”

Challenges: This example illustrates three key-features a solution for temporal pattern matching on instantaneous events should provide: (i) Situations are derived from point events on-the-fly, by identifying subsequences of the input stream for which the defined condition holds true (e.g., speed > 70 mph). Optional constraints can be applied to restrict the duration of situations. In addition to its validity (expressed as a time interval), a situation is enriched with meaningful summarizations of underlying events (e.g., the average speed of the speeding phase). (ii) The pattern language offers support for alternatives. That is, the order of the situations’ start and end points is not required to be fully fixed. Consider, for example, the two matches sketched in Figure 1: In the first match, the three defined situations *overlap*, while in the second match deceleration happens *during* the speeding situation. (iii) The pattern should be detected with the *lowest possible latency*. As depicted in Figure 1, both matches may be concluded at the beginning of the deceleration situation, since at this point in time speeding still holds true and the pattern allows any combination of their endpoints. Technically, this means the system should be able to conclude a successful match without exact knowledge about the validity of all situations.

State-of-the-Art: To the best of our knowledge, the only work on complex *temporal relations* in event stream pattern matching is the *ISEQ* operator [20]. However, *ISEQ* has several shortcomings concerning the desired features: First, the operator expects interval-events (i.e., situations) as input, leaving all aspects of (i) to an unspecified external entity. Being unaware of the origin of interval-events severely limits the operator in processing power (in terms of plan optimization) and most importantly renders a detection with the lowest possible latency (iii) impossible since there is no way to directly access an incomplete situation or indirectly manipulate the building of a situation through constraints.

¹<http://www.iii.org/fact-statistic/aggressive-driving>

Second, a *temporal pattern* is specified using a conjunction of endpoint relationships (i.e., an ordering on start (ts) and end (te) of intervals). This way, alternatives are expressed by omitting one or more endpoints. For example, the pattern $A.ts < B.ts < A.te \leq B.te \vee A.ts < B.ts < B.te < A.te$ on two situations A and B is expressed as $A.ts < B.ts < A.te$. Hence, disjunctions like $A.ts < B.ts < A.te < B.te \vee B.ts < A.ts < B.te < A.te$ are not expressible in a single query. Instead, they require multiple queries in an approach without any specified optimization component to detect shared processing opportunities. Finally, *ISEQ* relies on auxiliary index structures and punctuation mechanisms for efficient query execution, complicating the integration into existing systems.

Straw Man’s Approach: Besides *ISEQ*, we identified two approaches to solve the task of temporal pattern matching with point event streams. Thus, we can provide a point of comparison to CEP systems featuring pattern matching via regular expressions or equivalent techniques. The first approach works in two phases: In the first phase, a pattern matcher is deployed for each defined situation, computing its duration (start/end timestamp) and the desired aggregates. Technically, this means matching patterns of the form $!S S+ !S$ with S being derived from the input stream using the situation’s condition (e.g., $speed > 70 \text{ mph}$). This results in a dedicated stream per defined situation. Each of these streams is ordered according to the end timestamp, which allows to map the *temporal pattern* to a sequence of situations (reflecting the order of end timestamps, possibly containing alternatives). In the second phase, a dedicated pattern matching operator is used to find all matching sequences, whereby the proper ordering of start timestamps is checked via additional predicates. Even though this approach satisfies requirements (i) and (ii), it fails to produce early results (iii), because, just like in *ISEQ*, situations are fully derived before they are available for pattern matching.

The second approach uses a single pattern matching operator and expresses the *temporal pattern* as a single sequence of point events. To express temporal overlaps, the conditions of all involved situations must be connected via a logical AND. For example, *Acceleration overlaps Speeding* is expressed as $A B+ C$ with the following conditions: $A : accel > 8 \text{ m/s}^2$, $C : speed > 70 \text{ mph}$ and $B : A \wedge C$. Since patterns are expressed on the granularity of events, early results (iii) are achieved, by simply omitting the last portion of the pattern. At the same time summarizations of single situations and the validation of duration constraints (i) are left to a post-processing step, since situations are disassembled to express temporal overlaps.

Solution: We present *TPStream*, a holistic operator for complex temporal pattern matching on point event streams. Compared to the presented approaches, our contributions are:

- *TPStream* is the first CEP operator to closely couple derivation of situations with pattern matching, enabling match detection at the *earliest possible point in time*.
- We also improve upon existing work on temporal pattern matching (e.g. *ISEQ*) by allowing arbitrary alternatives and duration constraints in pattern definitions.
- We introduce an optimizer component for interval-based pattern matching which continuously adapts its execution strategy to deal with fluctuating data rates and changes in the data distribution of incoming streams.
- *TPStream* provides native query support for temporal pattern matching, making it easier to formulate and read *temporal*

patterns in comparison to most existing CEP solutions relying on a straw man’s approach.

- Unlike *ISEQ*, the operator and its low latency optimizations can easily be implemented in commonly available point-based systems, because time-intervals are used only internally and results are again point event streams.
- In experiments, we show our latency improvements and the performance limits of two existing CEP solutions from academia and industry when handling situations. We present that *TPStream* can outperform these systems by an order of magnitude and that alternatives, which have great impact on the performance of sequential pattern matching, influence *TPStream*’s matching performance only marginally.

The rest of the paper is organized as follows. Section 2 reviews related work, before we introduce *TPStream*’s query language in section 3. In section 4 we model all aspects of *TPStream* in an algebra. Efficient evaluation strategies, the algorithm for low-latency matching and our optimization techniques are presented in section 5. We evaluate the performance of *TPStream* in section 6 and conclude this paper in section 7.

2 RELATED WORK

So far, native ways to work with situations in systems capable of CEP have not been sufficiently addressed. Nevertheless, the concept can be related to working with time intervals, aggregating information and performing temporal joins, all of which have seen recent contributions. Since these are broad areas, we will loosely group the most relevant approaches under three headlines: Event Pattern Matching, Context/State in CEP and Spatio-Temporal Database Systems.

Event Pattern Matching: Systems capable of CEP (e.g. [3, 9]) are generally closely associated with a pattern matching operator. [27] features a discussion on the several different semantics of the operator and a recent survey [12] covers several implementations, that employ different techniques such as NFAs or Graphs, each featuring their own unique optimization techniques. Regardless of specific details, most approaches focus on data referring to points in time and thus lack *native* capabilities to query complex relations between time intervals as stated in [2] - a crucial aspect for dealing with long-lasting situations. Cayuga [8], ZStream [22] and Microsoft StreamInsight [1] are well-known approaches that associate time intervals with data, showcasing the interest in working with interval-based events. ZStream in particular shares similarities with our join-based, adaptive processing approach for pattern matching. However, each of the respective pattern languages is based around a strictly sequential relation (interval i ends before interval j begins) and/or explicitly order-independent relations (conjunction, disjunction). Not only does this limit their respective algorithmic support for complex *temporal relations*, but, just like point-based systems, formulating derivation queries naturally leads to the straw man’s approach mentioned above using Kleene Operators (or FOLDS in [8]). As we will show in our experiments, this approach results in significant performance deficiencies.

Context/State in CEP: There has been recent work on introducing *contexts* into a CEP environment. CAESAR [23] associates queries to long-lasting context windows, detects them from incoming events as soon as they start and suspends queries of inactive contexts. Similarly, contexts in [11] are used to group up event types to process them together. While contexts and

Relation (R)	Equivalent (R)	Visualization	Definition (δ_R)
A before B	B after A		$A.ts < A.te < B.ts < B.te$
A starts B	B started-by A		$A.ts = B.ts < A.te < B.te$
A meets B	B met-by A		$A.ts < A.te = B.ts < B.te$
A overlaps B	B overlapped-by A		$A.ts < B.ts < A.te < B.te$
A during B	B contains A		$B.ts < A.ts < A.te < B.te$
A finishes B	B finished-by A		$A.ts < B.ts < A.te = B.te$
A equals B			$A.ts = B.ts < A.te = B.te$

Table 1: Allen’s Interval Algebra

situations are related concepts, the key difference is that contexts are purposefully decoupled from events. Therefore, it is not possible to query the relation of different contexts to each other. In contrast, *TPStream* focuses on efficient, adaptive and low-latency implementations of those *temporal relations*. Likewise, work on states [18] and on aggregating windows [14, 17] focuses on derivation, but lacks interval relations [2] or pattern matching.

Spatio-Temporal Database Systems: The spatial databases community studied the problem of *spatio-temporal pattern queries* (STPQ) in trajectory databases [10]. In general, these approaches cannot be directly applied to an event processing environment, because they are built on top of a *persistent* trajectory database model, where movement histories are already stored and indexed in the database. However, the design of [25] in particular served as a foundation for our proposed *TPStream* operator as *TPStream* adapts similar concepts of temporal predicates and constraints. Furthermore, our evaluation method is related to temporal joins (see [13] for an excellent survey), but as most of the work is not based in stream processing, unique and important issues such as continuously arriving data, continuous query optimization and early result detection are overlooked. In comparison to join algorithms on streams [6, 15] as well as adaptive approaches [5], *TPStream* combines both the derivation of situations and the detection of patterns. Thus, the operator can offer new techniques for early result detection unique to CEP-style pattern matching.

3 QUERY LANGUAGE

In order to express *temporal relations* between situations, we adopt Allen’s Interval Algebra [2] depicted in Table 1 for two generic intervals A and B. Each interval has a starting point (ts) and an ending point (te), resulting in a total of four points. te is the first point in time when the interval is not valid, i.e. the interval is *half-open*. The *relation* (R) between A and B is represented through the relation between these four points as given by the *definition* (δ_R). As an example depicted in Table 1 A *before* B means the interval A ends before the interval B begins. Similarly, A *during* B means A happens during B, because A.ts and A.te are between both points of B. We introduce the *TPStream* query language by formulating and explaining the query to detect aggressively driving cars from the introductory example in Listing 1.

The operator works on streams containing data referring to points in time. In the case of aggressive drivers, we work on a singular stream CS, providing sensor data from cars, which is specified as an input (FROM). This stream is partitioned by the car_id to evaluate each driver individually (PARTITION BY). The important aspect of deriving situations from the stream is handled in the DEFINE clause: The acceleration situation is represented with the symbol A, the condition $CS.accel > 8 \text{ m/s}^2$ and the

```

FROM CarSensors CS PARTITION BY CS.car_id
DEFINE A AS CS.accel > 8m/s2 at least 5s,
       B AS CS.speed > 70 mph between 4s AND 30s,
       C AS CS.accel < -9m/s2 at least 3s
PATTERN A meets B; A overlaps B; A starts B; A during B
        AND C during B; B finishes C; B overlaps C; B meets C
        AND A before C
WITHIN 5 MINUTES
RETURN first(B.car_id) AS id,
        avg(B.speed) AS avg_speed;

```

Listing 1: Aggressive drivers query

(optional) duration constraint AT LEAST 5s, while speeding and deceleration are defined by B and C respectively. The derived situations are analyzed with a PATTERN. For aggressive drivers, an acceleration (A) may meet, overlap, start or occur during a phase of speeding (B). These are alternatives in the pattern definition, separated with semicolons in the query language. The same applies for deceleration (C) and speeding (B). The pattern is fulfilled if at least one of *each* alternatives is true. We apply a window condition on the evaluation period (WITHIN), specifying that the pattern should only be searched within situations derived in the past 5 minutes. Finally, in case of a match, we RETURN aggregated results from each situation, in this case the car_id and the average speed.

3.1 Expressiveness

Most common CEP systems define patterns based on symbols connected via regular expressions. Specific extensions, like aggregations, put the expressiveness of those languages between regular and context-free grammars [27]. However, only *ISEQ* provides a *native* way to process patterns based on *temporal relations*. This deficit is also reflected in the respective languages.

By design, *TPStream* can express all *temporal relations* (and unlike *ISEQ* alternatives among them) in a *single* query. In contrast, a single pattern matching query in CEP systems is designed to detect a sequence, i.e., a *before* relation. Nevertheless, as shown by both straw man’s approaches in our introduction, in a system supporting Kleene-closure it is possible to express other *temporal relations* through either multiple queries (decoupling derivation and detection) or a single query (without aggregation capabilities and the validation of duration constraints). Thus, our language does not express more than the *full* language of other systems.

Instead, we focus on enabling the user to express complex *temporal patterns* in a single, readable and maintainable query via the widely-known interval algebra (Table 1). For this purpose, we made two notable design choices that differ from some sequence-based approaches. First, some languages [27] allow to skip events while matching. In contrast, we derive the longest possible contiguous sequence of events, because this aligns well with the idea of long lasting situations and avoids ambiguity whether a situations is still ongoing during *other* events. Second, some languages [9] allow symbols to access aggregates of other symbols. Due to ambiguity in the expected results when dealing with situations, we do not allow this. For example, consider modifying the definition for symbol B in Listing 1 to $B \text{ AS } CS.speed > \max(A.speed)$. Then, for A overlaps B it is unclear whether $\max(A.speed)$ is accessed when A finishes, when B starts or is continuously monitored for each B. For a precise presentation of our approach, we chose those two concessions and will work on mitigating them in the future.

We would also like to sketch that, apart from those concessions, it is possible to express a purely sequence-based pattern with *TPStream*: A sequence can be expressed with a before relation and the implicit ongoing nature of situations can be eliminated with a duration constraint. Nevertheless, the basis for our implementation [19] features a standard sequence-based pattern matching operator that is optimized and thus preferable for this purpose. Similarly, our implementation can be easily integrated into other systems, because *TPStream* consumes and produces point-based event streams. In conclusion, this means that we do not change the expressiveness of other approaches, but by extending a query language with Allen’s Interval Algebra, our benefits can be almost universally adopted.

4 ALGEBRA

The goal in designing *TPStream* is to develop an operator capable of continuously deriving situations from a stream of events and relate those situations to each other. To achieve this, we need to be able to express both the derivation and relation. For this purpose, we will formally model those aspects (streams, data, deriving situations and temporal pattern matching) in an algebra.

4.1 Stream Model

Definition 1 (Data Stream). A data stream D is a potentially unbounded sequence of data items $\langle d_1, d_2, \dots \rangle$ totally ordered by a relation $<_D$. $d_i \in D$ refers to the i -th data item in the stream according to that order and all data items are from the same domain \mathcal{D} . \diamond refers to an empty data stream.

In order to refer to multiple data streams, we will utilize the notation D^1, D^2, D^3, \dots with $D^i = \langle d_1^i, d_2^i, \dots \rangle$, i.e. a superscript labels separate streams, while a subscript refers to the order within a stream. For the sake of simplicity and legibility, we will generally assume that each item in a data stream is unique and refer to previous work on the matter of handling potentially equal elements [8]. \diamond is mainly used to specify the case of *no output* in upcoming definitions.

Definition 2 (Continuous Subsequence). Based on a data stream D , $D_{[i,j]} = \langle d_i, \dots, d_j \rangle$ with $i < j$ refers to a continuous subsequence containing every data item as it pertains to $<_D$.

Definition 3 (Union). The union \uplus of two data streams D^1 and D^2 both totally ordered with $<_D$ results in a data stream D' with the same order $<_D$:

$$\uplus(D^1, D^2) := D' = \langle d'_1, d'_2, \dots \rangle$$

such that D' contains each element from both D^1 and D^2 . Analogous to set theory, the union of n data streams D^1, \dots, D^n is abbreviated with the notation $\biguplus_{i=1}^n D^i$.

4.2 Data Model

Our operator involves two kinds of data which we need to define: *events* and *situations*. In general, events refer to a notification that something happened instantaneously at exactly one point in time while situations span multiple points in time and contain aggregated information for that time period.

Definition 4 (Event). An event e is a pair (p, t) consisting of a payload p and an event timestamp t . p is from some domain \mathcal{D} and t is from a discrete and totally ordered time domain \mathcal{T} . The validity of p is the instant t .

Definition 5 (Situation). A situation s is a triple (p, ts, te) consisting of a payload p and two timestamps: ts (start timestamp) and te (end timestamp). p is from some domain \mathcal{D} . ts and te are from a discrete and totally ordered time domain \mathcal{T} with $ts < te$. The half-open time interval $[ts, te)$ specifies the validity of p .

Event streams are ordered by the event timestamp and will be represented with E . **Situation streams** are ordered by the end timestamp of situations and will be represented with S . We focus our efforts on presenting algorithms for streams with data arriving in-order and leave the adjustment to out-of-order data by adapting previous research on out-of-order pattern matching [7, 21] for future work.

4.3 Derivation

Situations are derived from event streams through aggregation and predicate evaluation. We will first formally define aggregation on continuous event subsequences before deliberating on predicates and how to derive situation streams.

Definition 6 (Aggregated Event Subsequence). An aggregate γ_{agg} is applied to an event stream subsequence $E_{[i,j]}$ by applying the aggregate agg to the events in the subsequence:

$$\gamma_{agg}(E_{[i,j]}) := (agg(e_i, \dots, e_j), e_i.ts, e_{j+1}.ts)$$

When obvious from context, we abbreviate γ_{agg} with γ .

The result in Definition 6 technically already is a situation. However, for the derivation process as a whole, we want to discover situations for which a set of circumstances hold true. In order to provide an unambiguous process to identify these situations we are looking for the longest possible sequences for which these circumstances apply.

Definition 7 (Derived Situation). Situations are derived with a function $derive_{\phi, \tau, \gamma}$ which aggregates information of a continuous event subsequence $E_{[i,j]}$ by applying γ iff the events in $E_{[i,j]}$ are the longest possible sequence of events to fulfill a given predicate ϕ and the covered timespan is within the given duration constraint $\tau := [d_{min}, d_{max}]$:

$$derive_{\phi, \gamma, \tau}(E_{[i,j]}) = \begin{cases} \forall l \in [i, j] : \phi(e_l) \wedge \\ \gamma(E_{[i,j]}) & \text{if } !\phi(e_{i-1}) \wedge !\phi(e_{j+1}) \wedge \\ & (e_{j+1}.ts - e_i.ts) \in \tau \\ \diamond & \text{otherwise} \end{cases}$$

Example. Assume the query in Listing 1 derives a speeding situation for a car with the time interval $[2, 10)$. This means $CS.speed \leq 70$ mph at $t = 1$ and $t = 10$ and in between those timestamps $CS.speed > 70$ mph. From an algebraic standpoint, assuming knowledge about the whole event stream, this aligns well with a natural interpretation: There are not multiple situations (e.g. $[2, 3), [2, 4), \dots$) but rather one continuous speeding phase which fulfills the duration constraint ($d_{min} = 4s$ and $d_{max} = 30s$). For that reason and because it results in unique situations, we choose to derive the longest possible subsequence in Definition 7.

Definition 8 (Derived Situation Stream). The $deriveStream_{\phi, \gamma, \tau}$ function derives a stream of situations from a given event stream E by applying the function $derive_{\phi, \gamma, \tau}$ to all possible subsequences and unifying the results:

$$deriveStream_{\phi, \gamma, \tau}(E) = \biguplus_{j=1}^j \biguplus_{i=1}^j derive_{\phi, \gamma, \tau}(E_{[i,j]})$$

Note that, due to assumption that each event in an event stream has a unique timestamp and the fact that $derive_{\phi, \gamma, \tau}$ derives the longest situations possible, it is easy to show that $deriveStream_{\phi, \gamma, \tau}$ produces a stream of situations with disjoint time intervals. This implies, that the order of situations using start timestamps is the same as the order using end timestamps, resulting in a beneficial pattern for query processing [16]. Due to space limitations, we omit a formal proof here.

4.4 Pattern Matching

TPStream matches multiple situation streams to a *temporal pattern* and produces a result event stream according to the given definitions. A *temporal pattern* is composed of *temporal constraints* between situation streams, which in turn comprise multiple *temporal relations* between exactly two streams. In this section, we present formal definitions of these terms, the output of a successful match and ultimately the *TPStream* operator.

Definition 9 (Temporal Relation). Given two situation streams S^A, S^B , a *temporal relation* $R^{A,B}$, defines a valid relationship between two situations $s^A \in S^A$ and $s^B \in S^B$ according to Allen's Interval Algebra (cf. Table 1). s^A and s^B fulfill $R^{A,B}$, iff they satisfy the corresponding algebraic definition (δ_R).

Definition 10 (Temporal Constraint). A *temporal constraint* $C^{A,B}$ between two situation streams S^A, S^B is a set of *temporal relations* $\{R_1^{A,B}, \dots, R_m^{A,B}\}$. Two situations $s^A \in S^A$ and $s^B \in S^B$ fulfill $C^{A,B}$, iff they at least fulfill one of the *temporal relations*.

In other words, *temporal constraints* allow to specify multiple valid relations between two situation streams, providing the desired flexibility in expressing alternatives.

Definition 11 (Temporal Pattern). For any number of situation streams (S^1, \dots, S^m) , a *temporal pattern* (\mathcal{P}) is a set of *temporal constraints* $\{C^{i,j} | 1 \leq i < j \leq m\}$. A *temporal pattern* is matched by a *temporal configuration* $\bar{s} = (s^1 \in S^1, \dots, s^m \in S^m)$, iff \bar{s} satisfies every *temporal constraint*:

$$match_{\mathcal{P}}(\bar{s}) : \Leftrightarrow \forall C^{i,j} \in \mathcal{P} : \exists R^{i,j} \in C^{i,j} : \delta_{R^{i,j}}(s^i, s^j)$$

Example. Consider the example query of Listing 1 and let s^A be an acceleration situation as defined by A and s^B, s^C be a speeding (B) and deceleration (C) situation respectively. The PATTERN describes how pairs of situations in $\bar{s} = (s^A, s^B, s^C)$ can relate to each other via *temporal constraints*: For s^A and s^B the *temporal relation* can be either A meets B, A overlaps B, A starts B or A during B. It does not matter if acceleration overlaps speeding or if speeding contains acceleration. Both cases may lead to the result of detecting aggressive drivers. The *temporal pattern* on the other hand is a conjunction of *temporal constraints*: In order to match the pattern, each *temporal constraint* must be fulfilled.

Definition 12 (Pattern Matching Output). A temporal pattern matching operator $PM_{w, \hat{\gamma}}$ matches a *temporal configuration* $\bar{s} = (s^1, s^2, \dots, s^m)$ to a *temporal pattern* \mathcal{P} . It aggregates the information of \bar{s} with some suitable aggregate $\hat{\gamma}$ and checks the *window* condition (cf. WITHIN clause):

$$window(\bar{s}, w) = w \leq \max_{s \in \bar{s}}(s.te) - \min_{s \in \bar{s}}(s.ts)$$

Figure 2: *TPStream* Architecture

The operator produces an output, if the *temporal configuration* matches the pattern during the specified window, i.e.:

$$PM_{w, \hat{\gamma}}(\bar{s}, \mathcal{P}) := \begin{cases} (\hat{\gamma}(\bar{s}), \max_{s \in \bar{s}}(s.te)) & \text{if } match_{\mathcal{P}}(\bar{s}) \wedge window(\bar{s}, w) \\ \diamond & \text{otherwise} \end{cases}$$

Similarly to how we extended derived situations to derived situation streams (Definition 7 to 8), we can extend Definition 12 to situation streams:

Definition 13 (*TPStream*). $TPStream_{w, \hat{\gamma}}$ matches multiple situation streams S^1, \dots, S^m to a *temporal pattern* \mathcal{P} by applying the corresponding pattern matching operator $PM_{w, \hat{\gamma}}$ to the cross product of the situation streams and unifying the results:

$$TPStream_{w, \hat{\gamma}}(S^1, \dots, S^m, \mathcal{P}) := \bigcup_{\bar{s} \in \times_{i=1}^m S^i} PM_{w, \hat{\gamma}}(\bar{s}, \mathcal{P})$$

Note that $TPStream_{w, \hat{\gamma}}$ results in an event stream and can thus easily be integrated into common CEP processing pipelines.

5 ALGORITHMS & IMPLEMENTATION

In this section, we present our algorithms and implementation details for detecting *temporal patterns* among streams of point events. Following the definitions from the previous section, the general architecture consists of two main components, as depicted in Figure 2. The *deriver-component* consumes events from the input stream and derives the defined situation streams. Then, those streams are passed to the *matcher-component*, which performs the actual pattern matching. In the following two subsections we will explain both components in detail. For the sake of simplicity we defer low latency detection to section 5.3 and initially wait for the end timestamp of derived situations before invoking the *matcher*. The last part of this section describes how *TPStream* computes efficient execution plans and dynamically adapts to changing workloads.

5.1 Deriving Situations

Definition 8 introduced derived situation streams, using knowledge about the whole input-stream. To compute situation streams incrementally as new events arrive the *deriver-component* manages a buffer for ongoing situations (B) and the situation stream definitions (D). Algorithm 1 shows how they are used to derive situations on-the-fly. For each defined situation, 3 cases are checked: If there is no started situation on the buffer, but the predicate holds true, a new situation is started. Therefore, we compute initial values for all defined aggregates (e.g., p.speed for an $\max(\text{speed})$ aggregate). Those values are bundled with the event's timestamp and stored on the buffer (Lines 4,5). The

Algorithm 1: DeriveSituations

Input: (p, t) : event
Data: $B := [(p', ts)_i]$: active situation buffer,
 $D := [(\phi, \gamma, \tau)_i]$: situation definitions

```
1  $R \leftarrow \emptyset$ ;  
2 foreach  $i \in |D|$  do  
3    $(\phi, \gamma, \tau) \leftarrow D[i]$ ;  
4   if  $B[i] = \emptyset \wedge \phi(p)$  then  
5      $B[i] \leftarrow (initAgg(p, \gamma), t)$ ;  
6   else if  $\phi(p)$  then  
7      $updateAgg(p, B[i], \gamma)$ ;  
8   else if  $B[i] \neq \emptyset$  then  
9     if  $(t - B[i].ts) \in \tau$  then  
10       $R \leftarrow R \cup \{(B[i].p', B[i].ts, t)\}$ ;  
11       $B[i] \leftarrow \emptyset$ ;  
12 if  $R \neq \emptyset$  then  
13    $updateMatcher(R, t)$ ;
```

Algorithm 2: UpdateMatcher

Input: S : set of finished situations, t : the current time

```
1  $purgeBuffers(t)$ ;  
2 foreach  $s \in S$  do  
3    $addToBuffer(s)$ ;  
4    $performMatch(\{s\}, 0)$ ;
```

temporal validity of a started situation is prolonged, if the current event fulfills the predicate. In this case, the buffered aggregates are updated using the event's payload (p) (Lines 6,7). Finally, a situation is finished on the first event not satisfying the defined predicate. In this case, the situation's end timestamp is fixed to the current time, it is added to the result-set R (provided it satisfies the duration constraint τ) and the corresponding buffer slot is cleared (Lines 8-11). After updating the state of each situation stream, the result-set is passed to the *matcher-component* (Lines 12,13).

5.2 Matching the Pattern

The *matcher* implements an incremental version of Definition 13 ($TPStream_{w, \hat{\gamma}}$). In other words, it detects matches on-the-fly as new situations are handed over from the *deriver-component*. The general idea is to employ a buffer for each situation stream and perform the pattern detection via a multi-way join between those buffers, using the *temporal constraints* as join-conditions. Recap that all situations within a stream are disjoint and thus imply the same order on both the start and end timestamps (Definition 8). We will use this fact to ensure efficient execution of the matcher component.

Each time the *deriver* distills new situations, Algorithm 2 is invoked: At first, expired situations are purged from the buffers (Line 1). That is, removing all situations s with $s.ts < t - window$. Because of the mentioned ordering, this effectively means, finding the first situation s' with $s'.ts \geq t - window$ and discarding all previous events. The buffers are implemented via array-backed ring buffers, which efficiently support these operations.

After purging outdated situations, each new situation is first added to its corresponding buffer, before the actual matching

Algorithm 3: PerformMatch

Input: ws : working-set, sc : current step count
Data: order: evaluation order

```
1 if  $sc = order.getNumSteps()$  then  
2    $publishResult(ws)$ ;  
3   return;  
4  $step \leftarrow order.getStep(sc)$ ;  
5 if  $step.isSet(ws) \wedge step.checkConstraints(ws)$  then  
6    $performMatch(ws, sc + 1)$ ;  
7 else if  $!step.isSet(ws)$  then  
8   foreach  $(p, ts, te) \in findMatches(step, ws)$  do  
9      $ws \leftarrow ws \cup \{(p, ts, te)\}$ ;  
10     $performMatch(ws, sc + 1)$ ;  
11     $ws \leftarrow ws \setminus \{(p, ts, te)\}$ ;
```

algorithm (Algorithm 3) is invoked (Lines 2-4). We force the new situation to be part of any successful match, by passing it as a parameter. This ensures the desired incremental creation of results, because we pass a new, not yet considered situation on every invocation.

The matching algorithm relies on a so called *evaluation order*, which we describe briefly upfront. An *evaluation order* determines the order in which situation buffers are joined and provides the required information for each processing step (a reference to the situation buffer and the set of *temporal constraints* to be fulfilled). Using this information and a partial *temporal configuration* (*working-set*), Algorithm 3 matches the *temporal pattern* as follows: In each step, the corresponding situation buffer is searched for situations satisfying all applicable *temporal constraints* (Line 8). Applicable means, that the counterpart of the constraint is already present in the *working-set*. Then, all returned situations are successively added to the *working-set* and for each of the new partial *temporal configurations*, the algorithm proceeds to the next step (Lines 9-11). Lines 5 and 6 intercept the evaluation, if the *working-set* already contains a situation for the current step, which accounts for situations passed as a parameter from Algorithm 2. In this case, the corresponding buffer is ignored and the step's *temporal constraints* are checked directly. Finally, a match is detected if the *working-set* contains a situation from every buffer (Lines 1-3). The *publishResult* function consumes this *working-set*, assembles the result and pushes it into the output stream.

Obviously, the evaluation performance of Algorithm 3 mainly depends on the efficiency of the *findMatches* function. A naïve approach would be, to scan the entire buffer and check the *temporal constraints* for each situation separately. With R_i denoting the i -th intermediate result, B_i the buffer traversed in step i and $|R_i| = |B_i|$, the costs (C) of *performMatch* following this approach can be estimated with:

$$C = |R_n| + \sum_{i=1}^{n-1} |R_i| \cdot |B_{i+1}| \quad (1)$$

To speed up the computation, we again use the order of situation streams: Because the order is reflected on the buffers, we are able to find all matching situations using binary searches.

Figure 3: Temporal Matching via Range Queries

We first discuss how this is done for a single *temporal relation* before extending it to (multiple) *temporal constraints*. Recall that a *temporal relation* explicitly defines a relationship between all four endpoints of two situations. For instance, this is $A.ts < B.ts < A.te < B.te$ for A overlaps B. Now, given an instance of situation A, we can obtain matching instances of B by (i) issuing two range-queries on the buffer of B, using the timestamps of A as boundaries and (ii) intersecting the results of those queries. For the example relation, these queries are:

- (1) $A.ts < ts < A.te$ for the start-timestamp and
- (2) $A.te < te < \infty$ for the end timestamp.

It is easy to see, that each situation falling into both ranges fulfills the given *temporal relation*. Figure 3 illustrates this using 3 situations: Situation A_1 in combination with the *temporal relation* is used to build the two search ranges. After intersecting the results ($\{B_1\}$ for the start range and $\{B_1, B_2\}$ for the end range), we receive our final result B_1 . Note that for *temporal relations* allowing more than one result (e.g., A before B), this strategy additionally eliminates the need for checking each combination individually.

Typically, a *temporal constraint* contains more than one *temporal relation*, stating each of them as a valid relationship between two situations. This can be easily integrated by executing the search separately for each of the defined relations and subsequently building the union of the obtained results. The conjunction of multiple *temporal constraints* can be implemented as an intersection of the results from the respective individual queries. Because the buffers are backed by a contiguous array, we can represent the search results as index-ranges and thus efficiently compute the required unifications and intersections. This approach reduces the estimated costs of *performMatch* to:

$$C = \sum_{i=2}^n \left(|R_{i-1}| \cdot |R_i| + C_{findMatches}(|B_i|) \right) \quad (2)$$

with $C_{findMatches}(|B_i|)$ being bounded by $|\mathcal{P}| \cdot 13 \cdot 4 \cdot \log_2(|B_i|)$. The constant factors 13 and 4 arise from the possible *temporal relations* per constraint and the binary searches to execute for each of them, respectively.

5.3 Low-Latency Matching

In this section, we will determine the earliest points in time (t_d) to detect a *temporal relation* ($t_d(R)$), *temporal constraint* ($t_d(C)$) and *temporal pattern* ($t_d(\mathcal{P})$). Then, we adjust our algorithms from the previous section to deliver matches as early as possible.

5.3.1 Analysis. Two situations A, B can only be related once we know they exist, making $\max(A.ts, B.ts) \leq t_d(R)$ a trivial lower bound for *all* relations. For exact $t_d(R)$ consider a relation's definition δ_R depicted in Table 2. Let $t_1 \leq t_2 \leq t_3 \leq t_4$ be the timestamps in the order they appear in δ_R . It is easy to see

Relation (R)	Definition (δ_R)	$t_d(R)$	Prefix-Group (G)	$t_d(G)$
A before B	$A.ts < A.te < B.ts < B.te$	B.ts		
A meets B	$A.ts < A.te = B.ts < B.te$	B.ts	$A.ts < A.te \leq B.ts$	B.ts
A starts B	$A.ts = B.ts < A.te < B.te$	A.te		
A equal B	$A.ts = B.ts < A.te = B.te$	$A.te = B.te$	$A.ts = B.ts$	B.ts
A started-by B	$A.ts = B.ts < B.te < A.te$	B.te		
A overlaps B	$A.ts < B.ts < A.te < B.te$	A.te		
A finishes B	$A.ts < B.ts < A.te = B.te$	$A.te = B.te$	$A.ts < B.ts$	B.ts
A contains B	$A.ts < B.ts < B.te < A.te$	B.te		

Table 2: Low-Latency Analysis

that the ordering of t_4 can implicitly be derived at t_3 , because $t_3 \leq t_4$ and there are no timestamps beyond that. Furthermore, at t_1 and t_2 there are other relations sharing the same definitions up to that point, i.e., it is not possible to distinguish them from each other. To show this, we have grouped relations starting with $A.ts$ as *prefix groups* in Table 2 (B.ts groups are analogous). For those reasons we can conclude $t_d(R) = t_3$.

A *temporal constraint* $C = (R_1, \dots, R_n)$ for A, B matches if at least one relation matches. Therefore, the earliest detection time is $t_d(C) = \{t_d(R_1), \dots, t_d(R_n)\}$. Note that $t_d(C)$ is a set and the actual detection time of two situations depends on the fulfilled relation. Further, if C contains *all* relations of a *prefix group* (cf. Table 2), the detection time of these relations is shifted to the trivial lower bound ($t_d(G)$).

Finally, for a pattern $\mathcal{P} = (C_1, \dots, C_m)$, each constraint must be matched. However, a single *temporal configuration* matching \mathcal{P} fulfills exactly one *temporal relation* (\bar{R}) from each constraint, making $t_d(\mathcal{P}) = \max(t_d(\bar{R} \in C_1), \dots, t_d(\bar{R} \in C_m))$. In general, $t_d(\mathcal{P})$ is among the constraint detection points: $t_d(\mathcal{P}) \subseteq \bigcup_{i=1 \dots m} t_d(C_i)$.

5.3.2 Implementation. For the ease of presentation, we ignore the optional duration constraints on situations as well as *prefix groups* during the development and discuss the required changes at the end of this section. We gained two implementation-relevant insights from the low-latency analysis. First, new matches can only be detected if a new situation starts or a situation ends. Second, only a subset of the defined situations can possibly produce a match at $t_d(\mathcal{P})$. Thus, the matching process can be delayed until a situation with at least one endpoint in $t_d(\mathcal{P})$ occurs without affecting the latency. We call those situations *trigger situations* since only they should *trigger* a *performMatch* call. These insights affect our algorithms in the following ways. Situations must be available for matching from their start on, which can easily be achieved by adjusting the *deriver*. Additionally, we need to determine for each situation stream if the derived situations are *trigger situations*. For *trigger situations* we need to identify the point in time to execute *performMatch* (at its start, end or both).

However, the following cases must be considered during the matching process. If a situation requires matching on both endpoints, care must be taken not to produce duplicate results. Further, started situations must not be visible to the matcher in all cases: If two situations are related via *finishes* or *equals*, they could be mistakenly matched, because their temporary end timestamps (i.e., the current time) are equal. On the other hand, if two situations are not explicitly related via a *temporal constraint* they may participate in a successful match, even if both end timestamps are unknown. To illustrate this, consider the following pattern on four situations (A, B, C, D): A before B AND A before C AND A before D AND (D during C OR C

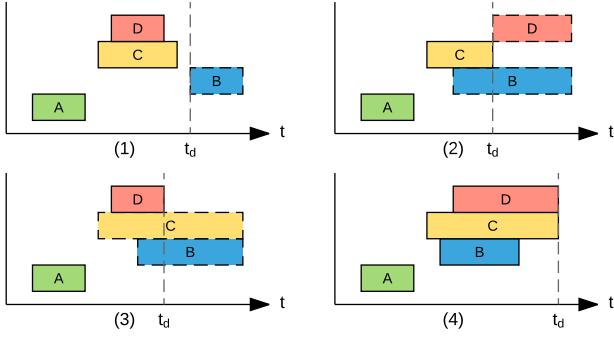

Figure 4: Earliest detection time (t_d) of different temporal configurations for the same pattern

finishes D OR C meets D). It defines situation A as starting point of every match. B is not explicitly related to C and D and required to happen after A. Consequently, B is a *trigger* situation and B.ts is in $t_d(\mathcal{P})$. For D both D.ts (via meets) and D.te (via during, finishes) are in $t_d(\mathcal{P})$. Figure 4 shows four representative *temporal configurations* for this pattern, highlighting the earliest point of detection (t_d). Configuration 1 showcases B as a *trigger* situation with $t_d = B.ts$. For the second configuration, D is the *trigger* with $t_d = D.ts$. This case also shows that two started relations may participate in a match if their end is unknown (B, D). The remaining configurations highlight D as a *trigger*, but with $t_d = D.te$.

Instead of handling these cases explicitly, our low latency algorithm avoids them by ensuring a unique combination of situations in the *working-set*, before passing it to the matching algorithm. In particular, this means started situations are managed in a separate buffer, inaccessible for the matching algorithm, and all valid combinations among them (i.e., all combinations of started situations, not explicitly related to the current one) are built upfront inside the *working-set*. Furthermore, to avoid duplicate results, the following fact is exploited: *temporal relations* enforcing matching on a situation's start require its counterpart to be finished in the past. On the other hand, *temporal relations* triggering matching on a situation's end require its counterpart to be either started (and not yet finished) or finished at the same time (cf. Table 2). Consequently, manually adding the started counterpart to the *working-set*, before executing the matching algorithm on a situation's end ensures uniqueness of the produced results.

The details are presented in Algorithm 4. After purging outdated situations from the buffers (Line 1), each started situation (s) is added to the additional buffer and if $s.ts \in t_d(\mathcal{P})$, the algorithm performs a regular match with s being the only constant in the *working-set* (Lines 2-5). Furthermore, if there are *started and unrelated* situations, we perform matches with s and each combination of them (Lines 6-8). This accounts for configurations as seen in Figure 4.2. All finished situations are migrated from the separate to the regular buffer (Lines 9-11) and if $s.te \in t_d(\mathcal{P})$, the matching process is triggered. This time with combinations of s and all *started and related* situations (Lines 15-16), further combined with all *started and unrelated* situations (Lines 17-18), which fuses the avoidance of duplicate results and false positives. An example for this case is shown in Figure 4.3. Note that, the actual constraint-checking among the created combinations is performed by the call to *performMatch* (Algorithm 3), since it is aware of pre-set situations in the *working-set*. As we will show

Algorithm 4: Low-Latency MatcherUpdate

Input: S_f, S_s : sets of finished/started, t : current time

```

1 purgeBuffers(t);
2 foreach  $s \in S_s$  do
3   startedBuffer.add(s);
4   if matchOnStart(s) then
5     performMatch( {s}, 0 );
6      $U \leftarrow$  getUnrelatedStarted(s);
7     foreach  $u \in \text{powerset}(U) \setminus \emptyset$  do
8       | performMatch(  $u \cup \{s\}$ , 0 );
9 foreach  $s \in S_f$  do
10  startedBuffer.remove(s);
11  addToBuffer(s);
12  if matchOnEnd(s) then
13     $R \leftarrow$  getRelatedStarted(s);
14     $U \leftarrow$  getUnrelatedStarted(s);
15    foreach  $r \in \text{powerset}(R) \setminus \emptyset$  do
16      | performMatch(  $r \cup \{s\}$ , 0 );
17      foreach  $u \in \text{powerset}(U) \setminus \emptyset$  do
18        | performMatch(  $r \cup u \cup \{s\}$ , 0 );
```

in section 6, the extensive building of combinations has only minimal impact on the runtime-performance, because it shifts load from joining to the update algorithm and does not introduce additional computation steps.

Duration constraints on situations are incorporated into low latency-matching with only a few modifications: First, if a maximum duration constraint is defined (regardless of a possibly specified minimum duration), the corresponding situation must not be included in the matching process until its end is known – and the constraint is fulfilled. Hence, these situations are excluded from the set of started situations (S_s) and if their start timestamp is in $t_d(\mathcal{P})$, matching is deferred to their end timestamp. Second, if a minimum but no maximum duration is defined, the inclusion into the set of started situations is deferred until the constraint is satisfied. This possibly implies the inclusion of its deferred start timestamp (\overline{ts}) into $t_d(\mathcal{P})$. As an example, consider the pattern A during B and the following order of timestamps: $B.ts < A.ts < A.te < B.\overline{ts} < B.te$. This match can not be detected at A.te, because B's duration does not exceed the lower bound at this point. Hence $B.\overline{ts}$ requires a matcher invocation.

To handle *prefix groups* the restriction that two *started and explicitly related* situations must not be matched is relaxed. That is, matching is performed if the corresponding *temporal constraint* contains one or more *prefix groups*. However, for still being able to omit false positives, the matcher must distinguish between *prefix group* and regular detection. Technically this means splitting the *temporal constraint* into two disjoint sets (one containing all *temporal relations* forming a *prefix group* and another one holding the remaining relations) and use the first set, when matching on a situation's start and the second one on its end.

5.4 Computing the Evaluation Order

The *matcher component* maps the problem of temporal pattern matching to a multi-way join between situation buffers. Like multi-join processing in traditional relational database systems,

Relation	before	during	overlaps	starts, finishes, meets	equal
Selectivity	0.445	0.03	0.01	0.0049	0.0006

Table 3: Initial estimates for the selectivity of temporal relations. Mirror relations are equivalent.

the performance of joining heavily depends on the order in which the join operations are executed. In this section, we discuss how the *matcher*'s evaluation order is computed and present the cost-model used during this process.

Analogous to classical join processing we implemented an optimizer that enumerates possible execution plans, computes the expected computational costs for each of them and suggests the most efficient plan for execution. We do not provide multiple implementations of the join operator, so that enumerating possible plans reduces to the enumeration of possible evaluation orders. To further reduce the number of plans to consider, we exclude orderings joining a situation buffer without an applicable *temporal constraint*. In other words: Plans involving the calculation of a cross product are omitted.

According to Equation 2, estimating the costs for a given plan boils down to estimating the size of intermediate results:

$$|R_i| := \begin{cases} |B_1| & \text{if } i = 1 \\ |R_{i-1}| \cdot |B_i| \cdot s_i & \text{otherwise} \end{cases} \quad (3)$$

s_i denotes the selectivity of the applicable *temporal constraints* in step i (C_i), which can be composed from the selectivities of the contained *temporal relations* as follows:

$$s_i := \prod_{C \in C_i} \left(\sum_{R \in C} s_R \right) \quad (4)$$

When a query is initially deployed into the system, the situation buffers are empty and we have no estimation on the selectivity of the *temporal constraints*. Hence, we initially assume the selectivities depicted in Table 3. These values are backed by the following back-of-the-envelope calculation: The combined selectivity of all possible relations should be 100%. Assuming equal sized buffers and an equal temporal distribution of the situations, the selectivity of a before relation will be around 50%. For during, the number of results is limited by the maximum of both buffer sizes, because a situation A can happen during at most one other situation (B), but B may contain multiple A situations. All other *temporal relations* define a 1:1 relationship, which limits the worst case to the minimum of both buffer sizes. As seen in Table 3, we additionally separate the last case by the number of stated equalities. Note that even though this is an initial estimate, the resulting plans prove to work well in most cases (cf. section 6.4.2).

5.4.1 Adaptivity. Once a query is deployed in a CEP-system, it is typically active for a long time. Hence, more important than the quality of an initial execution plan is the ability to tune this plan and adapt it to changing workloads. To do so, we keep track of the buffer sizes and selectivities imposed by *temporal constraints* during execution. The buffer-sizes are available at any point in time and at no cost, since they are tracked by the underlying data structure. However, to smooth out (potential) spikes, we monitor the buffer size using an *exponential moving average*, which is adjusted after each call to the *matcher*'s update method as follows:

$$EMA_i = \alpha * |B_i| + (1 - \alpha) * EMA_{i-1}$$

EMA_i holds after the i -th update. $|B_i|$ denotes the size of the considered buffer at update i and the *smoothing factor* $\alpha \in (0, 1)$ determines how much weight is given to previous values. For example, a value close to 1 assigns almost no weight to older values, while a value close to 0 decreases the influence of new values. The selectivities of the *temporal constraints* are also managed with EMAs using one EMA-value per constraint.

To check if a re-computation of the evaluation order is required, the active plan stores a snapshot of the statistics it is based on. After each update, we compare them to the current values and if any of them differs by more than the defined threshold (t), we trigger a re-computation.

Finally, if a migration is required, we are able to migrate to the new plan between any two invocations of the *matcher* component. Because the *matcher* does not store any intermediate results, but solely relies on the situation buffers this switch comes without any additional migration costs. As we will show in section 6.4.2, the total costs for adaptivity are negligible.

6 EXPERIMENTAL EVALUATION

In this section we present the results from our experimental evaluation of *TPStream*². First, we study *TPStream*'s evaluation performance in comparison to *ISEQ* and point based CEP systems. Then, we analyze the latency improvement of our approach in comparison to *ISEQ*. Finally, we prove the validity of our optimization techniques.

6.1 Setup

All experiments were conducted on a workstation equipped with an Intel i7-2600 3.4 GHz processor and 8GB of memory, running a Debian Linux (kernel version 4.11.11-1). The results presented for each experiment are averaged values from a total of 10 runs, whereby every run was preceded by a warm-up phase of evaluating at least 100,000 events before the measurement was started.

The main goal of this section is to compare *TPStream*'s processing performance and our low latency approach to the state-of-the-art solution for temporal pattern matching (*ISEQ*). There is no publicly available implementation of *ISEQ*, so we implemented it based on the available description in [20]. As required by the design of *ISEQ*, the input consists of interval streams ordered by endpoint. These streams are again generated with our *deriver* component.

In order to provide a comparison with point based systems, we also included CEP-solutions from the open-source community (Esper³ 6.0.1) and academia (SASE+⁴), when applicable. While Esper is a production ready CEP system, highly optimized for efficient query execution, SASE+ is one of the most popular CEP languages in the research community and served as foundation for the *ISEQ* operator. The rich query language of Esper allowed us to express both straw man's approaches as sketched in the introduction. We refer to the first approach (2 phase pattern matching) with *Esper-1* and the low latency approach is denoted as *Esper-2*. Because the SASE+ implementation does not feature chaining of queries, we only implemented the low-latency approach. *TPStream* and all its competitors are implemented in the JAVA programming language, whereby *TPStream* and *ISEQ* are based on JEPC [19] – an event processing middleware. We used

Figure 5: Processing time for aggressive driver detection as a function of the input size: (a) simplified pattern, (b) full pattern and processing time for disconnected pattern detection as a function of the window size (c)

Figure 6: Processing time for various query patterns

Oracle JDK 1.8.0.144 compile the systems and ran all experiments on that JVM with 6GB of heap space.

During the evaluation two data sources were used. The first source comprises trip data generated with the Linear Road Benchmark [4]. Besides other attributes, each event consists of a unique car id, its location, the current speed and acceleration. We generated data simulating 5 hours of traffic on a single expressway with 1000 active cars per hour. Each active car reports its state every second, leading to 887 million events (36 GB of data). The second source is a random event generator, tuned to pose high load on the system. It generates event streams with a configurable number of boolean attributes, each representing a single situation stream. The generated situations last between 10 and 100 seconds, while the gaps between two consecutive situations span 10 to 50 seconds (both uniformly distributed). Events are generated with a frequency of 1Hz, so that for a situation lasting n seconds, the corresponding attribute’s value is true for exactly n consecutive events.

Independent of the data-source, we used a single thread for both, reading/generating the data and evaluating the query. For each experiment, we measured the reading/generation time upfront and removed it from the presented results. The most important parameters throughout all experiments are as follows:

Event Rate The rate (events/s) with which events are pushed into the systems.

Window Size The size of the time window (s) during which a pattern must occur completely.

Event Count The total number of events to process.

6.2 Processing Time

This set of experiments compares the processing performance of *TPStream* with its competitors using various queries and parameter settings. The events were pushed into the system at the maximum possible rate and we used the processing time as main measure.

6.2.1 Aggressive Drivers. We injected different fractions (1M to 100M events) of the Linear Road dataset into the system and executed the example query of Listing 1 (without duration constraints). The thresholds for speeding, acceleration and deceleration were the 99th, 90th and 90th percentiles for the speed and positive/negative acceleration values of a 50M event sample. Besides chaining of queries, the SASE+ implementation also lacks support for disjunctions. Nevertheless, to include SASE+ in this experiment, we also evaluated a simplified query version which restricts the used *temporal relations* to meets and overlaps.

The results of this experiment are shown in Figure 5 (a – simplified pattern, b – full pattern). The x-axis shows the number of processed events, the processing time is shown on the y-axis. *TPStream* and *ISEQ* are head to head and their processing times increase linearly with the number of processed events. Further, they are insensitive to alternatives, resulting in almost identical processing times for both query variants. *TPStream* was not able to outperform *ISEQ* in this experiment, because in the given pattern all situations overlap which in turn allows to break the buffer scan early. Esper benefits from the simplified version of the pattern, but its evaluation performance is inferior to *TPStream* and *ISEQ* (up to 30x for the full query and 15x for the simplified version). When evaluating the full query, Esper hit the memory limit of 6GB and the system crashed if more than 30M (Esper-1) and 40M (Esper-2) events were processed. For the simplified version, the processing time of Esper-1 increases drastically when processing more than 50M events – Esper-2 runs out of memory and crashes. SASE+ managed the evaluation, but was clearly outperformed by *TPStream* and *ISEQ*.

6.2.2 Disconnected Pattern. The second experiment compares processing time and memory consumption of the systems using a pattern with high selectivity: A before B overlaps C. The difference to the first experiment is, that each A situation may be related to many B overlaps C sub-matches instead of contributing to at most one match. Hence, we expected the number of results and consequently the processing time/memory consumption to depend on the size of the configured time window. We injected 300M synthetic events into the systems and executed

Figure 7: (a) application time latency gain per temporal relation and comparison of result latency (b) under maximum possible throughput as a function of the window size, (c) under varying event rates with a fixed size window

the query with window sizes varying from 500s (8:20 minutes) to 100,000s (slightly more than one day).

Figure 5 (c) shows the processing time of all systems as a function of the window size (note the log-scale). In this experiment, *TPStream* is able to outperform *ISEQ* by a factor of 14 using a window of 100,000s. This is because *ISEQ* does not make use of the order on the situations' start timestamp and requires additional computational steps during result construction and buffer pruning. *SASE+* did not finish this experiment in a reasonable time for none of the window sizes and *Esper* barely managed two window sizes up to 20,000s. To measure the average memory consumption, we monitored the used heap space with a frequency of 20Hz during each run and averaged these values. Both, *TPStream* and *ISEQ* require only very little additional memory for increased window sizes: *TPStream* 911 - 1018 MB, *ISEQ* 903 - 1027 MB. *Esper* stays stable at 1 GB up to a window size of 10,000s but afterwards suffers from buffering single events rather than a compact representation like situations. For the last evaluable query (20,000s window) *Esper* already consumed 1,7 GB of memory.

6.2.3 Query Patterns. To give a comprehensive overview of *TPStream*'s processing performance, we evaluated 5 different query patterns and varied the number of situation streams from 4 to 10. Queries 1-3 (**Equal**, **Meets**, **Chain**) are of the form $S_1 \oplus_1 S_2 \oplus_2 \dots \oplus_{n-1} S_n$, with $\oplus_i = \text{equals}$, $\oplus_i = \text{meets}$ and \oplus_i a randomly drawn temporal relation, respectively. In query 4 (**Star**), S_1 is connected with every other situation, via a random temporal relation (i.e. $S_1 \oplus_1 S_2, S_1 \oplus_2 S_3, \dots, S_1 \oplus_{n-1} S_n$). Query 5 (**Combined**) combines the two generic patterns by connecting the first $n/2$ situations via the **Chain** pattern and the remaining situations according to the **Star** pattern. Each query-type was executed 100 times, using 50M synthetic events and a window size of 2,000s.

The box plots in Figure 6 provide the median as well as the 25th and 75th percentiles of the processing time. For all query types, the median processing time increases linearly with the number of situations. The generic **Chain** pattern incurs higher maximum values than **Equal** and **Meets**, because the possible temporal relations include before, which is highly selective. This forces the matcher to build many partial results – especially if three or more consecutive situations are in a before relationship. **Star** queries are more sensitive to the concrete pattern instance, because in the worst case every situation triggers the matching process. This effect can also be observed for the **Combined** pattern, but to a smaller degree, because only half of the situations are connected via a **Star** pattern.

6.3 Low Latency

This set of experiments compares the result latency of our approach with the state-of-the-art solution for temporal pattern matching, *ISEQ*.

6.3.1 Application Time. At first, we measure the latency improvement of *TPStream* compared to *ISEQ* in terms of application time. That is, we compare the timestamps of the events that produced a result in both approaches and calculate their difference. We evaluated each temporal relation independently using two synthetic situation streams (A, B). We varied the average duration ratio from 2:1 to 1:2, keeping A's average duration fixed at 55 seconds. Note that the window size has no impact here (as long as it is not too small to hold a match), so it was set to 1,000s.

Figure 7 (a) shows the average latency improvements per temporal relation. For sequential relations (before, meets), the gain in latency is equal to the average duration of B situations, because matches are detected at B.ts. For the remaining relations, the detection time is A.te and the average improvement depends on the concrete temporal relation. In the worst case (during) this is B.duration/2. Note that, equals and finishes were not included, because no latency improvements can be achieved.

6.3.2 Wall Clock Latency. We conducted two experiments, showing that *TPStream*'s processing techniques significantly reduce the result latency in terms of wall clock time which is a critical aspect in a streaming scenario. Therefore, we repeat the experiment from section 6.2.2 twice: first, we measure the time passed between the arrival of the first event that could produce a result and the receipt of that result. We varied the window size and pushed events with the maximum possible rate. For the second experiment we fixed the window size at 100,000s and varied the event rate from 1M to 1 events/s. This time, we split the measured latency in (i) processing latency: the time passed between arrival of the event that triggered the result and the actual receipt of that result and (ii) event latency: the time passed between arrival of the first event that could trigger the result and the arrival of the event that actually triggered that result.

The results are shown in Figure 7 (b,c). Both figures show the average latency per result (y-axis, note the log-scale for c). While (b) shows, that *TPStream*'s evaluation techniques provide latency savings through reduced processing time, (c) highlights the savings achieved with our low-latency matcher. Especially when the rate is in sync with application time (1 event/s), the event latency of *ISEQ* dominates the processing latency and almost reaches the application time savings (~35s, cf. Figure 7 a, 1:1, overlaps), while *TPStream* introduces no event latency at all.

Figure 8: (a) Quality of the initial plans for Q1 – Q3, (b) Throughput comparison: dynamic plan adaption vs. best initial plans

6.4 Plan Quality & Adaption

Finally, we evaluate the optimization techniques presented in section 5.4. Like in section 6.2, events were pushed with the maximum possible rate.

6.4.1 Initial Plan Quality. To evaluate the quality of the generated initial plans, we used the following queries on three situation streams: **Q1**: A overlaps B AND A overlaps C AND B starts C, **Q2**: A overlaps B AND A before C AND B overlaps C and **Q3**: A before B AND A before C AND B before C. For each query, we generated all 6 valid plans and measured the throughput (processed events/s) by evaluating synthetic events with a window size of 5,000s.

Figure 8 (a) shows the results for the best, worst and suggested plans and clearly confirms our approach. For queries **Q1** and **Q2** the best plan was suggested. The initial plan for **Q3** was $C \rightarrow B \rightarrow A$ even though the estimated costs for $C \rightarrow A \rightarrow B$ are the same. The experiments show, that $C \rightarrow A \rightarrow B$ would have been a slightly better choice, but the difference is negligible.

6.4.2 Dynamic Plan Adaption. To analyze the plan adaption capabilities of *TPStream*, we executed **Q3** again and processed 300M events. The occurrence ratio of situations A, B and C changed from 1:1:1 to 1:50:50 after 100M events and finally to 50:1:50 after 200M events. The window size, smoothing-factor (α) and threshold for plan migration (t) were set to 10,000s, 0.01 and 0.2, respectively. Besides the adaptive implementation (TPS-A), we ran the experiment with both best initial plans $C \rightarrow B \rightarrow A$ (TPS-1), $C \rightarrow A \rightarrow B$ (TPS-2), and an implementation, doing a hard coded switch to the best plan exactly when the characteristics of the stream changes (TPS-O).

Figure 8 (b) shows the throughput for all four configurations and the three different stream-characteristics: TPS-1 and TPS-2 both have drawbacks in either one of the skewed phases, while our adaptive approach is very close to the optimal solution TPS-O (suffering slightly from dynamic adaption). However, the total runtime of TPS-O (63,523ms) compared to TPS-A (64,612ms) reveals only a negligible overhead of 1,089ms (less than 2%) for plan adaption.

7 CONCLUSION

We presented *TPStream*, a novel event processing operator for detecting complex *temporal patterns* among event streams. We enabled *TPStream* to derive lasting situations directly from streams of events and developed new techniques for detecting *temporal patterns* at the earliest possible point in time. Furthermore, we demonstrated low-cost adaptive approaches suitable for a streaming scenario. We proved the potential of *TPStream* by comparing it to industrial and academic solutions for CEP in experiments.

Since research on situations in CEP is scarce, we focused our efforts on presenting a fundamental solution suited for this scenario and equipped it with the capabilities to handle the adaptive, low-latency nature of stream processing. For future work, we intend to extend *TPStream* to tackle out-of-order arrivals [7, 21] and parallel processing [24, 26].

ABSTRACT

With large-scale simulations of increasingly detailed models and improvement of data acquisition technologies, massive amounts of data are easily and quickly created and collected. Traditional systems require indexes to be built before analytic queries can be executed efficiently. Such an indexing step requires substantial computing resources and introduces a considerable and growing data-to-insight gap where scientists need to wait before they can perform any analysis. Moreover, scientists often only use a small fraction of the data — the parts containing interesting phenomena — and indexing it fully does not always pay off.

In this paper we develop a novel incremental index for the exploration of spatial data. Our approach, QUASII, builds a data-oriented index as a side-effect of query execution. QUASII distributes the cost of indexing across all queries, while building the index structure only for the subset of data queried. It reduces data-to-insight time and curbs the cost of incremental indexing by gradually and partially sorting the data, while producing a data-oriented hierarchical structure at the same time. As our experiments show, QUASII reduces the data-to-insight time by up to a factor of 11.4x, while its performance converges to that of the state-of-the-art static indexes.

1 INTRODUCTION

The advances in data acquisition technologies and supercomputing for large-scale simulations rapidly increase the amounts of spatial data generated and collected. For instance, in the Human Brain Project (HBP) [27], neuroscientists build spatial models of the brain which will ultimately feature 10^{11} neurons [42], each reconstructed with thousands of 3d cylinders. NASA released 500 TB of earth observation data generated through remote sensing [30], while the Dutch government released point cloud data with 640 billion points [31] acquired through airborne scanning. Similarly, volunteers generate large amounts of spatial data through services such as OpenStreetMap [33]. Given these massive and growing amounts of spatial data, algorithms to query them efficiently are crucial.

Previous research has proposed many techniques [11, 26, 42] for the fast and scalable querying of spatial datasets. Existing approaches, however, have two major drawbacks. First, they require a time-consuming step to build indexes before they can be used. This pre-processing step significantly delays the analyses: indexing a model in the HBP, for example, can take several hours [42]. With increasing dataset size, the data-to-insight time grows as well. Second, scientists frequently only analyse a small fraction of the data [1, 8]. In the HBP, for example, a scientist builds a

model of the brain but after a few queries may determine that it is not biorealistic (e.g., density in certain areas does not agree with measurements) and stops the analysis. Given the small number of queries executed, the overhead of indexing the entire model cannot be fully amortized.

The problems of delayed analysis (due to prior indexing) and the impossibility to amortize indexing cost (due to too few queries) are not exclusive to spatial data management. Database research has proposed incremental indexes for relational data (e.g., cracking [18] and adaptive merging [14]) and for time-series [45]. The core idea is to incrementally index only the parts of the data queried, spreading the cost of indexing over the first few queries. The major data-to-insight bottleneck is thus eliminated, i.e., queries are answered as soon as data is available (albeit the first queries run slower, as no index is initially available).

In this paper, we develop an incremental indexing approach for spatial data in main memory, with the aim of reducing data-to-insight time, as well as achieving performance comparable to traditional spatial indexes (after enough queries are executed). As no current incremental indexing approach for main memory exists, we demonstrate the limitations of applying current options to incrementally index spatial data. As we show, using the concepts for incrementally indexing one-dimensional data [18] to index three-dimensional data does not significantly reduce data-to-insight time, as the major bulk of work still has to be done for the first query. Adapting Space Odyssey [35], an incremental index for exploratory analyses of multiple spatial datasets on disk, to main memory leads to excessive reorganization of the data. As a consequence, a static index (including pre-processing cost) quickly outperforms the proposed incremental solution, in terms of total execution time.

We thus develop a QUery-Aware Spatial Incremental Index - QUASII: a novel data-oriented, query-driven incremental indexing approach. QUASII substantially reduces data-to-insight time and keeps the cost of incremental strategy low, by gradually and partially sorting the spatial objects considering all dimensions. QUASII thus distributes the cost of indexing across all queries, while preserving spatial proximity and producing a data-oriented style partitioning — which typically entails an expensive pre-processing step in the static setting. Finally, being data-oriented, it executes queries efficiently, as it adjusts to the distribution of the data, while avoiding data replication.

Our experiments show that QUASII substantially accelerates the exploratory analysis of spatial data in main memory by reducing the data-to-insight time by up to 11.4x, while achieving the query performance of current algorithms for spatial indexing. Static algorithms are not able to amortize their building cost over QUASII even after 10000 queries.

To our knowledge we are the first to develop and analyze incremental indexing for spatial data. Our contributions are:

- We demonstrate the challenges of adapting and using known incremental indexing [18, 35] to spatial data in main memory. We use the resulting approaches as motivation and baseline.
- We develop *QUASII*, an incremental approach that significantly reduces the data-to-insight time, while achieving the query performance of state-of-the-art spatial indexes.
- We experimentally analyse *QUASII*'s performance and the number of queries it needs to reach the performance of its static counterparts.

The remainder of the paper is structured as follows. We define the problem in Section 2 and motivate it in Section 3. We then describe *QUASII* in Sections 4 and 5 and experimentally evaluate it in Section 6. Section 7 gives an overview of related work before we conclude in Section 8.

2 PROBLEM DEFINITION

Our work is driven by the need for the exploratory analysis of spatial datasets through querying. The queries executed are ad hoc, i.e., the next query is only known after the results of the first query are analyzed, and they thus cannot be batched and executed with only one sequential read of the dataset.

Example Application. In the Human Brain Project, neuroscientists build spatial models of the brain [27]. Already now the models are so detailed that to simulate a neocortical volume of only 0.29 mm^3 supercomputers are needed [28].

Once the part of a model is built, neuroscientists need to validate it by choosing a subset of its regions at random and inspecting them. Each region is queried with several spatially close queries and the query results are used to verify the composition, density and other metrics agree with the real brain. The results of these analyses are crucial to determine whether or not the model can be simulated or should be abandoned (subsequently building a new one using a different configuration). Scientists currently only have two fundamentally different options: index all data a priori and execute queries with the index or scan all data each time to answer a query. Not knowing a priori how many queries will be executed (and if indexing can be amortized) makes it difficult to decide.

Data. We consider spatially extended (volumetric) objects enclosed by a minimum bounding box (MBB). In a three-dimensional ($3d$) setting, each MBB b is defined by two $3d$ points $lower(b)$ and $upper(b)$ corresponding to lower and upper coordinate at each dimension ($lower(b) = (x_l, y_l, z_l)$ and $upper(b) = (x_u, y_u, z_u)$) [11].

Queries. We focus on range (window) queries as they are broadly used in many applications and are also the building block for many other spatial queries (e.g., k -nearest neighbor queries [22]). Each query is a $3d$ box specified by two $3d$ points, e.g., (q_l, q_u) . Given a query q , all objects with their bounding box b intersecting with q , i.e., where $b \cap q \neq \emptyset$, are in the result.

Setting. We assume that all data and necessary index structures fit in main memory. We consider a static setting, i.e., all raw data is available before querying.

3 MOTIVATION

No current incremental indexing approach can index spatial data in main memory. Research has developed incremental indexing for relational, one-dimensional data in main memory, i.e., cracking [18] and for spatial data on disk [35]. In the following we extend the former [18] to the spatial domain and adapt the latter [35] to use in main memory — to demonstrate the limitations

of these ideas in reducing the data-to-insight time and to motivate the need for a new approach.

3.1 Cracking for Spatial Data

Relational Cracking. Database cracking [16, 18, 19] incrementally builds an index as a byproduct of query execution in the context of main memory column-stores. The proposed techniques partially sort elements based on the query execution, essentially performing an incremental quick sort. In its simplest form, cracking [18] rearranges elements in an array according to the end points of the query range (q_l, q_u) : all values $< q_l$ are moved towards the beginning of the array, while values $> q_u$ are moved towards the end. With each query, the index becomes more refined until it is fully sorted and indexed.

SFCracker. Using this strategy to index spatial data is inherently challenging: spatial data has multiple dimensions and, unlike $1d$ data, no total order can be directly imposed on it. Therefore, to be able to use the strategy of cracking we transform data from the multi- to the one-dimensional domain. We perform this transformation using a space-filling curve (SFC) — a common approach to impose a total, $1d$ order on spatial objects.

A SFC maps data to $1d$ domain by visiting all the points in a d -dimensional grid exactly once; the order in which the objects are visited defines their order in $1d$ space. When mapping spatial data, it is crucial to consider SFCs that preserve proximity (such as Z-order [34] or the Hilbert curve [21]), so that data points close in multi-dimensional space remain close in $1d$ space [10, 29].

The resulting approach, *SFCracker*, incrementally sorts SFC codes based on the queried region. Both, data and queries are transformed to $1d$ space. The data transformation takes place in the first query, which makes it the most expensive one. Once the data is transformed, the queries perform cracking based on the $1d$ intervals obtained through the query transformation.

A naive query transformation to $1d$ space results in a substantial number of false positives (needed to be tested for intersection) because the transformed $1d$ range can be significantly larger than the original multi-dimensional range if only the *lower* and *upper* coordinates of the range query are considered. An example is shown in Figure 1: the curve segments in blue belong to the transformed range ($SFCcode_l, SFCcode_u$),

Figure 1: 1d transformation: overhead.

but they are outside of the original query range (in red). To reduce the overhead of false positives, we use a technique that partitions the curve into multiple sub-intervals each of which is fully contained in the original range [43]. Consequently, a range query is transformed into a number of intervals and the data is thus cracked multiple times per query, once for every interval.

Limitations. Cracking in the relational domain decreases data-to-insight time, distributing the cost of sorting over all queries with fairly low overhead and initialization cost. These benefits, however, decrease for datasets with a higher number of dimensions. First, the initial query is expensive as it maps all the objects from the multi- to the one-dimensional domain. Second, as opposed to relational data, a single query has to perform multiple expensive cracks to avoid performance penalties introduced with the transformation to $1D$ space. Consequently, spatial cracking still has a considerable data-to-insight time, along with an

expensive incremental strategy. We demonstrate these limitations experimentally in Section 6.3.

3.2 Disk-based Incremental Indexing in Main Memory

Disk-based Incremental Indexing. Space Odyssey [35] is a recently proposed incremental index for the exploration of spatial data. However, it tackles a different problem: Space Odyssey is designed for exploratory analyses of multiple spatial datasets. Without prior information, it incrementally indexes the datasets and adapts the physical layout of the data on disk for datasets frequently queried together. Although Space Odyssey addresses a different problem, we use its ideas related to incremental indexing and adapt them for use in main memory in *Mosaic*.

Mosaic. Mosaic incrementally builds an Octree [20] by dividing the space uniformly into eight partitions. Figure 2 depicts the indexing process (in 2d for clarity). For every query, Mosaic identifies the partitions that overlap with the query, splits them into eight partitions and reassigns their objects to the newly created partitions. Frequently queried areas in a dataset are indexed fully, whereas less frequently queried areas are coarser grained. The top-down strategy is thus beneficial for consecutive queries, as they can reuse the previous partitioning, independent of the workload pattern. However, data in frequently queried areas is re-partitioned multiple times.

Figure 2: Mosaic: incremental strategy.

Limitations. Mosaic introduces significant overhead as the data in frequently queried areas is re-partitioned multiple times until it reaches its final configuration. Consequently, a static approach based on space-oriented partitioning, such as the uniform grid, outperforms quickly Mosaic in terms of total execution time (we provide more details in Section 6.3).

Mosaic additionally suffers from considering more objects than strictly necessary – a problem inherent in space-oriented partitioning and related to data assignment. For indexes based on space-oriented partitioning, objects can be assigned to cells with two strategies: replication and query extension. Replication assigns an object to all partitions that it overlaps with. As a consequence more objects need to be considered for intersection, the memory footprint increases and an expensive de-duplication step is needed. The alternative is to use query extension [40] which assigns an object to a cell based only on its center. This technique avoids object replication, however, it can considerably increase the number of objects necessary to be tested for intersection. More precisely, to ensure the correctness of the query result, it extends the query range by the maximum object extent. As a result, the area queried for is bigger than the initial query. Both strategies, replication and query extension, slow down query execution but, as we show in Section 6.2, replication is particularly expensive when working with volumetric spatial objects and we thus use query extension in Mosaic.

4 QUASII OVERVIEW

As discussed, an approach to incrementally index spatial data is not as straightforward as adapting known approaches. Besides the challenges, we also identify important design goals:

- (i) **minimal data-to-insight time:** the main requirement for incremental indexing is to enable instant access to the data, i.e., the first queries must not introduce undue overhead/processing;
- (ii) **efficient query performance:** the performance of frequently queried subsets of data should converge to that of the fully indexed approach (or better);
- (iii) **low cost incremental indexing:** indexing should introduce as little overhead as possible, i.e., its cumulative execution time should only exceed the one of static indexes after as many queries as possible (or not at all).

Given the design goals and our analyses, we develop QUery-Aware Spatial, Incremental Index, QUASII. QUASII is a data-oriented index, incrementally built as a side effect of query execution. It reduces data-to-insight time and curbs the cost of incremental indexing by gradually and partially sorting the data, while simultaneously producing a data-oriented hierarchical structure. It is based on a *nested reorganization strategy* which incrementally slices the space in each dimension and a *hierarchical, data-oriented structure* designed to accommodate the incremental indexing process and provide efficient query execution.

Overview. Figure 3a illustrates QUASII’s incremental strategy on a high level. Given range queries of the form $q = [q_l = (x_l, y_l, z_l), q_u = (x_u, y_u, z_u)]$, QUASII reorganizes the objects based on each query’s lower (q_l) and upper (q_u) coordinate by slicing each dimension and performing a nested reorganization. It first reorganizes objects on the x dimension, producing three x slices where the middle one contains the objects in the range $[x_l, x_u]$ given the query range in dimension x . Subsequently, it continues reorganizing the middle x slice on the y dimension, producing again three slices where the middle one contains objects in the range $[y_l, y_u]$. Finally, QUASII reorganizes the y slice on the z dimension producing the z slice which contains the query result. QUASII never performs a complete sort but reorganizes data locally, given the query’s boundaries.

The slices produced are organized in a hierarchical structure that incrementally forms the index. Figure 3b illustrates the structure of QUASII after the very first query (left) and after an arbitrary number of queries (right) are executed. QUASII forms a hierarchical structure with one level per dimension, i.e., the first (top), second, and third (bottom) levels correspond to slices at x , y , and z dimensions, respectively. The top level has the coarsest granularity as its objects are constrained with one dimension, while the bottom level is the most fine-grained since it is constrained by all dimensions. When executing the queries, QUASII traverses the structure depth-first, performing additional refinements when necessary, as we discuss later in Algorithm 1.

Nested Reorganization Strategy. The incremental strategy of QUASII is query-driven and data-oriented. Being query-driven, it reorganizes the minimal amount of data while executing queries. At the same time, being data-oriented, it achieves query efficiency as it adjusts to the data distribution, while avoiding replication. QUASII accomplishes both through its nested reorganization.

Data-oriented partitioning typically entails an expensive pre-processing step in the static setting as it preserves spatial proximity based on a strategy for ordering multi-dimensional objects. QUASII distributes the cost of this pre-processing across all queries by performing nested and partial reorganization. It reorganizes only a subset of data driven by queries, gradually curbing the amount of data partially sorted with every dimension. This strategy is inspired by the Sort-Tile-Recursive (STR)

Figure 3: QUASII incremental indexing strategy and data structure.

R-tree bulkloading algorithm [26]. STR produces tiles that form leaf-level nodes for the R-Tree by recursively, fully sorting spatial objects in each dimension. More precisely, STR for $3d$ objects first sorts the spatial objects on the x -axis and partitions them in vertical tiles of equal size (i.e., the same number of objects). Then, within each x tile, it recursively applies the same strategy first considering y and then z dimension. This tiling strategy is particularly efficient as the resulting R-Tree has less overlap than other approaches [26]. By only performing partial reorganizations for the parts of the data that is actually queried, QUASII outputs partitions targeting these characteristics at lower cost (as opposed to complete sorts in STR).

Index Structure. QUASII’s index structure is designed to support an efficient incremental strategy with as little performance penalty as possible. Its hierarchical structure is designed to accommodate the reorganization strategy: each level corresponds to one (reorganization) dimension and each parent node is represented by its children in a nested form along the dimensions QUASII reorganizes data. We discuss the data structure and how it accommodates incremental indexing in more detail in Section 5.1.

Benefits. Ultimately, the design choices behind our approach enable us to achieve the goals we outlined. To reduce data-to-insight time (i), QUASII keeps data in the multi-dimensional, spatial domain. This avoids transforming all data at the very beginning which significantly hurts performance of the first query. Next, to achieve query efficiency (ii), QUASII uses data-oriented partitioning that preserves spatial proximity, adjusts to the distribution of data, and avoids object replication. Finally, to keep the cost of the incremental indexing low (iii), QUASII gradually and partially sorts the data using a nested reorganization strategy.

5 DATA STRUCTURE & QUERY PROCESSING

In the following, we explain the QUASII index structure and data organization before we proceed with discussing querying and incremental indexing algorithms.

Throughout this section, we refer to a $2d$ example given in Figure 4. It depicts a dataset $D = \{o_0, \dots, o_9\}$ of ten (gray) rectangular spatial objects. All subfigures have three main parts: the top part shows a $2d$ view of the dataset D and how the space is conceptually “sliced” by QUASII, the middle (“Data array”) depicts how (raw) data objects are re-organized in main memory, and the bottom shows QUASII’s hierarchical data structure that is incrementally built. All x - and y -axis related slicing is marked in green and blue, respectively. Figure 4a) shows the initial state: the “slice-less” view of the data space with D objects and the very first query q_1 , the data array of spatial objects in an arbitrary initial order, and the data structure containing the initial slice, s_0 (capturing the entire dataset).

5.1 Data Structure

QUASII forms a d -level hierarchical structure, organized according to the number d of dimensions. Each level l has a one-to-one mapping to the corresponding dimension. That is, the first level ($l = 1$) represents slicing of data at x , the second level ($l = 2$) slices at y , and the third level ($l = 3$) slices at the z dimension. The top level always slices data objects at the coarsest granularity, while the bottom level is the most fine-grained. Each slice is described with four attributes: (i) its level, (ii) a minimum bounding box capturing all its objects, (iii) indices to the data array corresponding to the first and last entry of the objects that belong to the slice, and (iv) pointers to sub-slices refining the slice further on the subsequent dimension. In Figure 4, this corresponds to the four fields present in each node of the data structure (next to slice label, e.g., s_0): l , box , ids , and arrow pointers (when not null). In our two-dimensional view of the dataset, we mark $boxes$ with a solid line (in the corresponding color), while the slice cuts are marked as dashed lines.

Data-oriented Slicing. One of the main advantages of data-oriented partitioning is that each spatial object is always assigned to just one partition (slice). However, QUASII determines the slices in each dimension based on query ranges. Given volumetric spatial objects, objects can be sliced through and thus overlap with multiple slices. To overcome this problem, QUASII represents each object using only one of its coordinates and uses this coordinate to identify a slice where an object will be assigned to. In particular, during indexing, it uses each object’s lower coordinate (x_l, y_l, z_l). Being part of object’s MBB, this does not require any additional computation or storage¹. In Figure 4, this coordinate is marked as a black dot for all objects. Figure 4b illustrates slicing based on the very first query q_1 and its range $[2, 4]$ on the x -axis. Slicing at $x = 2$ and $x = 4$ results in three x -slices (s_1, s_2 , and s_3). While object o_6 overlaps two slices (s_2 and s_3), it is assigned to s_2 based on its lower coordinate (x_l). Note how the objects are re-organized in the data array and correspond to three partitions (slices) with coordinates $x < 2$, $2 \leq x \leq 4$, and $4 < x$. Accordingly, the data structure is updated with three new (more refined) slices replacing the initial (coarser) slice s_0 (capturing the whole dataset).

While QUASII assigns objects to slices based on their single (lower) coordinate, it records a minimum bounding box for each slice taking into account the actual spatial extent of the objects and thus ensures the correctness of the query result. This also results in slice representations (their MBBs) that are often much smaller but not necessarily within the originally sliced bounds. For example, s_1 contains only one object and thus has a very small MBB (i.e., its $box = o_2$), while the MBB of s_2 is b_2 and exceeds the original cut at $x = 4$ (Figure 4b). As we show later, this enables QUASII to discard many unnecessary slices during

¹The upper coordinate (x_u, y_u, z_u) or the object’s center (requires to be computed, though) can equally be used.

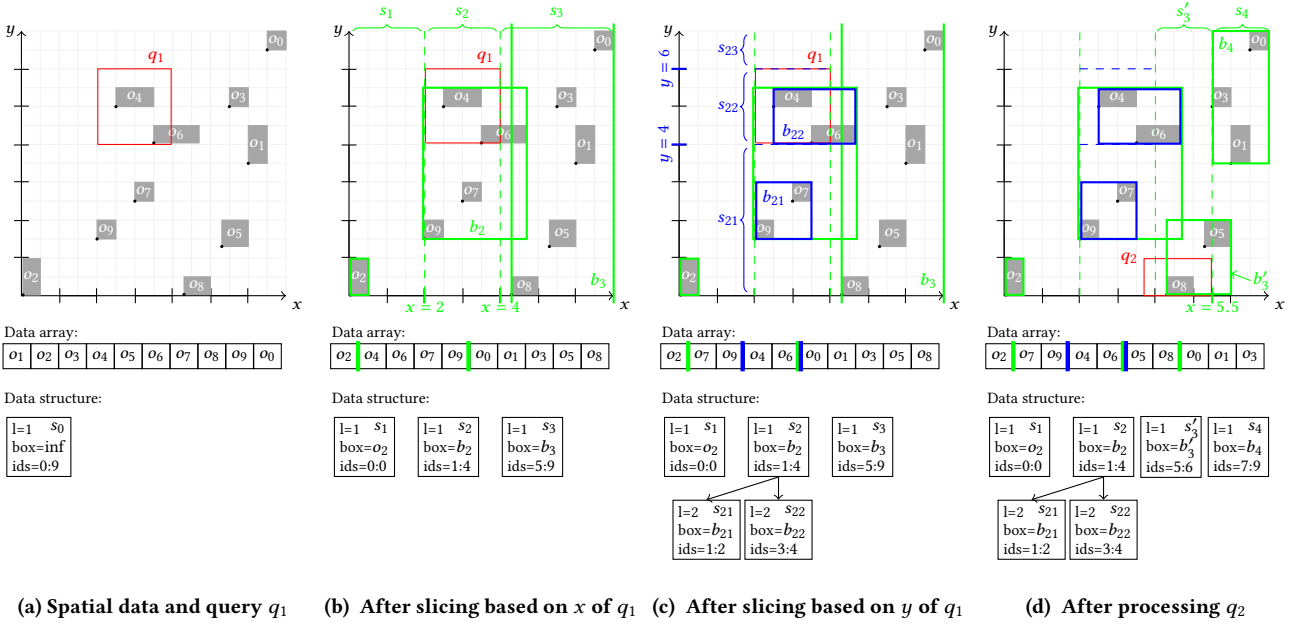

Figure 4: An example of query processing and incremental indexing in QUASII (configured with $\tau_x = 4$ and $\tau_y = 2$), given ten spatial objects (o_0 – o_9) and two range queries (q_1 and q_2).

query execution. To limit unnecessary computation (as a slice can be reorganized multiple times until it is fully refined), QUASII computes a full MBB only when a slice is completely refined. Otherwise, a slice is represented with an open-ended MBB, i.e., the MBB has bounds only on the dimension it has been sliced on.

Configuration. QUASII has only one configuration parameter, a size threshold τ , that determines the maximum number of objects in a slice at the finest level. That is, at the bottom level, whenever a slice s contains less or τ number of objects (i.e., $|s| \leq \tau$), it is considered to be fully refined. Intuitively, this is similar to setting a (leaf) node size in the R-Tree.

The sizes of the remaining $d-1$ levels are calculated as follows. Since QUASII performs data-oriented slicing, the total number of partitions required to satisfy threshold τ is $\lceil n/\tau \rceil$, where n is the total number of objects (i.e., $n = |D|$). Consequently, the number of times QUASII has to slice the data space across each dimension to produce $\lceil n/\tau \rceil$ partitions is equal to:

$$r = \lceil \sqrt[d]{n/\tau} \rceil \quad (1)$$

If we use τ_d to denote the slice threshold at the bottom level $l = d$ (i.e., $\tau_d = \tau$), then the maximum number of objects per slice for the remaining levels (up to the top) can be expressed recursively as $\tau_{d-1} = r \times \tau_d$. Note that r corresponds to the number of sub-slices (within a slice) at each index level.

Turning to our $2d$ example², after x -based slicing in Figure 4b, s_1 contains one object and thus is considered fully refined (i.e., $|s_1| = 1 \leq \tau_x$), while s_3 has five objects and may be refined in the future. Also note that s_3 stores an open-ended MBB ($s_3.box = b_3$).

The number of levels in QUASII is fixed and always equals to the dimensionality of the queried dataset. That is, it does not depend on the size of the dataset. Therefore, to accommodate the index growth (the index grows in breadth) and enable efficient query execution, QUASII keeps the children (within a slice) organized/sorted according to the level’s dimension. QUASII uses this order and the minimum bounding boxes (box) of each node

²To minimize the required number of objects in Figure 4, we fix $\tau_x = 4$ and $\tau_y = 2$.

to prune the amount of objects necessary to be tested during the query execution.

5.2 Query Processing and Index Refinement

Having defined QUASII’s data structure, we discuss how it is incrementally built and maintained as a side effect of each query.

Query Processing. Algorithm 1 shows the pseudo-code for query processing. Each query traverses the d -level structure depth-first, starting from the first level (having x -slices). Because the slices are sorted, QUASII performs a binary search (Line 3) to find the starting slice. It then scans all the slices $S[i]$ within the query range on the current dimension (i.e., while the loop conditions in Line 4 hold). The loop conditions guarantee that each slice $S[i]$ intersects q only in the current dimension. To discard potential false positive slices early, Line 5 checks if its actual boundaries ($S[i].box$) also intersect with the query range.

Next, QUASII potentially refines $S[i]$ (Line 6), which may be further sliced into multiple more fine-grained slices S'' if it is larger than the maximum size threshold τ (discussed in the next algorithm). In Lines 7–16, QUASII traverses (potentially refined) slices S'' . For each $s \in S''$, it either checks all s objects for intersection in case of the bottom level or recursively proceeds querying its children based on the next level/dimension (a default child is assigned to a not fully refined slice, Line 15). Finally, all the newly created slices are accumulated in S' (Line 17), appended to S (Line 19), and re-sorted (Line 20). The slices are sorted based on their ids , i.e., the position (index) of the first slice’s object in the data array.

Index Refinement. With each query, QUASII attempts to refine all query intersecting slices (i.e., Line 6 in Algorithm 1). Algorithm 2 provides the simplified pseudo-code for this refinement process. Note that the processing within Algorithm 2 is always based only on the current dimension/level of slice s ($s.l$).

The input slice s is considered for slicing only if it exceeds the threshold τ . Given s is coarse enough, QUASII proceeds with determining the type of slicing based on the intersection between

Algorithm 1: query(query q , data D , slices S , result R)

```

1:  $S' \leftarrow \emptyset$  // to store newly created (refined) slices
2:  $dim \leftarrow S[0].l$  // current level/dimension of slices in  $S$ 
3:  $i \leftarrow \text{binarySearch}(S, \text{lower}(q[dim]))$ 
4: while  $i < |S|$  and  $\text{lower}(S[i].\text{box}[dim]) \leq \text{upper}(q[dim])$ 
   do
5:   if  $q \cap S[i].\text{box} = \emptyset$  then continue
6:    $S'' \leftarrow \text{refine}(S[i], D, q)$  // as per Algorithm 2
7:   for each slice  $s \in S''$  do
8:     if  $q \cap s.\text{box} \neq \emptyset$  then
9:       if  $s.l$  is the bottom level then
10:        for each  $j \in \{s.ids\}$  do
11:          if  $D[j] \cap q \neq \emptyset$  then
12:             $R \leftarrow R \cup D[j]$ 
13:        else
14:          if  $|s.children| = 0$  then
15:            createDefaultChild( $s$ )
16:            query( $q, D, s.children, R$ )
17:           $S' \leftarrow S' \cup S''$ 
18:           $i \leftarrow i + 1$ 
19:  $S \leftarrow S \cup S'$ 
20: sort( $S$ )

```

query q and slice s . It considers three types of slicing. If both q 's lower and upper coordinates are within s , a three-way slicing is performed splitting s into three sub-slices (Line 5). If only one of q 's coordinates is within s , a two-way slicing is performed splitting s into two sub-slices (Line 6). Finally, if q contains s (i.e., both q 's coordinates are outside of s 's bounds), QUASII performs a two-way slicing based on an artificially introduced coordinate.

QUASII iterates through the generated slices and for the ones that still exceed τ (and overlap with the query) it applies additional refinement according to artificially introduced boundaries in Line 10 (it repeats the process recursively until a slice is fully refined in the corresponding dimension). The three- and two-way slicing algorithms (Line 5 and Line 6) reorganize the data (D) following the incremental quick sort strategy introduced in database cracking [18]. In the reorganization process, QUASII also records the information about the boundaries (box) of newly created or modified slices.

Example. Continuing with our example in Figure 4, after refining s_0 into three x sub-slices in Line 6 of Algorithm 1 (and resulting in Figure 4b), QUASII recursively continues with the intersecting (and just refined) slice s_2 based on the y dimension (Figure 4c). As such, s_2 is further refined based on the queried y range and results in three new slices (s_{21} , s_{22} , and s_{23}). In this step, only the objects within the s_2 range ($ids = [1..4]$) are three-way sliced and re-organized in the data array. The two new slices (s_{23} is empty) are appended to the data structure as children of s_2 . They are fully refined (as $|s_{21}| \leq 2$ and $|s_{22}| \leq 2$) and have much smaller MBBs (b_{21} and b_{22} , respectively) than the initial slice cuts. Finally, because it is the bottom level, the objects within s_{22} are checked against the query range and the two qualifying objects (o_4, o_6) are added to the result set (R).

The subsequent query q_2 benefits greatly from previous slicing, as illustrated in Figure 4d. For example, x -slices s_1 and s_2 are skipped completely because query q_2 does not intersect with their MBBs (i.e., test on Line 5 in Algorithm 1). Therefore, QUASII proceeds with the only intersecting slice s_3 , which is not fully refined and requires further slicing. As per Algorithm 2, this time a two-way slicing is performed (at $x = 5.5$) resulting in two finer

Algorithm 2: refine(slice s , data D , query q) \rightarrow slices S

```

1: if  $|s| \leq \tau[s.l]$  then
   return  $\{s\}$ 
2:  $S \leftarrow \emptyset$  // to store refined slices
3:  $t \leftarrow \text{determineSliceType}(s, q)$ 
4: switch ( $t$ )
5:   case both:  $S' \leftarrow \text{sliceThreeWay}(s, q, D)$ 
6:   case one:  $S' \leftarrow \text{sliceTwoWay}(s, q, D)$ 
7:   default:  $S' \leftarrow \text{sliceArtificial}(s, q, D)$ 
8: for each slice  $s \in S'$  do
9:   if  $|s| > \tau[s.l]$  and  $q[s.l] \cap s.\text{box}[s.l] \neq \emptyset$  then
10:     $S'' \leftarrow \text{sliceArtificial}(s, q, D)$ 
11:     $S \leftarrow S \cup S''$ 
12:   else
13:     $S \leftarrow S \cup s$ 
14: return  $S$ 

```

slices (s'_3 and s_4) replacing the previous slice s_3 . Next, QUASII continues with y -based slicing of the fully q_2 -contained slice s'_3 . Since s'_3 reaches the size threshold τ_y , it is not refined further. Finally, the actual data array objects within s'_3 range ($ids = [5..6]$) are checked for intersection with q_2 and the qualifying o_8 is added to the result set.

Artificial Refinement. To produce a balanced hierarchical structure QUASII has to conform with the defined thresholds when forming the slices and using only query boundaries does not meet these requirements. One query is usually not sufficient and we cannot use the subsequent queries for this purpose, as they may interfere with the existing order of the slices. For instance, reorganizing a slice again (that has been organized according to all dimensions) based on the x dimension, may disrupt the previously established partitioning for y and z dimensions.

To address this problem, QUASII reorganizes a slice s (Lines 7 and 10 in Algorithm 2) until it meets a size threshold τ in the corresponding dimension. It achieves this by forcing a two-way slicing based on artificially introduced coordinate and thus splitting the slice into two sub-slices. Given the range (x_l, x_u) , the new coordinate is $c = \lfloor (x_l + x_u)/2 \rfloor$. The two new slices are recursively sliced further until the threshold τ is satisfied.

While more advanced approaches, e.g., based on the concepts from R*-Tree node splitting algorithms [6], would minimize overlap in data structure, they would also significantly increase the cost of incremental strategy. Therefore, QUASII employs the above uniform and low-cost artificial slicing strategy to meet τ thresholds at each of d levels.

Query & Refine. The outcome of QUASII's reorganization strategy are the slices that are within the query range and consequently only the objects in these slices are checked for intersection. However, performing the reorganization following strictly the query's boundaries would produce an incomplete result, as illustrated in Figure 5.

For instance, the object o overlaps with the query range q , however, its lower coordinate is outside the query's boundaries and consequently o would not be identified as a part of the result.

To ensure correct query execution while performing refinement, QUASII employs the query extension technique [40]. More

Figure 5: Refinement step: query extension.

precisely, it extends the query for maximum object extent in each dimension, considering lower coordinate. This extension is done only when performing refinement and only within not fully refined slice. Consequently, the query that performs refinement potentially considers more objects for intersection as its range is enlarged. However, this introduces a minimal overhead as the only alternative is the expensive scan of the entire unrefined slice. We apply the same logic for the binary search where, to avoid missing any slices due to the overlap within them, we extend the query range (while performing binary search) for the maximum slice extent in the corresponding dimension.

6 EXPERIMENTAL EVALUATION

In this section, we first describe the experimental setup & methodology and then present a thorough experimental analyses that illustrates the benefits of our incremental approach, both on a real-world neuroscience and synthetic datasets. We start the analyses by outlining the shortcomings of the approaches based on space-oriented partitioning in Section 6.2. We then study the incremental approaches by comparing them with their static counterparts in Section 6.3 and cross-evaluating their performance in Section 6.4. Finally, Section 6.5 describes the sensitivity analyses of QUASII.

6.1 Experimental Setup & Methodology

Hardware. We run our experiments on a Red Hat Enterprise Linux Server release 7.3 machine equipped with 2 Intel Xeon CPU E5-2650L processors at 1.80GHz and 768GB of RAM. Each processor has 12 cores (24 hardware threads) with private L1 (32KB) and L2 (256KB) caches and 30MB of shared L3 cache.

Implementations. All indexing techniques are implemented in C++ and compiled with g++ 4.9.3 with the maximum optimization level. The list below summarizes the implementations that we study:

Scan: performs a full data scan to answer each query.

SFCracker: is our incremental variant of database cracking [18] for spatial data, described in Section 3.1. We use the Z-order as a SFC order. The average farthest distance of neighbours in the Z-order is (slightly) higher than in the Hilbert order [10] (i.e., it has better locality), however, we opt to use the Z-order due to its simplicity and the huge body of work on its efficient range query algorithms [5, 39, 43, 44]. We use 32-bit to represent *zcodes* (i.e., 10 bits per dimension) as a trade-off between memory resources and precision (the number of false positives to be filtered).

SFC: is a static counterpart of SFCracker. In the pre-processing phase, SFC transforms data from multi- to one-dimensional domain and sorts it according to the produced SFCcodes. During querying, a ($3d$) query range is also converted to a $1d$ range and a binary search is used to locate the objects in the $1d$ interval. We employ the same representation of *zcodes* and query optimization as in SFCracker (described in Section 3.1).

QUASII: is our incremental approach discussed in Section 4. We use 60 objects as a node capacity τ_z .

R-Tree: According to our setting, all data is available before querying. Therefore, we use a bulk-loading approach to build the R-Tree index as it reduces overlap and decreases pre-processing time compared to the R-Tree built by inserting one object at a time [26]. For this purpose, we use an efficient STR [26] bulk-loading strategy that balances well the overhead of partitioning the data and query performance. It outperforms Hilbert R-Tree [23] in terms of query performance [26], while its pre-processing cost is not

Figure 6: The impact of space-oriented partitioning.

significantly higher [42]. Similarly, TGS [12] and PR-Tree [4] can outperform STR on datasets with extreme skew and aspect ratio, however, they incur considerable overhead for data partitioning. We use the same configuration for node capacity (60) as in QUASII.

Mosaic: corresponds to the space-oriented incremental approach described in Section 3.2.

Grid: is a uniform grid-based index used as a static counterpart of Mosaic. We use query extension [40] technique (as discussed in Section 3.2) to assign an object to a grid cell. We use two configurations with 100 and 220 partitions per dimension for synthetic and neuroscience datasets, respectively. Both configurations are obtained through a parameter sweep.

Dataset and Queries. We use real-world neuroscience and synthetic datasets.

Neuroscience: we use a small part of the rat brain model represented with 450 million cylinders as elements in a volume of $285 \mu m^3$. We approximate the cylinders with MBBs, resulting in the total number of 450 million MBBs with a size of 21GB on disk. Based on the previously described use cases, we synthetically generate queries, each having a fixed volume *qvol* of $10^{-2}\%$ of the queried brain volume and a clustered distribution. We generate 5 query clusters each with 100 queries, where query centers are distributed around the cluster centers following a Gaussian distribution ($\mu = 0, \sigma = qvol$).

Synthetic: we create synthetic datasets by distributing spatial boxes in a space of 10 000 units in each dimension of the $3d$ space. The length of each side of each box is determined uniform randomly between 1 and 10 for 99% of the objects, while 1% of the objects has a side ranging from 10 - 1000 units. The spatial elements are distributed according to a uniform distribution. The datasets have 500 million and 1 billion elements (size on disk 22.5GB and 45GB). For completeness and to test non-skewed cases, we generate *uniform* workload. The uniform workload contains up to 10 000 uniformly distributed queries. To have range queries of different selectivity, we vary *qvol*: $10^{-3}\%$, $10^{-1}\%$, 1%, and 10% of the universe.

6.2 Space-oriented Partitioning Challenges

Both, Mosaic and SFCracker (introduced in Section 3), use space-oriented partitioning at their core — Mosaic partitions space, while SFCracker assigns the SFCcodes using a uniform grid. Before we start the analysis of incremental approaches we experimentally demonstrate the shortcoming of space-oriented partitioning — the overhead introduced with data assignment strategy — since it also affects incremental solutions. Further on, we illustrate why a static approach based on space-oriented partitioning, such as a uniform grid, is not a suitable replacement for an incremental index despite having a comparatively cheap pre-processing step (once properly configured).

Figure 7: Convergence of a) one-dimensional, b) space-oriented c) data-oriented based approaches.

Figure 8: Cumulative time of a) one-dimensional, b) space-oriented c) data-oriented based approaches.

Data Assignment. In the first experiment we illustrate the impact of data assignment strategies by comparing the performance of Grid and R-Tree. We use two variants of the Grid approach: GridQueryExt avoids the objects replication by using the query extension technique – it assigns an object to the grid partition based on its center, while GridReplication replicates the objects – it assigns an object to all the overlapping partitions.

Figure 6a) shows the results of the experiments where we execute 500 clustered queries of selectivity 0.01% on the neuroscience dataset. GridReplication is heavily affected by object replication which increases the number of objects necessary to be checked for intersection and introduces an expensive de-duplication step (needed due to objects replication). GridQueryExt achieves better performance, however, it still considers $3.1\times$ more objects for intersection than the R-Tree as it extends the initial query for the maximum object extent. The R-Tree clearly outperforms both GridReplication and GridQueryExt with a speedup of $19.4\times$ and $3.7\times$ respectively.

Configuration. In the second experiment we demonstrate the difficulty to configure the grid-based approaches. We use two datasets with identical extent and number of elements but different data distributions: Uniform (uniform distribution, synthetic dataset) and Neuro (skewed distribution, the neuroscience dataset). We use the same experimental setup as for the previous experiment. The best configuration (number of partitions per dimension) is 100 for Uniform and 220 for the Neuro dataset and is determined in a parameter sweep. We measure the execution time when using both configurations for each dataset and illustrate the results in Figure 6b).

Although both datasets have the same number of elements and extent, the best configuration significantly depends on the data distribution – the neuroscience dataset requires more partitions compared to the Uniform dataset since it has the very dense regions that require fine grained partitioning. Furthermore, the grid configuration significantly affects performance – the grid performance on the Uniform dataset deteriorates notably when using the Neuro dataset configuration and vice versa.

Summary. Space-oriented partitioning introduces performance penalties. Depending of data assignment strategy, we either consider more elements or suffer from replication. Additionally, the grid configuration is non-trivial and using the wrong one has a detrimental impact on the execution time. In practice we have to use a parameter sweep to find the configuration for a given workload. Consequently, grid configuration turns into a time-consuming process, increasing data-to-insight time.

6.3 Incremental versus Static

We first analyze the incremental approaches by comparing their performance with the performance of their static counterparts (introduced in Section 6.1). Each static approach has similar properties as its incremental counterpart, however, it involves necessary pre-processing. We categorize the approaches according to these properties as a) one-dimensional, b) space-oriented and c) data-oriented approaches. For each category we present the performance of the incremental approach, its static counterpart and Scan. We first evaluate if and when the approaches converge to the performance of their static counterparts and then analyze the overhead of the incremental strategy. For this purpose we execute the clustered query workload with 500 queries of selectivity 0.01% on the *neuroscience* dataset.

Convergence. In the first experiment we evaluate the convergence of the incremental approaches – how fast an approach converges to the execution time of a fully indexed dataset. Figure 7 measures the execution time of each query for all approaches.

The results show five peaks in execution time, one for each query cluster. The execution of the first cluster of queries (and the associated processing of the data) takes the longest as no index structure exists at the beginning. The first queries therefore exceed the cost of Scan, because at this point, the entire dataset has to be scanned along with building partial index structures. Subsequent queries within a cluster use a partial index and thus execute in less time than a full scan, but take longer than queries on the static approach. This process continues as queries in the

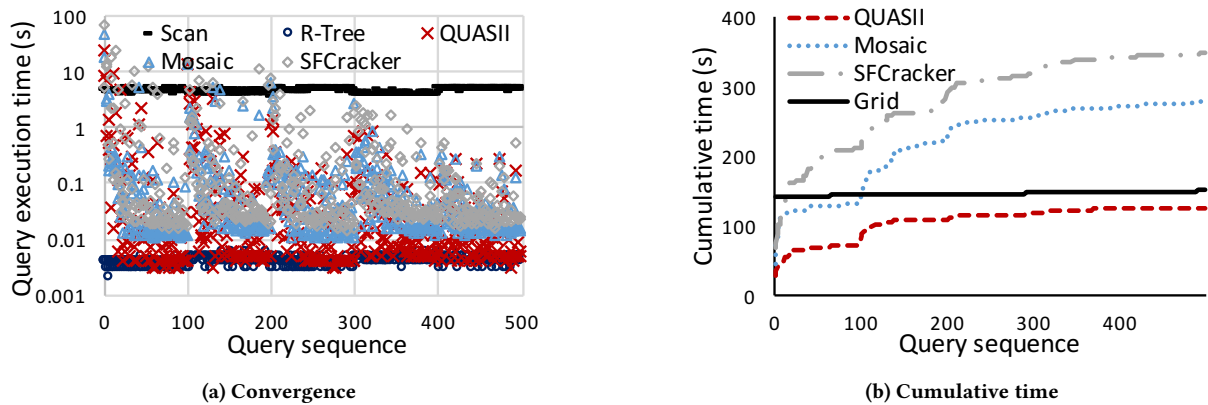

Figure 9: Comparative analysis of incremental approaches.

same cluster further refine the index. Queries in one cluster not only refine the index locally but also carry out limited, global refinement. The queries in a subsequent cluster thus benefit from previous clusters and execute faster. As the index converges to its full structure, the query execution time approaches that of the static approach.

Cumulative Response Time. While in the previous set of experiments we measure the individual query performance, in this analysis we measure the cumulative execution time (including index building step for the static approaches). Figure 8 illustrates the experimental results.

Similar to the convergence experiment, the query clusters are visible: the cumulative response time jumps each time the experiment moves to a new cluster. The most expensive is the transition from the first to the second cluster while subsequent transitions become less evident as the index becomes more refined.

The cumulative cost of SFCracker is comparatively high and, crucially, with a very expensive first query. One reason is that the first query takes 12.9% of the total pre-processing by assigning the objects to the grid cells and calculating the *zcode* values for the entire dataset. Adding to this the cost of cracking, the total execution time of the first query grows to 43% of the total pre-processing time. More precisely, in order to minimize the overhead introduced by the transformation to $1d$ space, we partition the $1d$ query range into sub-intervals that tightly cover its original $3d$ range. This optimization [43] results in a high number of small intervals per query — on average 197. As a consequence, the first queries crack the previously uncracked area into a number of small adjacent intervals and therefore reorganize significant amounts of data.

The static (SFC) index, on the other hand, is not substantially slower for the first queries or, put differently, the building cost of SFC is not much higher than the first query of SFCracker. In fact, the cumulative execution time of SFCracker exceeds the one of SFC after 23 queries already. The incremental approach SFCracker thus does not offer a considerable benefit over SFC.

The incremental strategy of Mosaic is less expensive compared to SFCracker — the objects within the partition queried are potentially reassigned to the eight newly created partitions based on their location. Therefore, it takes Mosaic longer, i.e., 100 queries, before it exceeds the cumulative time of the static Grid. However, its cumulative execution time is still considerable with the biggest overhead being its top-down incremental strategy. The top-down strategy ensures fast convergence but it also introduces overhead

as the data in frequently queried areas is re-partitioned multiple times until Mosaic reaches its final level of refinement.

QUASII, at the same time, does not exceed the cumulative execution of the R-Tree in our experiments. Even after 500 executed queries, the cumulative execution time for QUASII is 39.4% of that of the R-Tree. The main benefit comes from its partial reorganization strategy where the objects are gradually reorganized within the query boundaries, as opposed to the complete sort.

Summary. While all the incremental approaches reach the performance of their static counterparts, the incremental strategies of SFCracker and Mosaic are comparatively expensive. As we show for SFCracker, the major bulk of work has to be done when executing the first query — as the data needs to be transformed to $1d$ space and a single query has to perform multiple cracking operations to avoid performance penalties due to the transformation to $1d$ space. Mosaic increases its cumulative time considerably due to its top-down partitioning strategy — it reorganizes data in frequently queried areas multiple times until it reaches its final level of refinement. Only the cumulative execution time of QUASII does not exceed the one of its static counterpart, the R-Tree, in our experiments.

6.4 Comparative Analysis

We now compare the performance of incremental approaches. We use the same setup as previously and measure the convergence of execution time as well as the cumulative execution time.

Convergence. Figure 9a) depicts the single query execution time for all the incremental approaches compared with the R-Tree and Scan. We use the R-Tree approach as a reference because it is the fastest approach among the static indexes for the workloads tested. We analyze the execution time of the first query and then focus on the performance of the converged data structure.

The execution time of the first query determines data-to-insight time and thus has to be as small as possible. Among the incremental approaches, SFCracker has the most expensive first query due to the transformation of data to the $1d$ space. Mosaic’s first query is faster, but still expensive as it has to reassign all the objects to new partitions, examining all three coordinates. Finally, QUASII has the least expensive first query due to the nested data reorganization — the number of objects necessary to be examined and reorganized becomes smaller as more dimensions are taken into account: all objects are scanned on the x -dimension, but on the y -dimension only the objects with a x -value satisfying the

Figure 10: Convergence and cumulative time: the first 500 (a & c) and last 100 (b & d) queries.

query will be scanned (accordingly for the z-dimension). Overall, Scan is 13.7, 9.2 and 4.6 times faster compared to SFCracker, Mosaic and QUASII respectively, when executing the first query.

Among the incremental approaches, only QUASII attains the query execution time of R-Tree on a fully converged index. Mosaic and SFCracker have at their core space-oriented partitioning and therefore, their performance is affected by the data assignment strategy as well as the skew in distribution, as Section 6.2 shows. SFCracker additionally transforms data to 1d domain and thus cannot preserve spatial proximity to the same extent as the other approaches. Consequently, QUASII outperforms Mosaic and SFCracker with a speedup of 3.68x and 4.9x respectively for the average execution time of a query in a fully refined area.

Cumulative Execution Time. We use the cumulative execution time as metric to evaluate the decrease in the data-to-insight time as well as the "break-even" point — the point when the cumulative cost of incremental exceeds that of static indexing — to assess the quality of an incremental index. Figure 9b) shows the experimental results. We use Grid as a reference since it has the smallest cumulative execution time among the static approaches — its pre-processing step is comparatively cheap (once its optimal configuration is determined).

As discussed in Section 6.3, SFCracker and Mosaic have comparatively expensive strategies and thus reach the performance of Grid after 13 and 100 queries respectively. Grid, on the other hand, compared to QUASII, has not amortized its building cost after 500 queries. More precisely, QUASII reaches 84% of the Grid cumulative execution time and, more importantly, it achieves 3.66x faster query performance for completely refined areas. QUASII executes the first query the fastest and consequently achieves the highest decrease in data-to-insight time — 5.1x and 11.4x compared to Grid and R-Tree.

For single query execution, the major benefit of QUASII comes from its data-oriented partitioning. Similar to R-Tree, it adjusts to the distribution of the data and, as opposed to Grid and SFC, it does not replicate the objects or extend the query. It additionally keeps the data in multidimensional space and does consequently not suffer from decrease in dimensionality. Its low cumulative cost is mostly attributed to its incremental strategy. QUASII does not sort all objects, but rather reorganizes them within the specific bounds, gradually curbing the amount of data necessary to be reorganized.

Summary. QUASII outperforms other incremental approaches with respect to the convergence of execution time and cumulative time. It achieves performance comparable to the R-Tree (the fastest static approach) in the areas of the dataset where enough queries have been executed, while not exceeding the cumulative time of Grid (the static approach with the least expensive pre-processing) or the R-Tree. Its major benefits come from the data-oriented partitioning and the nested reorganization strategy which reorganizes precisely the data touched and used.

Figure 11: Analysis of QUASII: scalability.

6.5 Analysis of QUASII

In this section we focus on QUASII. We evaluate its performance on the workloads other than neuroscience, analyze its scalability and the impact of query selectivity.

6.6 Uniform Workload

In the previous analyses we used workloads with query clusters that show the benefit of incremental approaches: the index quickly converges to the final performance as the queries are targeting the same areas. In this experiment we evaluate the performance of QUASII for a uniform workload. We execute 10000 uniformly distributed queries of selectivity 0.1% on the dataset with uniform distribution and 500M elements. We compare the performance of QUASII with Scan and R-Tree and additionally consider Grid for the cumulative execution time. Figure 10 illustrates both convergence and cumulative time for the first 500 and last 100 queries of the workload.

None of the first 500 queries is executed on a completely refined index. Starting with the 300th query, however, the single query execution is close to the final performance. Among the last 100 queries, 64 are executed on a completely refined index. The performance of queries on the refined structure is equal or very close to the performance of the R-Tree, i.e., on average 7.5% slower than the R-Tree.

After 10000 executed queries QUASII reaches 75% and 63.8% of the cumulative time of the R-Tree and Grid approaches respectively (*y* axis is in log scale). Likewise, it decreases data-to-insight time by 10.3x and 5.6x compared to R-Tree and Grid. Although the pre-processing step of Grid is significantly cheaper compared to the R-Tree, its cumulative time deteriorates with more queries executed due to the expensive single query performance.

6.7 Performance Trends

In the following experiment we evaluate the scalability of QUASII by executing 10000 queries of selectivity 0.1% on datasets with

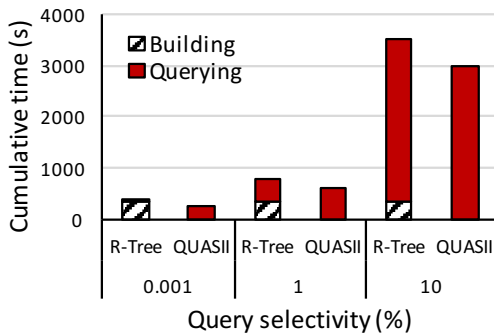

Figure 12: Analysis of QUASII: impact of selectivity.

500 million and 1 billion elements. In Figure 11 we compare the cumulative time of QUASII with R-Tree, where we additionally split the execution time of R-Tree into Building and Querying.

After 10000 executed queries QUASII reaches 75% and 73.7% of the cumulative time of the R-Tree with datasets of 500M and 1B elements respectively. By the time the R-Tree finishes its building process QUASII has executed around 8000 queries in both cases. QUASII also decreases data-to-insight time by 10.3x (on the 500M dataset) and 10.6x (on the 1B dataset) compared to the R-Tree. As illustrated in this experiment, QUASII maintains the performance trends as the dataset size increases.

6.8 Impact of Selectivity

In this set of experiments we evaluate the impact of query selectivity on the performance of QUASII. We measure the cumulative time for a uniform workload: 500M dataset and 5000 queries of 0.001%, 1%, and 10% selectivity. Figure 12 illustrates the results where we consider both the R-Tree and QUASII.

Intuitively, a static index (R-Tree) takes more time to amortize its building cost when executing 0.001% selectivity queries. On the other hand, the lower selectivity queries (10%) touch and reorganize a significant amount of data and QUASII thus reaches the break-even point with the R-Tree faster. Overall, after 5000 executed queries, QUASII reaches 68.8%, 79.8% and 85.6% of the cumulative time of the R-Tree for queries with 0.001%, 1%, and 10% selectivity.

7 RELATED WORK

To the best of our knowledge, no incremental strategy has been proposed to spatial indexing in main memory. While recently an incremental indexing technique has been proposed for exploration of multiple spatial datasets [35], the addressed problem is different (spatial search within multiple datasets) and the proposed solution focuses solely on disk-based efficiency, i.e., reducing the number of expensive disk I/O operations. Nevertheless, there has been considerable interest in incremental data processing within relational databases. Therefore, before giving an overview of related (but not incremental) spatial indexing techniques, we briefly describe incremental approaches used by relational database systems.

7.1 Relational Incremental Indexing

Incremental (one-dimensional) indexing techniques are extensively studied in database cracking [16, 18, 19] and adaptive merging [13, 14]. The former partially sorts keys in an in-memory

relation, essentially performing quicksort. The latter, adaptive merging, takes the idea further and devises an incremental, external sort to make use of external memory as well.

Driven by the same goal (minimize data-to-insight time), novel systems have been proposed that bypass data pre-processing step and execute queries on raw data files. Instead, auxiliary data structures are built incrementally so that the most popular data subsets are serviced at the speeds of fully loaded/indexed data. For example, NoDB [2], RAW [25], and ViDa [24] incrementally build positional maps to track the position of frequently accessed data fields. This enables the systems to “jump” to previously queried data regions and potentially reduce the costs of tokenizing and parsing raw data sources.

7.2 Spatial Indexing

Research in indexing spatial data has produced numerous approaches in past decades [11]. In the following we briefly review spatial indexing approaches that we group into three classes depending on how amenable they are to incremental indexing.

One-dimensional Indexing. One way to address the curse of dimensionality in the context of spatial data is to transform it from multi- to one-dimensional domain. Typical methods to perform this transformation are space-filling curves like the Z-order [34], the Hilbert curve [21], and the Gray-code curve [9]. They impose a total order and preserve spatial proximity between objects - if the objects are close in higher-dimensional space, they are also close on the space-filling curve - reasonably well. Given such a mapping of spatial data, the existing 1d access methods, such as B-Tree [5], can be used for querying.

Data-oriented Indexing. The data-oriented partitioning approaches create an index structure taking into consideration the data distribution, where the prominent representatives are the KD-Tree [7], the R-Tree [15], and its variants. The R-Tree, arguably the most important data-oriented spatial index, is multi-dimensional generalization of the B-Tree which recursively encloses objects in minimum bounding rectangles (MBRs). The basic R-Tree definition faces the problems of overlap and dead space, both detrimental to query execution performance [15, 42]. Multiple approaches have been devised to address the issue. The R*-Tree [6], for example, uses an improved version of the node split algorithm and reinsertion of objects while the R+-Tree [37] tries to avoid overlap through the duplication of MBRs (leading to a bigger index). A priori knowledge of the entire dataset may help to reduce the above problems of the R-Tree by packing spatially close objects on the same disk page. The Hilbert R-Tree [23] achieves this using the Hilbert curve, Sort-Tile-Recursive (STR) [26] recursively sorts objects in all dimensions to do so, while Top-down Greedy Split (TGS) [12] recursively splits the data set into partitions minimizing the area on each level.

Adaptive index structures [41] rearrange the nodes of data-oriented hierarchical indexes (including the R-Tree index) in response to queries so that they can be accessed sequentially on disk. However, this reorganization is performed to improve query performance by optimizing disk-access without taking into consideration data-to-insight time.

A recently proposed partitioning mechanism for large-scale spatial data also adapts to an incoming query workload [3]. In contrast to QUASII, however, its primary goal is not to minimize data-to-insight time (as all necessary data structures are still built during pre-processing), but to efficiently accommodate changes in data and workload. Also, it considers a distributed setting.

Space-oriented Indexing. The space-oriented partitioning approaches assign the data to the partitions based on space, regardless of data distribution. A typical representative is the uniform grid that partitions the space uniformly into partitions of equal size [38]. Similarly, the Quadtree [36] and its variant for 3d space, the Octree [20], recursively divide space into four/eight partitions of equal size to build a hierarchy of partitions. Further approaches, for example the grid file [32], use a non-uniform grid to better accommodate skew in the data (and to also optimize for disk access). The downside, is a more complex query execution due to the cells of different size and location. The two level grid file [17] addresses the issue by introducing an additional level with a coarser grid. Still, the overhead of testing the query against multiple cells can be substantial.

8 CONCLUSIONS

The advances in data acquisition technologies and supercomputing for large-scale simulations rapidly increase the amounts of spatial data generated and collected. This data helps the scientist tremendously to gain insights and understand natural phenomena, however, at the same time, it leaves them with the challenge of analyzing it. Known approaches to spatial indexing have two major drawbacks with respect to exploratory analyses. First, they require a time-consuming pre-processing step that delays analyses. Second, given the massive amounts of data, a scientist frequently only analyzes a small fraction of it and consequently indexing the entirety of the data does not always pay off.

In this paper we propose a novel incremental index for the exploration of spatial data, where the ultimate goal is to let the scientists perform exploratory analyses as soon as the data is available, while using their queries to incrementally index the data. Our approach, QUASII, reduces data-to-insight time and curbs the cost of incremental indexing, by gradually and partially sorting the data, while producing a data-oriented hierarchical structure. As our experiments show, QUASII reduces the data-to-insight time by up to a factor of 11.4x, while its performance converges to that of the fastest state-of-the-art static indexes.

ABSTRACT

As with general graph processing systems, partitioning data over a cluster of machines improves the scalability of graph database management systems. However, these systems will incur additional network cost during the execution of a query workload, due to inter-partition traversals. Workload-agnostic partitioning algorithms typically minimise the likelihood of any edge crossing partition boundaries. However, these partitioners are sub-optimal with respect to many workloads, especially queries, which may require more frequent traversal of specific subsets of inter-partition edges. Furthermore, they are largely unsuited to operating incrementally on dynamic, growing graphs.

We present a new graph partitioning algorithm, Loom, that operates on a stream of graph updates and continuously allocates the new vertices and edges to partitions, taking into account a query workload of graph pattern expressions along with their relative frequencies. First we capture the most common patterns of edge traversals which occur when executing queries. We then compare sub-graphs, which present themselves incrementally in the graph update stream, against these common patterns. Finally we attempt to allocate each match to single partitions, reducing the number of inter-partition edges within frequently traversed sub-graphs and improving average query performance.

Loom is extensively evaluated over several large test graphs with realistic query workloads and various orderings of the graph updates. We demonstrate that, given a workload, our prototype produces partitionings of significantly better quality than existing streaming graph partitioning algorithms Fennel & LDG.

1 INTRODUCTION

Subgraph pattern matching is a class of operation fundamental to many “real-time” applications of graph data. For example, in social networks [9], and network security [3]. Answering a subgraph pattern matching query usually involves exploring the subgraphs of a large, labelled graph G then finding those which match a small labelled graph q . Fig.1 shows an example graph G and a set of query graphs Q which we will refer to throughout. **Efficiently partitioning large, growing graphs to optimise for given workloads of such queries** is the primary contribution of this work.

In specialised graph database management systems (GDBMS), pattern matching queries are highly efficient. They usually correspond to some index lookup and subsequent traversal of a small number of graph edges, where edge traversal is analogous to pointer dereferencing. However, as graphs like social networks may be both large and continually growing, eventually they saturate the memory of a single commodity machine and must be partitioned and distributed. In such a distributed setting, queries which require inter-partition traversals, such as q_2 in Fig. 1, incur network communication costs and will perform poorly. A

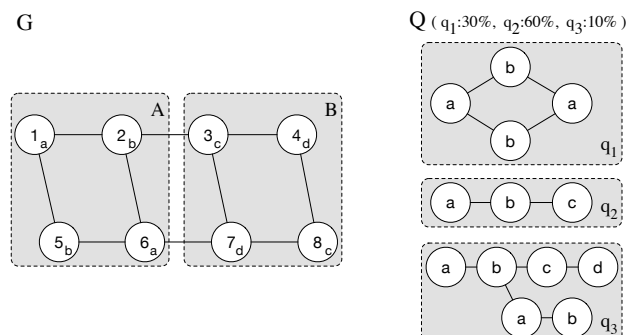

Figure 1: Example graph G with query workload Q

widely recognised approach to addressing these scalability issues in graph data management is to use one of several k -way balanced graph partitioners [2, 11, 14, 18, 30–32]. These systems distribute vertices, edges and queries evenly across several machines, seeking to optimise some global goal, e.g. minimising the number of edges which connect vertices in different partitions (a.k.a *min. edge-cut*). In so doing, they improve the performance of a broad range of possible analyses.

Whilst graphs partitioned for such global measures mostly work well for global forms of graph analysis (e.g. Pagerank), no one measure is optimal for all types of operation [28]. In particular, the workloads of pattern matching query workloads, common to GDBMS, are a poor match for these kinds of partitioned graphs, which we call *workload agnostic*. This is because, intuitively, a min. edge-cut partitioning is equivalent to assuming uniform, or at least constant, likelihood of traversal for each edge throughout query processing. This assumption is unrealistic as a query workload may traverse a limited subset of edges and edge types, which is specific to its graph patterns and subject to change.

To appreciate the importance of a workload-sensitive partitioning, consider the graph of Fig.1. The partitioning $\{A, B\}$ is optimal for the balanced min. edge-cut goal, but may not be optimal for the query graphs in Q . For example, the query graph q_2 matches the subgraphs $\{(1, 2), (2, 3)\}$ and $\{(6, 2), (2, 3)\}$ in G . Given a workload which consisted entirely of q_2 queries, every one would require a potentially expensive inter-partition traversal (*ipt*). It is easy to see that the alternative partitioning $A' = \{1, 2, 3, 6\}$, $B' = \{4, 5, 7, 8\}$ offers an improvement (*0 ipt*) given such a workload, whilst being strictly worse *w.r.t* min. edge-cut.

Mature research of workload-sensitive online database partitioning is largely confined to relational DBMS [4, 23, 26]

1.1 Contributions

Given the above motivation, we present Loom: a partitioner for online, dynamic graphs which optimises vertex placement to improve the performance of a given stream of sub-graph pattern matching queries.

The simple goals of Loom are threefold: a) to discover patterns of edge traversals which are common when answering queries

from our given workload Q ; b) to efficiently detect instances of these patterns in the ongoing stream of graph updates which constitutes an online graph; and c) to assign these pattern matches wholly within an individual partition or across as few partitions as possible, thereby reducing the number of *ipt* and increasing the average performance of any $q \in Q$.

This work extends an earlier “vision” work [7] by the authors, providing the following additional contributions:

- A compact ¹ trie based encoding of the most frequent traversal patterns over edges in G . We show how it may be constructed and updated given an evolving workload Q .
- A method of sub-graph isomorphism checking, extending a recent probabilistic technique[29]. We show how this measure may be efficiently computed and demonstrate both the low probability of false positives and the impossibility of false negatives.
- A method for efficiently computing matches for our frequent traversal patterns in a graph stream, using our trie encoding and isomorphism method, and then assign these matching sub-graphs to graph partitions, using heuristics to preserve balance. Resulting partitions do not rely upon replication and are therefore agnostic to the complex replication schemes often used in production systems.

As online graphs are equivalent to graph streams, we present an extensive evaluation comparing Loom to popular streaming graph partitioners Fennel [31] and LDG[30]. We partition real and synthetic graph streams of various sizes and with three distinct stream orderings: breadth-first, depth-first and random order. Subsequently, we execute query workloads over each graph, counting the number of expensive *ipt* which occur. Our results indicate that Loom achieves a significant improvement over both systems, with between 15 and 40% fewer *ipt* when executing a given workload.

1.2 Related work

Partitioning graphs into k balanced subgraphs is clearly of practical importance to any application with large amounts of graph structured data. As a result, despite the fact that the problem is known to be NP-Hard [1], many different solutions have been proposed [2, 11, 14, 18, 30–32]. We classify these partitioning approaches into one of three potentially overlapping categories: streaming, non-streaming and workload sensitive. Loom is both a streaming and workload-sensitive partitioner.

Non-streaming graph partitioners [2, 14, 18] typically seek to optimise an objective function global to the graph, e.g. minimising the number of edges which connect vertices in different partitions (*min. edge-cut*).

A common class of these techniques is known as multi-level partitioners [2, 14]. These partitioners work by computing a succession of recursively compressed graphs, tracking exactly how the graph was compressed at each step, then trivially partitioning the smallest graph with some existing technique. Using the knowledge of how each compressed graph was produced from the previous one, this initial partitioning is then “projected” back onto the original graph, using a local refinement technique (such as Kernighan-Lin [15]) to improve the partitioning after each step. A well known example of a multilevel partitioner is METIS [14], which is able to produce high quality partitionings for small and

medium graphs, but performance suffers significantly in the presence of large graphs [31]. Other multilevel techniques [2] share broadly similar properties and performance, though they differ in the method used to compress the graph being partitioned.

Other types of non-streaming partitioner include Sheep [18]: a graph partitioner which creates an elimination tree from a distributed graph using a map-reduce procedure, then partitions the tree and subsequently translates it into a partitioning of the original graph. Sheep optimises for another global objective function: minimising the number of different partitions in which a given vertex v has neighbours (*min. communication volume*).

These non-streaming graph partitioners suffer from two main drawbacks. Firstly, due to their computational complexity and high memory usage[30], they are only suitable as offline operations, typically performed ahead of analytical workloads. Even those partitioners which are distributed to improve scalability, such as Sheep or the parallel implementation of METIS (ParMETIS) [14], make strong assumptions about the availability of global graph information. As a result they may require periodic re-execution, i.e. given a dynamic graph following a series of graph updates, which is impractical online [13]. Secondly, as mentioned, partitioners which optimise for such global measures assume uniform and constant usage of a graph, causing them to “leave performance on the table” for many workloads.

Streaming graph partitioners [11, 30, 31] have been proposed to address some of the problems with partitioners outlined above. Firstly, the strict streaming model considers each element of a graph stream as it arrives, efficiently assigning it to a partition. Additionally, streaming partitioners do not perform any refinement, i.e. later reassigning graph elements to other partitions, nor do they perform any sort of global introspection, such as spectral analysis. As a result, the memory usage of streaming partitioners is both low and independent of the size of the graph being partitioned, allowing streaming partitioners to scale to very large graphs (e.g. billions of edges). Secondly, streaming partitioners may trivially be applied to continuously growing graphs, where each new edge or update is an element in the stream.

Streaming partitioners, such as Fennel [31] and LDG [30], make partition assignment decisions on the basis of inexpensive heuristics which consider the local neighbourhood of each new element at the time it arrives. For instance, LDG assigns vertices to the partitions where they have the most neighbours, but penalises that number of neighbours for each partition by how full it is, maintaining balance. By using the local neighbourhood of a graph element e **at the time e is added**, such heuristics render themselves sensitive to the ordering of a graph stream. For example, a graph which is streamed in the order of a *breadth-first traversal* of its edges will produce a better quality partitioning than a graph which is streamed in random order, which has been shown to be pseudo adversarial[31].

In general, streaming algorithms produce partitionings of lower quality than their non-streaming counterparts but with much improved performance. However, some systems, such as the graph partitioner Leopard [11], attempt to strike a balance between the two. Leopard relies upon a streaming algorithm (Fennel) for the initial placement of vertices but drops the “one-pass” requirement and repeatedly considers vertices for reassignment; improving quality over time for dynamic graphs, but at the cost of some scalability. Note that these Streaming partitioners, like their non-streaming counterparts, are workload agnostic and so share those disadvantages.

¹Grows with the size of query graph patterns, which are typically small

Workload sensitive partitioners [4, 23, 24, 26, 28, 32] attempt to optimise the placement of data to suit a particular workload. Such systems may be streaming or non-streaming, but are discussed separately here because they pertain most closely to the work we do with Loom.

Some partitioners, such as LogGP [32] and CatchW [28], are focused on improving graph analytical workloads designed for the *bulk synchronous parallel* (BSP) model of computation². In the BSP model a graph processing job is performed in a number of supersteps, synchronised between partitions. CatchW examines several common categories of graph analytical workload and proposes techniques for predicting the set of edges likely to be traversed in the next superstep, given the category of workload and edges traversed in the previous one. CatchW then moves a small number of these predicted edges between supersteps, minimising inter-partition communication. LogGP uses a similar log of activity from previous supersteps to construct a hypergraph where vertices which are frequently accessed together are connected. LogGP then partitions this hypergraph to suggest placement of vertices, reducing the analytical job’s execution time in future.

In the domain of **RDF stores**, Peng et al. [24] use frequent sub-graph mining ahead of time to select a set of patterns common to a provided SPARQL query workload. They then propose partitioning strategies which ensure that any data matching one of these frequent patterns is allocated wholly within a single partition, thus reducing average query response time at the cost of having to replicate (potentially many) sub-graphs which form part of multiple frequent patterns. Harbi et al. [10] also detect patterns common to workloads of SPARQL queries; their system, called AdPart, redistributes data between partitions over time such that more queries may be executed without *ipt*. However, like Peng et al’s work, AdPart makes significant use of replication. Additionally, AdPart’s re-partitioning approach relies upon an initial input generated by a naive Hash partitioner. Thus, it could potentially be used in conjunction with a streaming system like Loom: a workload-aware initial partitioning reducing the amount of data redistribution required later.

For **RDBMS**, systems such as Schism [4] and SWORD [26] capture query workload samples ahead of time, modelling them as hypergraphs where edges correspond to sets of records which are involved in the same transaction. These graphs are then partitioned using existing non-streaming techniques (METIS) to achieve a min. edge-cut. When mapped back to the original database, this partitioning represents an arrangement of records which causes a minimal number of transactions in the captured workload to be distributed. Other systems, such as Horticulture [23], rely upon a function to estimate the cost of executing a sample workload over a database and subsequently explore a large space of possible candidate partitionings. In addition to a high upfront cost [4, 23], these techniques focus on the relational data model, and so make simplifying assumptions, such as ignoring queries which traverse > 1-2 edges [26] (i.e. which perform nested joins). Larger traversals are common to sub-graph pattern matching queries, therefore its unclear how these techniques would perform given such a workload.

Overall, the works reviewed above either focus on different types of workload than we do with Loom (namely offline analytical or relational queries), or they make extensive use of

replication. Loom does not use any form of replication, both to avoid potentially significant storage overheads [25] and to remain interoperable with the sophisticated replication schemes used in production systems.

1.3 Definitions

Here we review and define important concepts used throughout the rest of the paper.

A **labelled graph** $G = (V, E, L_V, f_l)$ is of the form: a set of vertices $V = \{v_1, v_2, \dots, v_n\}$, a set of pairwise relationships called edges $e = (v_i, v_j) \in E$ and a set of vertex labels L_V . The function $f_l : V \rightarrow L_V$ is a surjective mapping of vertices to labels. Note that throughout this work, for simplicity, we consider only *undirected* graphs. However, all techniques subsequently presented may be extended to directed graphs, which we highlight inline. We view an **online graph** simply as a (possibly infinite) sequence of edges which are being added to a graph G , over time. We consider *fixed width* sliding windows over such a graph, i.e. a sliding window of time t is equivalent to the t most recently added edges. Note that an online may be viewed as a **graph stream** and we use the two terms interchangeably.

A **pattern matching query** is defined in terms of sub-graph isomorphism. Given a pattern graph $q = (V_q, E_q)$, a query should return R : a set of sub-graphs of G . For each returned sub-graph $R_i = (V_{R_i}, E_{R_i})$ there should exist a bijective function f such that: *a*) for every vertex $v \in V_{R_i}$, there exists a corresponding vertex $f(v) \in V_q$; *b*) for every edge $(v_1, v_2) \in E_{R_i}$, there exists a corresponding edge $(f(v_1), f(v_2)) \in E_q$; and *c*) for every vertex $v \in R_i$, the labels match those of the corresponding vertices in q , $l(v) = l(f(v))$. A query workload is simply a multiset of these queries $Q = \{(q_1, n_1) \dots (q_h, n_h)\}$, where n_i is the relative frequency of q_i in Q .

A **query motif** is a graph which occurs, with a frequency of more than some user defined threshold \mathcal{T} , as a sub-graph of query graphs from a workload Q .

A vertex centric **graph partitioning** is defined as a disjoint family of sets of vertices $P_k(G) = \{V_1, V_2, \dots, V_k\}$. Each set V_i , together with its edges E_i (where $e_i \in E_i$, $e_i = (v_i, v_j)$, and $\{v_i, v_j\} \subseteq V_i$), is referred to as a *partition* S_i . A partition forms a proper sub-graph of G such that $S_i = (V_i, E_i)$, $V_i \subseteq V$ and $E_i \subseteq E$. We define the quality of a graph partitioning relative to a given workload Q . Specifically, the number of inter-partition traversals (*ipt*) which occur while executing Q over $P_k(G)$. Whilst min. edge-cut is the standard scale free measure of partition quality [14], it is intuitively a proxy for *ipt* and, as we have argued (Sec. 1), not always an effective one.

1.4 Overview

Once again, Loom continuously partitions an online graph G into k parts, optimising for a given workload Q . The resulting partitioning $P_k(G, Q)$ reduces the *probability* of expensive *ipt*, when executing a random $q \in Q$, using the following techniques.

Firstly, we employ a trie-like datastructure to index all of the possible sub-graphs of query graphs $q \in Q$, then identify those sub-graphs which are motifs, i.e. occur most frequently (Sec. 2). Secondly, we buffer a sliding window over G , then use an efficient graph stream pattern matching procedure to check whether each new edge added to G creates a sub-graph which matches one of our motifs (Sec. 3). Finally, we employ a combination of novel and existing partitioning heuristics to assign each motif matching

²e.g. Pagerank executed using the Apache Giraph framework: <http://bit.ly/2eNVCnv>.

Figure 2: TPSTry++ for Q in fig. 1

sub-graph which leaves the sliding window entirely within an individual partition, thereby reducing ipt for Q (Sec. 4).

2 IDENTIFYING MOTIFS

We now describe the first of the three steps mentioned above, namely the encoding of all query graphs found in our pattern matching query workload Q . For this, we use a trie-like data-structure which we have called the *Traversal Pattern Summary Trie* (TPSTry++). In a TPSTry++, every node represents a graph, while every parent node represents a sub-graph which is common to the graphs represented by its children. As an illustration, the complete TPSTry++ for the workload Q in Fig. 1 is shown in Fig. 2.

This structure not only encodes all sub-graphs found in each $q \in Q$, it also associates a support value p with each of its nodes, to keep track of the relative frequency of occurrences of each sub-graph in our query graphs.

Given a threshold \mathcal{T} for the frequency of occurrences, a *motif* is a sub-graph that occurs at least \mathcal{T} times in Q . As an example, for $\mathcal{T} = 40\%$, Q 's motifs are the shaded nodes in Fig. 2.

Intuitively, a sub-graph of G which is frequently traversed by a query workload should be assigned to a single partition. We can identify these sub-graphs as they form within the stream of graph updates, by matching them against the motifs in the TPSTry++. Details of the motif matching process are provided in Sec.3. In the rest of this section we explain how a TPSTry++ is constructed, given a workload Q .

A TPSTry++ extends a simpler structure, called TPSTry, which we have recently proposed in a similar setting [8]. It employs *frequent sub-graph mining*[12] to compactly encode general labelled graphs. The resulting structure is a Directed Acyclic Graph (DAG), to reflect the multiple ways in which a particular query pattern may extend shorter patterns. For example in Fig. 2 the graph in node $a-b-a-b$ can be produced in two ways, by adding a single $a-b$ edge to either of the sub-graphs $b-a-b$, and $a-b-a$. In contrast, a TPSTry is a tree that encodes the space of possible traversal **paths** through a graph as a conventional trie of strings, where a path is a string of vertex labels, and possible paths are described by a stream of regular path queries [20].

Note that the trie is a relatively compact structure, as it grows with $|L_V|^t$, where t is the number of edges in the largest query graph in Q and L_V is typically small. Also note that the TPSTry++ is similar to, though more general than, Ribiero et al's G-Trie [27] and Choudhury et al's SJ-Tree [3], which use trees (not DAGs) to encode unlabelled graphs and labelled paths respectively.

2.1 Sub-graph signatures

We build the trie for Q by progressively building and merging smaller tries for each $q \in Q$, as shown in Fig. 3. This process relies

Figure 3: Combining tries for query graphs q_1, q_2

on detecting graph isomorphisms, as any two trie nodes from different queries that contain identical graphs should be merged. Failing to detect isomorphism would result, for instance, in two separate trie nodes being created for the simple graphs $a-b-c$ and $c-b-a$, rather than a single node with a support of 2, as intended. One way of detecting isomorphism, often employed in frequent sub-graph mining, involves computing the lexicographical canonical form for each graph [19], whereby two graphs are isomorphic if and only if they have the same canonical representation.

Computing a graph's canonical form provides strong guarantees, but can be expensive[27]. Instead, we propose a probabilistic, but computationally more efficient approach based on *number theoretic signatures*, which extends recent work by Song et al. [29]. In this approach we compute the signature of a graph as a large, pseudo-unique integer hash that encodes key information such as its vertices, labels, and nodes degree. Graphs with matching signatures are likely to be isomorphic to one another, but there is a small probability of collision, i.e., of having two different graphs with the same signature.

Given a query graph $G_q = \{V_q, E_q\}$ we compute its signature as follows. Initially we assign a random value $r(l) = [1, p)$, between 1 and some user specified prime p , to each possible label $l \in L_{V_i}$ from our data graph G ; recall that the function f_l maps vertices in G to these labels. We then perform three steps:

- (1) Calculate a factor for each edge $e = (v_i, v_j) \in E_q$, according to the formula:

$$edgeFac(e) = (r(f_l(v_i)) - r(f_l(v_j))) \bmod p$$

- (2) Calculate the factors that encode the degree of each vertex. If a vertex v has a degree n , its degree factor is defined as:

$$degFac(v) = ((r(f_l(v)) + 1) \bmod p) \cdot ((r(f_l(v)) + 2) \bmod p) \cdot \dots \cdot ((r(f_l(v)) + n) \bmod p)$$

- (3) Finally, we compute the signature of $G_q = (V_q, E_q)$ as:

$$\left(\prod_{e \in E_i} edgeFac(e) \right) \cdot \left(\prod_{v \in V_i} degFac(v) \right)$$

Note that for the factors of *directed* edges, the random value for the target vertex's label is subtracted from the random value for the source vertex's label (i.e. v_j is the target vertex). For *undirected* edges the ordering of subtraction does not matter, provided it is consistent (e.g. lexicographical).

To illustrate this signature calculation process, consider query q_1 from Fig. 1. Given a p of 11 and random values $r(a) = 3$, $r(b) = 10$ we first calculate the edge factor for an $a-b$ edge: $edgeFac((a, b)) = (3 - 10) \bmod 11 = 7$. As q_1 consists of four $a-b$ edges, its total edge factor is $7^4 = 2401$. Then we calculate the

degree factors ³, starting with a b labelled vertex with degree 2: $\text{degFac}(b) = ((10+1) \bmod 11) \cdot ((10+2) \bmod 11) = 11$, followed by an a labelled vertex also with degree 2: $\text{degFac}(a) = 20$. As there are two of each vertex, with the same degree, the total degree factor is $11^2 \cdot 20^2 = 48400$. The signature of $q_1 = 2401 \cdot 48400 = 116208400$.

This approach is appealing for two reasons. Firstly, since the factors in the signature may be multiplied in any order, a signature for G can be calculated incrementally if the signature of any of its sub-graphs G_i is known, as this is the combined factor due to the additional edges and degree in $G \setminus G_i$. Secondly, the choice of p determines a trade-off between the probability of collisions and the performance of computing signatures. Specifically, note that signatures can be **very** large numbers (thousands of bits) even for small graphs, rendering operations such as remainder costly and slow. A small choice of p reduces signature size, because all the factors are mapped to a finite field [17] ($\text{factor} \bmod p$) between 1 and p , but it increases the likelihood of collision, i.e., the probability of two unrelated factors being equal. We discuss how to improve the performance and accuracy of signatures in Section 2.3.

2.2 Constructing the TPSTry++

Algorithm 1 Recursively add a query graph G_q to a TPSTry++

```

1:  $\text{factors}(e, g) \leftarrow$  degree/edge factors to multiply a graph  $g$ 's
   signature when adding edge  $e$ 
2:  $\text{support}(g) \leftarrow$  map of TPSTry++ nodes (graphs) to  $p$ -values
3:  $\text{tpstry} \leftarrow$  TPSTry++ for workload  $Q$ 
4:  $\text{parent} \leftarrow$  TPSTry++ node, initially root (an empty graph)
5:  $G_q \leftarrow$  query graph defined by a query  $q$ 
6:  $g \leftarrow$  some sub-graph of  $G_q$ 

7: for  $e$  in edges from  $G_q$  do
8:    $g \leftarrow$  new empty graph
9:   corecurse( $\text{parent}, e, \text{tpstry}, g$ )
10:     $\text{sig} \leftarrow \text{factor}(e, g) \cdot \text{parent.signature}$ 
11:    if  $\text{tpstry.signatures}$  contains  $\text{sig}$  then
12:       $n \leftarrow$  node from  $\text{tpstry}$  with signature  $\text{sig}$ 
13:       $\text{support}(n) \leftarrow \text{support}(n) + 1$ 
14:    else
15:       $n \leftarrow$  new node with graph  $g + e$  and signature  $\text{sig}$ 
16:       $\text{support}(n) \leftarrow 1$ 
17:       $\text{tpstry} \leftarrow \text{tpstry} + n$ 
18:    if not  $\text{parent.children}$  contains  $n$  then
19:       $\text{parent.children} \leftarrow \text{parent.children} + n$ 
20:     $\text{newEdges} \leftarrow$  edges incident to  $g + e$  and not in  $g + e$ 
21:    for  $e'$  in  $\text{newEdges}$ 
22:      corecurse( $n, e', \text{tpstry}, g + e$ )
23: return  $\text{tpstry}$ 

```

Our approach to constructing the TPSTry++ is to incrementally compute signatures for sub-graphs of each query graph q in a trie, merging trie nodes with equal signatures to produce a DAG which encodes the sub-graphs of all $q \in Q$. Alg. 1 formalises this approach.

Essentially, we recursively “rebuild” the graph $G_q | E_q |$ times, starting from each edge $e \in E_q$ in turn. For an edge e we calculate its edge and degree factors, initially assuming a degree of 1 for

³Note we don't consider 0 a valid factor, and replace it with p (e.g. $11 \bmod 11 = 11$)

each vertex. If the resulting signature is not associated with a child of the TPSTry++'s root, then we add a node n representing e . Subsequently, we “add” those edges e' which are incident to $e \in G_q$, calculating the additional edge and degree factors, and add corresponding trie nodes as children of n . Then we recurse on the edges incident $e + e'$.

Consider again our earlier example of the query graph q_1 : as it arrives in the workload stream Q , we break it down to its constituent edges $\{a-b, a-b, a-b, a-b\}$. Choosing an edge at random we calculate its combined factor. We know that the edge factor of an $a-b$ edge is 7. When considering this single edge, both a and b vertices have a degree of 1, therefore the signature for $a-b$ is $7 \cdot ((3 + 1) \bmod 11) \cdot ((10 + 1) \bmod 11) = 308$. Subsequently, we do the same for all other edges and, finding that they have the same signature, leave the trie unmodified. Next, for each edge, we add each incident edge from q_1 and compute the new combined signature. Assume we add another $a-b$ edge adjacent to b to produce the sub-graph $a-b-a$. This produces three new factors: the new edge factor 7, the new a vertex degree factor $((3 + 1) \bmod 11)$ and an additional degree factor for the existing b vertex $((10 + 2) \bmod 11)$. The combined signature for $a-b-a$ is therefore $308 \cdot 7 \cdot 4 \cdot 1 = 8624$; if a node with this signature does not exist in the trie as a child of the $a-b$ node, we add it. This continues recursively, considering larger sub-graphs of q_1 until there are no edges left in q_1 which are not in the sub-graph, at which point, q_1 has been added to the TPSTry++.

2.3 Avoiding signature collisions

As mentioned, number theoretic signatures are a probabilistic method of isomorphism checking, prone to collisions. There are several scenarios in which two non-isomorphic graphs may have the same signature: *a*) two factors representing different graph features, such as different edges or vertex degrees, are equal; *b*) two distinct sets of factors have the same product; and *c*) two different graphs have identical sets of edges, vertices and vertex degrees.

The original approach to graph isomorphic checking [29] makes use of an expensive authoritative pattern matching method to verify identified matches. Given a query graph, it calculates its signature in advance, then incrementally computes signatures for sub-graphs which form within a window over a graph stream. If a sub-graph's signature is ever divisible by that of the query graph, then that sub-graph should contain a query match.

There are some key differences in how we compute and use signatures with Loom, which allow us to rely solely upon signatures as an efficient means for mining and matching motifs. Firstly, remember our overall aim is to heuristically lower the probability that sub-graphs in a graph G which match our discovered motifs straddle a partition boundary. As a result we can tolerate some small probability of false positive results, whilst the manner in which signatures are executed (Sec. 2.1) precludes false negatives; i.e. two graphs which **are** isomorphic are guaranteed to have the same signature. Secondly, we can exploit the structure of the TPSTry++ to avoid ever explicitly computing graph signatures. From Fig. 2 and Alg. 1, we can see that all possible sub-graphs of a query graph G_q will exist in the TPSTry++ by construction. We calculate the edge and degree factors which would multiply the signature of a sub-graph with the addition of each edge, then associate these factors to the relevant trie branches. This allows us to represent signatures as sets of their constituent factors,

Figure 4: Probability of < 5% factor collisions for various numbers of factors and finite fields p

which eliminates a source of collisions, e.g. we can now distinguish between graphs with factors $\{6, 2\}$, $\{4, 3\}$ and $\{12\}$. Thirdly, we never attempt to discover whether some sub-graph **contains** a match for query q , only whether it **is** a match for q . In other words, the largest graph for which we calculate a signature is the size of the largest query graph $|G_q|$ for all $q \in Q$, which is typically small⁴. This allows us to choose a larger prime p than Song et al. might, as we are less concerned with signature size, reducing the probability of factor collision, another source of false positive signature matches.

Concretely, we wish to select a value of p which minimises the probability that more than some acceptable percentage $C\%$ of a signature’s factors are collisions. From Section 2.1 there are three scenarios in which a factor collision may occur: *a)* two edge factors are equal despite different vertices with different random values from our range $[1, p)$; *b)* an edge factor is equal to a degree factor; and *c)* two degree factors are equal, again despite different vertices. Song et al. show that all factors are uniform random variables from $[1, p)$, therefore each scenario occurs with probability $\frac{1}{p}$.

For either edge or degree factors, from the above it is clear that there are two scenarios in which a collision may occur, giving a collision probability for any given factor of $\frac{2}{p}$. The Handshaking lemma tells us that the total degree of a graph must equal $2|E|$, which means that a graph must have $3|E|$ factors in its signature: one per edge plus one per degree. Combined with the binary measure of “success” (collision / no collision), this suggests a binomial distribution of factor collision probabilities, specifically $Binomial(3|E|, \frac{2}{p})$. Binomial distributions tell us the probability of exactly x “successes” occurring, however we want the probability that no more than $C_{max} = C\% \cdot 3|E|$ factors collide and so must sum over all acceptable outcomes $x \in C_{max}$:

$$\sum_{x=0}^{C_{max}} Pr(X = x) \text{ where } X \sim Binomial(3|E|, \frac{2}{p})$$

Figure 4 shows the probabilities of having fewer than 5% factor collisions given query graphs of 8, 12 or 16 edges and p choices between 2 and 317. In Loom, when identifying and matching motifs, we use a p value of 251, which as you can see gives a negligible probability of significant factor collisions.

⁴Of the order of 10 edges.

3 MATCHING MOTIFS

We have seen how motifs that occur in Q are identified. By construction, motifs represent graph patterns that are frequently traversed during executions of queries in Q . Thus, the sub-graphs of G that match those motifs are expected to be frequently visited together and are therefore best placed within the same partition. In this section we clarify how we discover pattern matches between sub-graphs and motifs, whilst in the next Section we describe the allocation of those sub-graphs to partitions.

Loom operates on a sliding window of configurable size over the stream of edges that make up the growing graph G . The system monitors the connected sub-graphs that form in the stream within the space of the window, efficiently checking for isomorphisms with any known motif each time a sub-graph grows. Upon leaving the window, sub-graphs that match a motif are immediately assigned to a partition, subject to partition balance constraints as explained in Section 4.

Note that this technique introduces a delay, corresponding to the size of the window, between the time edges are submitted to the system and the time they are assigned and made available. In order to allow queries to access the new parts of graph G , Loom views the sliding window *itself* as an extra partition, which we denote P_{temp} . In practice, vertices and edges in the window are accessible in this temporary partition prior to being permanently allocated to their own partition.

To help understand how the matching occurs, note that in the TPSTry++, by construction, *all* ancestors of any node n must represent strict sub-graphs of the graph represented by n itself. Also, note that the support of a node n is the relative frequency with which n ’s sub-graph G_n occurs in Q . As, by definition, each time G_n occurs in Q so do all of *its* sub-graphs, a trie node n must have a support lower than any of its ancestors. This means that if any of the nodes in the trie, including those representing single edges, are not motifs, then none of their descendants can be motifs either. Thus, when a new edge $e = (v_1, v_2)$ arrives in the graph stream, we compute its signature (Sec. 2.1) and check if e matches a single-edge motif at the root of the TPSTry++. If there is no match, we can be certain that e will never form part of any sub-graph that matches a motif. We therefore immediately assign e to a partition and do not add it to our stream window P_{temp} . If, on the other hand, e does match a single-edge motif then we record the match into a map, *matchList*, and add e to the window. The *matchList* maps vertices v to the set of motif matching sub-graphs in P_{temp} which contain v ; i.e. having determined that $e = (v_1, v_2)$ is a motif match, we treat e as a sub-graph of a single edge, then add it to the *matchList* entries for both v_1 and v_2 . Additionally, alongside every sub-graph in *matchList*, we store a reference to the TPSTry++ node which represents the matching motif. Therefore, entries in *matchList* take the form $v \rightarrow \{\langle E_i, m_i \rangle, \langle E_j, m_j \rangle, \dots\}$, where E_i is a set of edges in P_{temp} that form a sub-graph g_i with the same signature as the motif m_i .

Given the above, any edge e which is added to P_{temp} must at least match a single edge motif. However, if e is incident to other edges already in P_{temp} , then its addition may also form larger motif matching sub-graphs which we must also detect and add to *matchList*. Thus, having added $e = (v_1, v_2)$ to *matchList*, we check the map for existing matches which are connected to e ; i.e we look for matches which contain one of v_1 or v_2 . If any exist, we use the procedure in Alg. 2, along with the TPSTry++,

- 14: **for** each edge e_2 in m_2 **do**
- 15: **if** n_1 has child c_1 w. $factor = factors(e_2, m_1)$ **then**
- 16: **recurse**(*tpstry*, $m_2 - e_2, m_1 + e_2, c_1$)
- 17: **if** m_2 is empty **then** //Match found!
- 18: add $\langle m_1 + m_2, n_1 \rangle$ to *matchList* for $v_1 \& v_2$

to determine whether the addition of edge e to these sub-graphs creates another motif match.

Essentially, for each sub-graph g_i from *matchList* to which e is connected, we calculate the set of edge and degree factors $fac(e, g_i)$ which would multiply the signature of g_i upon the addition e , as in Sec. 2. Recall, also from Sec. 2, that a TPSTry++ node contains a signature for the graph it represents, and that these signatures are stored as sets of factors, rather than their large integer products. As each sub-graph in *matchList* is paired with its associated motif n from the trie, we can efficiently check if n has a child c where $a) c$ is a motif; and $b)$ the difference between n 's factor set and c 's factor set corresponds to factors for the addition of e to g_i , i.e., $fac(e, g_i) = c.signatures \setminus n.signatures$. If such a child exists in the trie then adding e to a graph which matches motif n (g_i) will likely create a graph which matches motif c : the addition of e to P_{temp} has formed the new motif matching sub-graph $g_i + e$.

We also detect if the joining of two existing multi edge motif matches ($\langle E_1, m_1 \rangle, \langle E_2, m_2 \rangle$) forms yet another motif match, in roughly the same manner. First we consider each edge from the smaller motif match (e.g. $e \in E_2$ from $\langle E_2, m_2 \rangle$), checking if the addition of any of these edges to E_1 ⁵ constitutes yet another match; if it does then we add the edge to E_1 and recursively repeat the process until E_2 is empty. If this process **does** exhaust E_2 then $E_1 \cup E_2$ constitute a motif matching sub-graph. Once this process is complete, *matchList* will contain entries for **all** of

the motif matching sub-graphs currently in P_{temp} . Note that as more edges are added to P_{temp} , *matchList* may contain multiple entries for a given vertex where one match is a sub-graph of another, i.e. new motif matches don't replace existing ones.

As an example of the motif matching process, consider the portion of a graph stream (left), motifs (center) and *matchList* (right) depicted in Fig. 5. Our window over the graph stream G is initially empty, with the depicted edges being added in label order (i.e. e_1, e_2, \dots). As the edge e_1 is added, we first compute its signature and verify whether e_1 matches a single-edge motif in the TPSTry++. We can see that, as an a - b labelled edge, the signature for e_1 must match that of motif m_1 , therefore we add e_1 to P_{temp} , and add the entry $\langle e_1, m_1 \rangle$ to *matchList* for both e_1 's vertices 1,2. As e_1 is not yet connected to any other edges in P_{temp} , we do not need to check for the formation of additional motif matches. Subsequently, we perform the exact same process for edge e_2 . When e_3 is added, again we verify that, as a b - c edge, e_3 is a match for the single-edge motif m_3 and so update P_{temp} and *matchList* accordingly. However, e_3 is connected to existing motif matching sub-graphs in P_{temp} therefore the union of *matchList* entries for e_3 's vertices 4,5 (line 4 Alg. 2) returns $\{\langle e_2, m_1 \rangle\}$. As a result, we calculate the factors to multiply e_2 's signature by, when adding e_3 . Remember that when computing signatures, each edge has a factor, as well as each degree. Thus, when adding e_3 to e_2 our *new* factors are an edge factor for a b - c labelled edge, a first degree factor for the vertex labelled c (5) and a second degree factor for the vertex labelled b ⁶ (4) (Sec. 2.1). Subsequently we must check whether the motif for e_2, m_1 , has any child nodes with additional factors consistent with the addition of a b - c edge, which it does: m_3 . This means we have found a new sub-graph in P_{temp} which matches the motif m_3 , and must add $\{\langle e_2, e_3 \rangle, m_3\}$ to the *matchList* entries for vertices 3, 4 and 5. Similarly, the addition of b - c labelled edge e_4 to our graph stream produces the new motif matches $\langle e_4, m_2 \rangle$ and $\langle e_1, e_4 \rangle, m_3$, as can be seen in our example *matchList*.

Finally, the addition of our last edge, e_5 , creates several new motif matches (e.g. $\langle e_1, e_5 \rangle, m_4 \rangle, \langle e_2, e_5 \rangle, m_5$ etc...). In particular, notice that the addition of e_5 creates a match for the motif m_6 , combining the new motif match $\langle e_1, e_5 \rangle, m_4$ with an existing one $\langle e_2, m_1 \rangle$. To understand how we discover these slightly more complex motif matches, consider Alg. 2 from line 11 onwards. First we retrieve the updated *matchList* entries for vertices 2 and 3, including the new motif matches gained by simply adding the single edge e_5 to connected existing motif matches, as above. Next we iterate through all possible pairs of motif matches for both vertices. Given the pair of matches ($\langle e_1, e_5 \rangle, m_4 \rangle, \langle e_2, m_1 \rangle$), we discover that the addition of any edge from the smaller (i.e. e_2) to the larger produces factors which correspond to a child of m_4 in the TPSTry++: m_6 . As e_2 is the only edge in the smaller

⁵Treating E_1 as a sub-graph.

⁶As, with the addition of e_3 , vertex 4 has degree 2.

match, we simply add the match $\langle \{e_1, e_2, e_5\}, m_6 \rangle$ to the *matchList* entries for 1, 2, 3 and 4. In the general case however, we would not add this new match but instead recursively “grow” it with new edges from the smaller match, updating *matchList* only if all edges from the smaller match have been successfully added.

4 ALLOCATING MOTIFS

Following graph stream pattern matching, we are left with a collection of sub-graphs, consisting solely of the most recent t edges in G , which match motifs from Q . As new edges arrive in the graph stream, our window P_{temp} grows to size t and then “slides”, i.e. each new edge added to a full window causes the oldest ($t + 1^{th}$) edge e to be dropped. Our strategy with Loom is to then assign this old edge e to a permanent partition, along with the other edges in the window which form motif matching sub-graphs with e . The sole exception to this is when an edge arrives that may not form part of any motif match and is assigned to a partition immediately (Sec. 3). This exception does not pose a problem however, because Loom behaves as if the edge was never added to the window and therefore does not cause displacement of older edges.

Recall again that with Loom we are attempting to assign motif matching sub-graphs wholly within individual partitions with the aim of reducing *ipt* when executing our query workload Q . One naive approach to achieving this goal is as follows: When assigning an edge $e = (v_1, v_2)$, retrieve the motif matches associated with v_1 and v_2 from P_{temp} using our *matchList* map, then select the subset M_e that contains e , where $M_e = \{\langle E_1, m_1 \rangle, \dots, \langle E_n, m_n \rangle\}$, $e \in E_i$ and E_i is a match for m_i . Finally, treating these matches as a single sub-graph, assign them to the partition which they share the most incident edges. This approach would greedily ensure that no edges belonging to motif matching sub-graphs in G ever cross a partition boundary. However, it would likely also have the effect of creating highly unbalanced partition sizes, potentially straining the resources of a single machine, which prompted partitioning in the first place.

Instead, we rely upon two distinct heuristics for edge assignment, both of which are aware of partition balance. Firstly, for the case of non-motif-matching edges that are assigned immediately, we use the existing *Linear Deterministic Greedy* (LDG) heuristic [30]. Similar to our naive solution above, LDG seeks to assign edges⁷ to the partition where they have the most incident edges. However, LDG also favours partitions with higher residual capacity when assigning edges in order to maintain a balanced number of vertices and edges between each. Specifically, LDG defines the residual capacity r of a partition S_i in terms of the number of vertices currently in S_i , given as $|\mathcal{V}(S_i)|$, and a partition capacity constraint C : $r(S_i) = 1 - \frac{|\mathcal{V}(S_i)|}{C}$. When assigning an edge e , LDG counts the number of e 's incident edges in each partition, given as $N(S_i, e)$, and weights these counts by S_i 's residual capacity; e is assigned to the partition with the highest weighted count. The full formula for LDG's assignment is:

$$\max_{S_i \in P_k(G)} N(S_i, e) \cdot \left(1 - \frac{|\mathcal{V}(S_i)|}{C}\right)$$

Secondly, for the general case where edges form part of motif matching sub-graphs, we propose a novel heuristic, *equal opportunism*. Equal opportunism extends ideas present in LDG but, when assigning clusters of motif matching sub-graphs to a single partition as we do in Loom, it has some key advantages.

By construction, given an edge e to be assigned along with its motif matches $M_e = \{\langle E_1, m_1 \rangle, \dots, \langle E_n, m_n \rangle\}$, the sub-graphs E_i, E_j in M_e have significant overlap (e.g. they all contain e). Thus, individually assigning each motif match to potentially different partitions would create many inter-partition edges. Instead, equal opportunism greedily assigns the match cluster to the single partition with which it shares the most vertices, weighted by each partition's residual capacity. However, as these vertices and their new motif matching edges may not be traversed with equal likelihood given a workload Q , equal opportunism also prioritises the shared vertices which are part of motif matches with higher support in the TPSTry++.

Formally, given the motif matches M_e we compute a score for each partition S_i and motif match $\langle E_k, m_k \rangle \in M_e$, which we call a *bid*. Let $\mathcal{N}(S_i, E_k) = |\mathcal{V}(S_i) \cap \mathcal{V}(E_k)|$ denote the number of vertices in the edge set E_k (which is itself a graph) that are already assigned to S_i ⁸. Additionally, let $supp(m_k)$ refer to the support of motif m_k in the TPSTry++ and recall that C is a capacity constraint defined for each partition. We define the bid for partition S_i and motif match $\langle E_k, m_k \rangle$ as:

$$bid(S_i, \langle E_k, m_k \rangle) = \mathcal{N}(S_i, E_k) \cdot \left(1 - \frac{|\mathcal{V}(S_i)|}{C}\right) \cdot supp(m_k) \quad (1)$$

We could simply assign the cluster of motif matching sub-graphs (i.e. $E_1 \cup \dots \cup E_n$) to the single partition S_i with the highest bid for all motif matches in M_e . However, equal opportunism further improves upon the balance and quality of partitionings produced with this new weighted approach, limiting its greediness using a rationing function we call l . $l(S_i)$ is a number between 0 and 1 for each partition, the size of which is inversely correlated with S_i 's size relative to the smallest partition $S_{min} = \min_{S \in P_k(G)} |\mathcal{V}(S)|$, i.e. if S_i is as small as S_{min} then $l(S_i) = 1$. Equal opportunism sorts motif matches in M_e in descending order of support, then uses $l(S_i)$ to control both the number of matches used to calculate partition S_i 's total bid, and the number of matches assigned to S_i should its total bid be the highest. This strategy helps create a balanced partitioning by a) allowing smaller partitions to compute larger total bids over more motif matches; and b) preventing the assignment of large clusters of motif matches to an already large partition. Formally we calculate $l(S_i)$ as follows:

$$l(S_i) = \frac{|\mathcal{V}(S_i)|}{S_{min}} \cdot \alpha, \quad \alpha = \begin{cases} 1, & |\mathcal{V}(S_i)| = |\mathcal{V}(S_{min})| \\ 0, & |\mathcal{V}(S_i)| > |\mathcal{V}(S_{min})| \cdot b \\ \alpha, & \text{otherwise} \end{cases} \quad (2)$$

where α is a user specified number $0 < \alpha \leq 1$ which controls the aggression with which l penalises larger partitions and b limits the maximum imbalance. Throughout this work we use an empirically chosen default of $\alpha = \frac{2}{3}$ and set the maximum imbalance to $b = 1.1$, emulating Fennel [31].

Given definitions (1) and (2), we can now simply state the output of equal opportunism for the sorted set of motif matches M_e , as:

$$\max_{S_i \in P_k(G)} l(S_i) \cdot |M_e| \sum_{k=0} bid(S_i, \langle E_k, m_k \rangle) \quad (3)$$

Note that motif matches in M_e which are not bid on by the winning partition are dropped from the *matchList* map, as some of their constituent edges (e.g. e , which all matches in M_e share) have been assigned to partitions and removed from the sliding window P_{temp} .

⁷LDG may partition either vertex or edge streams.

⁸Note that \mathcal{N} is a generalisation of LDG's function \mathcal{N}

To understand how the rationing function l improves the quality of equal opportunism’s partitioning, not just its balance, consider the following: Just because an edge e' falls within the motif match set M_e of our assignee e , does not necessarily imply that placing them within the same partition is optimal. e' could be a member of many other motif matches in P_{temp} besides those in M_e , perhaps with higher support in the TPSTry++ (i.e. higher likelihood of being traversed when executing a workload Q). By ordering matches by support and prioritising the assignment of the smaller, higher support motif matches, we often leave e' to be assigned later along with matches to which it is more “important”.

As an example, consider again the graph and TPSTry++ fragment in Fig. 5. If assigning the edge e_1 to a partition at the time $t + 1$, its **support ordered** set of motif matches M_{e_1} would be $\langle e_1, m_1 \rangle, \langle \{e_1, e_4\}, m_3 \rangle, \langle \{e_1, e_5\}, m_4 \rangle$ and $\langle \{e_1, e_2, e_5\}, m_6 \rangle$. Assume two partitions S_1 and S_2 , where S_1 is 33.3% larger than S_2 and vertex 2 already belongs to partition S_1 , whilst all other vertices in the window are as yet unassigned (i.e. this is the first time edges containing them have entered the sliding window). In this scenario, S_1 is guaranteed to win all bids, as S_2 contains no vertices from M_{e_1} and therefore $\mathcal{N}(S_2, _)$ will always equal 0. However, rather than greedily assign all matches to the already large S_1 , we calculate the ration l for S_1 as $\frac{1}{1.33} \cdot \frac{1}{1.5} = \frac{1}{2}$, given $\alpha = 1.5$. In other words, we only assign edges from the first half of M_{e_1} ($\langle e_1, m_1 \rangle, \langle \{e_1, e_4\}, m_3 \rangle$) to S_1 ; edges such as e_5 and e_2 remain in the window P_{temp} . Assume an edge $e_6 = (4, 6)$ subsequently arrives in the graph stream G , where vertex 6 already belongs to partition S_2 and e_6 matches the motif m_2 (i.e. has labels $b-c$). If we had already assigned e_5 to partition S_1 then this would lead to an inter-partition edge which is more likely to be traversed together with e_5 than are other edges in S_1 , given our workload Q . Instead, we compute a match in P_{temp} between $\langle e_5, e_6 \rangle$ and the motif m_3 , and will likely later assign e_5 to partition S_2 . Within reason, the longer an edge remains in the sliding window, the more of its neighbourhood information we are likely to have access to, the better partitioning decisions we can make for it.

5 EVALUATION

Our evaluation aims to demonstrate that Loom achieves high quality partitionings of several large graphs in a single-pass, streaming manner. Recall that we measure graph partitioning quality using the number of inter-partition traversals when executing a realistic workloads of pattern matching queries over each graph.

Loom consistently produces partitionings of around 20% superior quality when compared to those produced by state of the art alternatives: LDG [30] and Fennel [31] Furthermore, Loom partitionings’ quality improvement is robust across different numbers of partitions (i.e. a 2-way or a 32-way partitioning). Finally we show that, like other streaming partitioners, Loom is sensitive to the arrival order of a graph stream, but performs well given a pseudo-adversarial random ordering.

5.1 Experimental setup

For each of our experiments, we start by streaming a graph from disk in one of three predefined orders: **Breadth-first**: computed by performing a breadth-first search across all the connected components of a graph; **Random**: computed by randomly permuting the existing order of a graph’s elements; and **Depth-first**: computed by performing a depth-first search across the connected

Figure 6: Examples of q for MusicBrainz, DBLP & ProvGen

components of a graph. We choose these stream orderings as they are common to the evaluations of other graph stream partitioners [11, 22, 30, 31], including LDG and Fennel.

Subsequently, we produce 4 separate k -way partitionings of this ordered graph stream, using each of the following partitioning approaches for comparison: **Hash**: a naive partitioner which assigns vertices and edges to partitions on the basis of a hash function. As this is the default partitioner used by many existing partition graph databases⁹, we use it as a baseline for our comparisons. **LDG**: a simple graph stream partitioner with good performance which we extend with our work on Loom. **Fennel**: a state-of-the-art graph stream partitioner and our primary point of comparison. As suggested by Tsourakakis et al, we use the Fennel parameter value $\gamma = 1.5$ throughout our evaluation. **Loom**: our own partitioner which, unless otherwise stated, we invoke with a window size of 10k edges and a motif support threshold of 40%.

Finally, when each graph is finished being partitioned, we execute the appropriate query workload over it and count the number of inter-partition traversals (ipt) which occur.

Note that we avoid implementation dependent measures of partitioning quality because, as an isolated prototype, Loom is unlikely to exhibit realistic performance. For instance, lacking a distributed query processing engine, query workloads are executed over logical partitions during the evaluation. In the absence of network latency, query response times are meaningless as a measure of partitioning quality.

All algorithms, data structures, datasets and query workloads are publicly available¹⁰. All our experiments are performed on a commodity machine with a 3.1Ghz Intel i7 CPU and 16GB of RAM.

5.1.1 Graph datasets. Remember that the workload-agnostic partitioners which we aim to supersede with Loom are liable to exhibit poor workload performance when queries focus on traversing a limited subset of edge types (Sec. 1). Intuitively, such skewed workloads are more likely over heterogeneous graphs, where there exist a larger number of possible edge types for queries to discern between, e.g. $a-a$, $a-b$, $a-c$... vs just $a-a$. Thus, we have chosen to test the Loom partitioner over five datasets with a range of different heterogeneities and sizes; three of these datasets are synthetic and two are real-world. Table 1 presents information about each of our chosen datasets, including their size and how heterogeneous they are ($|L_V|$). We use the DBLP, and LUBM datasets, which are well known. MusicBrainz¹¹ is a freely available database of curated music metadata, with vertex

labels such as *Artist*, *Country*, *Album* and *Label*. ProvGen[6] is a synthetic generator for PROV metadata [21], which records detailed provenance for digital artifacts.

5.1.2 Query workloads. For each dataset we must propose a representative query workload to execute so that we may measure partitioning quality in terms of ipt . Remember that a query workload consists of a set of distinct query patterns along with a frequency for each (Sec. 1.3). The LUBM dataset provides a set of query patterns which we make use of. For every other dataset, however, we define a small set of common-sense queries which focus on discovering implicit relationships in the graph, such as potential collaboration between authors or artists¹². The full details of these query patterns are elided for space¹⁰, however Fig. 6 presents some examples. Note that whilst the TPSTry++ may be trivially updated to account for change in the frequencies of workload queries (Sec. 2), our evaluation of Loom assumes that said frequencies are fixed and known *a priori*. Recall that, for online databases, we argue this is a realistic assumption (Sec. 1). However, more complete tests with changing workloads are an important area for future work.

¹²If possible, workloads are drawn from the literature, e.g. common PROV queries [5]

5.2 Comparison of systems

Figures 7 and 8 present the improvement in partitioning quality achieved by Loom and each of the comparable systems we describe above. Initially, consider the experiment depicted in Fig. 7. We partition ordered streams of each of our first 4 graph datasets¹³ into 8-way partitionings, using the approaches described above, then execute each dataset’s query workload over the appropriate partitioning. The absolute number of inter-partition traversals (ipt) suffered when querying each dataset varies significantly. Thus, rather than represent these results directly, in Fig. 7 (and 8) we present the results for each approach as **relative** to the results for Hash; i.e. how many ipt did a partitioning suffer, as a **percentage** of those suffered by the Hash partitioning of the same dataset.

As expected, the naive hash partitioner performs poorly: it produces partitionings which suffer twice as many inter-partition traversals, on average, when compared to partitionings produced by the next best system (LDG). Whilst the LDG partitioner does achieve around a 55% reduction in ipt vs our Hash baseline, its produces partitionings of consistently poorer quality than those of Fennel and Loom. Although both LDG and Fennel optimise their partitionings for the balanced min. edge-cut goal (Sec. 1), Fennel is the more effective heuristic, cutting around 25% fewer edges than LDG for small numbers of partitions (including $k = 8$) [31]. Intuitively, the likelihood of *any* edge being cut is a coarse proxy for the likelihood of a query $q \in Q$ traversing a cut edge. This explains the disparity in ipt scores between the two systems.

Of more interest is comparing the quality of partitionings produced by Fennel and Loom. Fig. 7 clearly demonstrates that Loom offers a significant improvement in partitioning quality over Fennel, given a workload Q . Loom’s reduction in ipt relative to Fennel’s is present across all datasets and stream orders, however

¹³Excluding LUBM-4000

Dataset	LDG (ms)	Fennel (ms)	Loom (ms)	Hash (ms)
DBLP	91	96	235	28
ProvGen	144	146	240	33
MusicBrainz	48	52	129	18
LUBM-100	47	51	147	22
LUBM-4000	45	49	138	16

Table 2: Time to partition 10k edges

it is particularly pronounced over ordered streams of more heterogeneous graphs; e.g. MusicBrainz in Sub-figure 8b(b), where Loom’s partitioning suffers from 42% fewer *ipt* than Fennel’s. This makes sense because, as mentioned, pattern matching workloads are more likely to exhibit skew over heterogeneous graphs, where query graphs G_q contain a, potentially small, subset of the possible vertex labels. Across all the experiments presented in Fig. 7, the median range of Loom’s *ipt* reduction relative to Fennel’s is 20 – 25%. Additionally, Fig. 8 demonstrates that this improvement is consistent for different numbers of partitions. As the number of partitions k grows, there is a higher probability that vertices belonging to a motif match are assigned across multiple partitions. This results in an increase of *absolute ipt* when executing Q over a Loom partitioning. However, increasing k actually increases the probability that any two vertices which share an edge are split between partitions, thus reducing the quality of Hash, LDG and Fennel partitionings as well. As a result, the difference in *relative ipt* is largely consistent between all 4 systems.

On the other hand, neither Fig. 7, nor Fig. 8, present the runtime costs of producing a partitioning. Table 2 presents how long (in ms) each partitioner takes to partition 10k edges. Whilst all 3 algorithms are capable of partitioning many 10s of thousands of edges per second, we do find that Loom is slower than LDG and Fennel by an average factor of 2-3. This is likely due to the more complex map-lookup and pattern-matching logic performed by Loom, or a nascent implementation. The runtime performance of Loom varies depending on the query workload Q used to generate the TPSTry++ (Sec. 2), therefore the performance figures presented in Table 2 are averaged across many different Q . The minimum slowdown factor observed between Loom and Fennel was 1.5, the maximum 7.1. Note that popular non-streaming partitioner METIS [14] is around 13 times slower than Fennel for large graphs [31].

We contend that this performance difference is unlikely to be an issue in an online setting for two reasons. Firstly, most production databases do not support more than around 10k transactions per second (TPS) [16]. Secondly, it is considered exceptional for even applications such as twitter to experience >30k-40k TPS¹⁴. Meanwhile, the lowest partitioning rate exhibited by Loom in Table 2 is equivalent to ~ 42k edges per second, the highest 72k.

Note that Figures 7 and 8 do not present the relative *ipt* figures for the LUBM-4000 dataset. This is because measuring relative *ipt* involves reading a partitioned graph into memory, which is beyond the constraints of our present experimental setup. However, we include the LUBM-4000 dataset in Table 2 to demonstrate that, as a streaming system, Loom is capable of partitioning large scale graphs. Also note that none of the figures present partitioning imbalance as this is broadly similar between all approaches and

Figure 9: *ipt* (y-axis) when executing Q over Loom partitionings with multiple window sizes t (x-axis)

datasets¹⁵, with LDG varying between 1%–3%, Loom and Fennel between 7% and their maximum imbalance of 10% (Sec. 4).

5.3 Effect of stream order and window size

Fig. 7 indicates that Loom is sensitive to the ordering of its given graph stream. In fact, Sub-figure 7(a) shows Loom achieve a smaller reduction in *ipt* over Fennel and LDG, than in 7(b) and 7(c). Specifically Loom achieves a 42% greater reduction in relative *ipt* than Fennel given a breadth-first stream of the MusicBrainz graph, but only a 26% when the stream is ordered randomly, despite Fennel and LDG also being sensitive to stream ordering [30, 31]. This implies that Loom is particularly sensitive to random orderings: edges which are close to one another in the graph may not be close in the graph stream, resulting in Loom detecting fewer motif matching subgraphs in its stream window.

Intuitively, this sensitivity can be ameliorated by increasing the size of Loom’s window, as shown in Fig. 9. As Loom’s window grows, so does the probability that clusters of motif matching subgraphs will occur within it. This allows Loom’s equal opportunism heuristic to make the best possible allocation decisions for the subgraph’s constituent vertices. Indeed, the number of *ipt* suffered by Loom partitionings improves significantly, by as much as 47%, as the window size grows from 100 to 10k. However, increasing the window size past 10k clearly has little effect on *ipt* suffered to execute Q if your graph stream is ordered. The exact impact of increasing Loom’s window size depends upon the degree distribution of the graph being partitioned. However, to gain an intuition consider the naive case of a graph with a uniform average vertex degree of 8, along with a TPSTry++ whose largest motif contains 4 edges. In this case, a breadth-first traversal of 8^4 edges from a vertex a (i.e. window size $t \approx 4k$) is highly likely to include all the motif matches which contain a . Regardless, Fig. 9 might seem to suggest that Loom should run with the largest window size possible. However, besides the additional computational cost of detecting more motif matches, remember that Loom’s window constitutes a temporary partition (Sec. 3). If there exist many edges between other partitions and P_{temp} , then this may itself be a source of *ipt* and poor query performance.

¹⁵Except Hash, which is balanced.

6 CONCLUSIONS AND FUTURE WORK

In this paper, we have presented Loom: a practical system for producing k -way partitionings of online, dynamic graphs, which are optimised for a given workload of pattern matching queries Q . Our experiments indicate that Loom significantly reduces the number of inter-partition traversals (ipt) required when executing Q over its partitionings, relative to state of the art (workload agnostic) streaming partitioners.

There are several ways in which we intend to expand our current work on Loom. In particular, as a workload sensitive technique, Loom generates partitionings which are vulnerable to workload change over time. In order to address this we must integrate Loom with an existing, workload sensitive, graph repartitioner [8, 10] or consider some form of restreaming approach [11]. In addition to the query workloads already considered, it would be necessary to evaluate such an integrated approach using a dynamic, changing query workload.

Furthermore, due to our approaches reliance upon graph pattern matching in a single stream window, Loom is single threaded. The ability to have multiple instances of the Loom algorithm assign motif matches to the same graph partitioning would doubtless increase system scalability, and is therefore an important focus of ongoing research.

ABSTRACT

The efficient management of metric data is extremely important in many challenging applications as they occur e.g. in the life sciences. Here, data typically cannot be represented in a vector space. Instead, a distance function only allows comparing individual elements with each other to support distance queries. As high-dimensional data suffers strongly from the curse of dimensionality, distance-based techniques also allow for better handling of such data. This has already led to the development of a plethora of metric indexing and processing techniques. So far, the important problem of cardinality estimation on metric data has not been addressed in the literature. Standard vector-based techniques like histograms require an expensive and error-prone embedding. Thus, random sampling seems to be the best choice for selectivity estimation so far, but errors are very high for moderately small queries. In this paper, we present a native cardinality estimation technique for distance queries on metric data based on kernel-density estimation. The basic idea is to apply kernels to the one-dimensional distance function among metric objects and to use novel global and local bandwidth optimization methods. Our results on real-world data sets show the clear advantage of our method in comparison to its competitors.

1 INTRODUCTION

Statistics about the distribution of data in a database are used for two very important aspects of data management: query optimization and data exploration. In query optimization, they allow estimating the costs of operations, choosing appropriate algorithms, and computing the order of joins. For very large databases, where computations take a very long time, small in-memory statistics can deliver approximate answers. Those are often sufficient to determine whether it is worth further investigating the data in a particular direction.

While one- and multidimensional vector data is very common in traditional applications, there are many domains for which data is in a metric space only. This means data is not describable by a d -dimensional vector, instead there exists only a metric measuring distances between pairs of objects. Examples include the life sciences, where e.g. proteins are usually described by their geometrical structure or at least a sequence of amino acids. Multimedia data comes in different datatypes such as JPEG or MPEG which are also not appropriate for a relational representation.

In such domains there is a severe lack of native statistical support. Thus, a standard approach is to transform metric data into a multidimensional vector space and to apply one of the standard estimation techniques [18]. There are two serious opposing effects. First, a metric embedding causes in general a considerable information loss. In order to alleviate this, the number of dimensions needs to be sufficiently high. Second, the well-known curse

of dimensionality is already noticeable for a moderate number of dimensions. Thus, statistics provide only accurate results for low-dimensional vector spaces [1].

In this paper, we present the first native method for cardinality estimation of distance queries in metric spaces. The basic idea is to consider the distances of objects in a metric space and to use kernel techniques to estimate the underlying distance distribution. By tuning the bandwidth of the kernels and the kernel function, we obtain a robust estimator for the cardinality of distance queries in metric spaces. Moreover, our approach is also beneficial for high-dimensional vector spaces by treating them as metric spaces, thus considering only the distance among objects, to overcome the shortcomings of standard vectorial statistics.

The main contributions of this paper are:

- We show the deficiencies of traditional cardinality estimation techniques on metric data sets.
- We present the first effective and efficient method for cardinality estimation in metric space.
- Extensive experiments on real-world data show the validity of our approach.

The rest of the paper is structured as follows. Section 2 describes several applications for cardinality estimation in metric spaces, formally defines the problem, and emphasizes the differences of vector and metric data. Section 3 presents related work in the areas of cardinality estimation in general, techniques for embedding metric data into vector space and kernel-based techniques for cardinality estimation. Section 4 presents our distance-based kernel estimator approach in metric space. Section 5 describes our methods for global and local bandwidth optimization. Section 6 presents our experimental findings. Finally, Section 7 concludes the paper.

2 PRELIMINARIES

We first give a formal description of the problem of cardinality estimation on metric data. Then, we discuss several applications that greatly benefit from a suitable solution to this problem. Finally, we discuss the fundamental differences between vector and metric data that lead to the ineffectiveness of established methods.

2.1 Problem Specification

Let X be a set of N objects $\{x_1, \dots, x_N\} \subseteq \mathcal{X}$. These objects are all of a certain type, in particular a type which can differ from \mathbb{R}^n . Moreover a distance function $dist_{\mathcal{X}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}_+$ is given which fulfills the three properties of a metric, namely

- identity of indiscernibles: $dist_{\mathcal{X}}(x, y) = 0 \Leftrightarrow x = y$,
- symmetry: $dist_{\mathcal{X}}(x, y) = dist_{\mathcal{X}}(y, x)$ and
- triangle inequality: $dist_{\mathcal{X}}(x, z) \leq dist_{\mathcal{X}}(x, y) + dist_{\mathcal{X}}(y, z)$,

with $x, y, z \in \mathcal{X}$. We will refer to the combination of X and $dist_{\mathcal{X}}$ as metric data. In mathematics the pair $(\mathcal{X}, dist_{\mathcal{X}})$ is called metric space.

Cardinality estimation for metric data can be formalized as follows: Given a distance query $Q = (x_Q, r_Q)$, with object $x_Q \in \mathcal{X}$

and distance $r_Q \in \mathbb{R}_+$, *efficiently* approximate the cardinality of the set $\{x \in X \mid \text{dist}_X(x_Q, x) \leq r_Q\}$. We will refer to the distance r_Q as query radius. The true cardinality is denoted by $c(Q)$ and the estimated cardinality by $\tilde{c}(Q)$. The goal is to minimize the error of the estimation, but also the construction costs and the size, as well as the query time of the estimator. Note that the actual cardinality can, of course, be calculated by computing the distance to every other item in the data set. This requires a linear number of distance calculations. Each of them can be very costly as, e.g., in video dissimilarity. Hence, we want to minimize the computational costs induced by an estimator.

2.2 Applications

Cardinality estimation in metric spaces has many applications. Among others we want to mention the domain of Machine Learning and Data Mining, where algorithms are usually based on a distance measure. The most prominent example is the so-called k -nearest neighbor (k NN) classifier which can be used to classify any kind of data, if it is endowed with a distance measure.

The basic idea is to retrieve the k objects from a database which have the smallest distances to a certain query object. Assuming that the objects within the database carry a certain class label (e.g. customers of an insurance with label *churn* or *no churn*), the query is classified with the majority label from the set of the k nearest neighbors. k NN classifiers are known to be inefficient since for each run of such an algorithm a complete scan of the data set is required. To accelerate this algorithm typically metric index structures [28] are employed that allow the efficient retrieval of elements within a given distance of a query object. However, it is hard to specify the radius for the corresponding queries since the k NN classifier requires rather the set of k nearest neighbors than a certain set of neighbors exhibiting a certain maximal distance to the query object. For calculating the minimum radius, leading to a retrieval of k results, cardinality estimation can be used. For example, [14] make use of cardinality estimation to assign objects to different Locality Sensitive Hashing tables of different radii. This improves k NN queries on data sets where the distances of the k nearest neighbours of items vary greatly over the data set. A single LSH table could not sufficiently answer such queries.

Another example is the estimation of densities, e.g. for Bayes Classifiers, where the density around an element x is proportional to the amount of elements in a database that are in a small vicinity to x . This vicinity is typically specified by a certain small distance. Obviously, a reliable cardinality estimation approach would increase the efficiency of such classifiers enormously.

If a query is expressed as a conjunction of multiple proximity predicates, each of them with a different distance function, cardinality estimation is useful for computing an efficient order of their computation. In an optimal execution plan queries should be applied in an order that leads to quickly decreasing result sets. Cardinality estimation can be used to answer exactly this question and to find an order in which the different distance measures are to be applied. Applications in which such scenarios occur are, e.g., pharmaceutical chemistry, where different distance measures covering certain requirements are applied onto protein and/or ligand databases to get the final result in form of a very small set of therapeutically effective drugs. In general, this is a metric scenario, since proteins cannot be described on the structural level by vectors without a considerable loss of information.

2.3 Vector Data vs. Metric Data

In order to emphasize the fundamental differences of metric data to vector data that lead to the in-applicability of established methods, we now briefly review important properties of a vector space. We limit our discussion to vector spaces over the real numbers. Here, a d -dimensional vector space consists of elements $\mathbf{x} = (x_1, \dots, x_d)$ with a real value $x_i \in \mathbb{R}$ called *coordinate* for each dimension. Individual elements can be added to each other and multiplied with scalar values $v \in \mathbb{R}$. This, e.g., allows to compute the mean of multiple elements which is not possible in a metric space. Thus one of the most basic data summarization operators is not available in a metric space. Furthermore, the coordinates of the vector allow determining the location of an element with respect to other elements. Such a *direction* cannot be determined in a metric space.

A set of vectors can be ordered globally by component-wise sorting or by a space-filling curve [27] that better preserves the proximity of subsequent elements. In contrast, elements in a metric space can only be ordered based on the distance to a single reference object. Furthermore, it is straight-forward to divide a vector space into a finite number of distinct subsets by incrementally subdividing the space along the dimensions. In a metric space such subsets have to be defined using a center object and a radius. In general, such partitions will overlap if the complete data space should be covered.

A vector space has a *measure* that allows calculating the volume of subspaces and their intersections. In particular, this is the foundation for the definition of a density and a distribution of a data set. The notions of volume, density and distribution are not available in a metric space.

Finally, in a vector space, the costs of distance calculations between elements is linear in the number of dimension if an L_p norm (typically $p = 2$ for Euclidean distance) is used. In a metric space a distance function can be arbitrarily complex, such as e.g. the edit distance between two strings which has a quadratic runtime. Furthermore, we can calculate a bounding box of a vector data set in linear time by finding the minimum and maximum value for each dimension. In contrast, finding the maximum distance between elements in a metric space requires a quadratic number of distance computations. In summary, metric data lacks most of the tools available in traditional scenarios for cardinality estimation. This makes most established methods infeasible as we discuss in the Section 3.

However, as discussed previously, metric data appears in many different applications naturally. Furthermore, it supports distance queries, which are also highly relevant for vector data [4]. As our experiments will show later, using distance-based techniques helps lowering the impact of the curse of dimensionality.

3 RELATED WORK

The most basic idea for estimating the size of a query result is to perform the query on a sample of the data and scale up the resulting cardinality by the sample's fraction of the total data size. Using Reservoir Sampling [32], a random data selection can be computed in linear time. We can apply this method also on metric data. However, small sample sizes result in underestimates often equal to zero because metric spaces are sparse.

Histograms are the most popular technique for cardinality estimation in database systems [18]. They divide a domain into multiple buckets and store the number of contained elements. When estimating the cardinality within a given query range, they

approximate the actual cardinality usually by assuming a uniform distribution within the buckets. Computing optimal histograms that minimize the error induced by this assumption is NP-hard [25]. The most prominent example of an efficient heuristic is MinSkew [2]. It recursively subdivides the space by splitting the most skewed bucket until the desired number of buckets is reached. Other techniques like rkHist [11] and R-V histogram [1] start from the leaves of a spatial index structure and merge them together for limiting the amount of buckets.

The introduced histograms are, however, not applicable for metric data. There is no straight-forward criterion for subdividing a metric space into a finite amount of disjoint buckets. The missing notion of uniform distribution within a bucket and the unavailability of a volume measure make the incorporation of such buckets into a cardinality estimate impossible. It is possible to transform metric data into vector data in order to build a spatial histogram, though. We can then extract the cardinality estimate for a distance query by calculating the intersection of the query (in form of a hyper-sphere) with the histogram buckets. However, such a transformation into a vector space is costly and introduces an error in form of distance distortions.

Compression techniques like wavelets and cosine transformations are also suitable for cardinality estimation [24]. Both techniques are applicable to multi-dimensional vector data and are shown to provide accurate results. They approximate the actual data distribution by means of a basis function and several coefficients, thus drastically reducing the amount of data. The cardinality estimate is computed as a cumulative joint distribution of the individual dimensions of the data set. However, in a metric space we are not able to use these techniques as the data has no such dimensions and there is no notion of a distribution.

Another method for approximate query processing is Local Sensitive Hashing (LSH). LSH performs very well on data from a high-dimensional vector space. It is for example used for approximate similarity search [15] and thus related to distance queries in metric spaces. There has been work in cardinality estimation of similarity joins using LSH [21]. Also, multiple LSH indexes with different radii can be used for cardinality estimation by counting collisions of hash buckets [14]. However, LSH requires a similarity-preserving hash function which does not universally exist for metric data.

A more recent approach uses Machine Learning [4] for cardinality estimation. It is, to the best of our knowledge, the only method supporting distance queries. The query-driven approach learns to differentiate several prototype queries and predicts the cardinality of unseen queries by assignment to a prototype and subsequent interpolation using regression. The optimization of the query prototypes is performed via gradient descent where the prototype query is moved across the data space. This manipulation of a query object is not possible in a metric space. Thus, like the other approaches, this approach is infeasible for metric data, unless it is mapped into a vector space first.

A distance preserving mapping of data from a metric space to a vector space is called *embedding*. The goal is to find for each $x_i \in X$ an embedding $y_i \in \mathbb{R}^d$, such that the induced *stress* [19] on the distances is minimized. This stress measure incorporates the deviations of the resulting distances among objects with respect to the original distances.

There are different approaches available to embed metric data into a vector space [3]. One prominent example is Multidimensional scaling (MDS) [20]. It tries to preserve the pairwise distances in vector space by using such a stress function [19] and minimizing it subsequently. This minimization can be performed by eigendecomposition or gradient descent. However, both methods are expensive to compute, and thus, not suitable for very large data sets. Landmark MDS [9] was introduced as an alternative to MDS for big data scenarios. It uses samples of the data called landmarks and applies MDS on them. The remaining points are then embedded based on the distances to the l landmark elements.

Kernel estimators [26] are a competitor of histograms which exhibit a fast convergence for 1-dimensional data [7] and have been generalized to multi-dimensional data [16]. Note, that both approaches do not support distance queries on metric data. Here, samples distribute their *weight* using a kernel function K , e.g. Epanechnikov [12] or Gaussian. This weight corresponds to the probability of data points existing in the vicinity of the sample. One approximates the underlying probability density function \hat{f} of a data set at the evaluation point x by using a set of samples S and summing up over all samples: $\hat{f}(x) = \frac{1}{|S| \cdot h} \sum_{s \in S} K(\frac{x-s}{h}) = \frac{1}{|S|} \sum_{s \in S} K_h(x-s)$. Here, h is the smoothing-factor called *bandwidth*. The cardinality estimate results from integrating the kernel density function within a given rectangle query and scaling the result up. In a d -dimensional vector space typically product kernels are used where the density function is integrated for each dimension separately. This is only feasible for rectangular queries and not for distance queries. Hence, the application of existing kernel-density estimators for distance queries on metric data embedded into a vector space is not straight-forward. Approximating the distance query as a hyper-sphere introduces an error that is also influenced by the curse of dimensionality. Our approach makes use of kernels, but we avoid the curse of dimensionality by using the one-dimensional distance function.

The choice of the actual kernel function is considered to be of low impact according to the literature [8]. Nevertheless, we consider different kernel functions in the experiment section of this paper. However, the selection of the kernel bandwidth h has a much more crucial impact on the resulting estimator quality.

There are two general approaches for the bandwidth selection: global and locally adaptive methods [31]. Using a global (fixed) bandwidth means that all samples and evaluation points use the same bandwidth. One method of obtaining this bandwidth is by minimizing the mean integrated squared error (MISE) [30]. In contrast to traditional applications, the underlying distribution that shall be fitted by the kernel estimator is known in cardinality estimation. It is given by the data itself. This enables other optimization techniques than those used in the statistics literature. Recent work [17] used a gradient descent based approach to find the optimal bandwidth for a given set of training queries. They fit a global bandwidth for each dimension of the vector space. However, a global bandwidth is usually not optimal, as the resulting estimator oversmooths the distribution in dense regions and undersmooths in sparse regions of the data set. While the authors of [17] were able to exploit the different distributions in the individual dimensions, we found the error of a global bandwidth for different query sizes in our metric scenario to be significantly high. Furthermore, a gradient descent based approach to bandwidth estimation turned out to get stuck in local optima of poor quality in our experiments. We thus also investigate locally adaptive kernel estimators that vary the bandwidth either based on

Figure 1: The incorporation of a kernel-sample s into the cardinality estimation for a query $Q = (x_Q, r_Q)$. The omitted y-axis corresponds to the probability density.

Algorithm 1: Generic Kernel Estimation Algorithm

Input : Kernel function $K_h : \mathbb{R} \rightarrow \mathbb{R}_+$, centered at 0
 Optimized bandwidths $\mathcal{B} : X \times \mathcal{X} \times \mathbb{R}_+ \rightarrow \mathbb{R}_+$
 Samples $S \subset X \subseteq \mathcal{X}$
 Total data set size $|X|$
 Distance function $dist_{\mathcal{X}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}_+$
 Query $Q = (x_Q, r_Q)$ with object and radius

Output: Estimated cardinality $\tilde{c}(Q)$

```

1 total ← 0.0;
2 foreach s ∈ S do
3   h ← B(s, x_Q, r_Q);
4   s-tilde ← dist_X(x_Q, s);
5   contribution ← ∫_0^{r_Q} K_h(x - s-tilde) dx;
6   total ← total + contribution;
7 end
8 probability ← total/|S|;
9 return ⌊probability · |X|⌋;
```

the sample point or the evaluation point. The latter is also called *balloon estimator* [30].

Other work in kernel-based techniques for cardinality estimation in vector spaces focuses also on improving the efficiency of the estimation process. One approach is reducing the number of samples to a so-called coreset [33] that maximizes both quality and efficiency of the estimator. In the scope of this paper we do not yet consider such improvements but focus on demonstrating the general applicability of kernel estimators to this new scenario of metric data.

4 DISTANCE-BASED KERNEL ESTIMATORS

Kernel estimators allow us to overcome a fundamental problem of using a sample directly for estimating the cardinality of a query result. Namely that the information is concentrated at a sample point. In contrast to a histogram we also get a continuous distribution. In a metric space it is, however, not straight-forward how we can apply a kernel function on a sample point, as there are no dimensions in which they could gradually distribute the mass of a sample. The central idea of our proposed technique is therefore to apply the kernel function on the distance to a sample point in order to incorporate the probability of elements in the vicinity fractionally.

In the following we show how to incorporate a sample point into the cardinality estimate. Here, the query $Q = (x_Q, r_Q)$ with object x_Q and radius r_Q is located at distance $\tilde{s} := dist_{\mathcal{X}}(x_Q, s)$

Figure 2: Influence of the bandwidth on the estimation error on the Moby data set (cf. Section 6) for a fixed query size. The left-hand side shows the median of the relative errors (Equation (2)). The right-hand side shows the sum of squared errors (measure M_{LS}).

from the sample point s . As depicted in Figure 1, we introduce an axis expressing the distance to x_Q . For that we map x_Q to $\tilde{x}_Q := 0$, the origin of the axis. The sample point s is then mapped onto \tilde{s} . The kernel function K_h is then centered at point \tilde{s} by subtracting \tilde{s} from its argument. We take the area under the curve of the kernel function between \tilde{x}_Q and r_Q as the *contribution* of this sample to the cardinality estimate.

Algorithm 1 shows the full estimation process. For each sample point we calculate the contribution and compute the sum. For this we first compute the optimized bandwidth by calling the function \mathcal{B} for the given sample point and query with object and radius. In case of a global bandwidth, this function ignores the parameters and always returns the same bandwidth. In case of a locally adaptive approach, it either uses the sample or evaluation point (query) to obtain a specific bandwidth. We detail algorithms for computing the bandwidth in the next section. Given the optimized bandwidth, the distance between sample and query object, and the radius, we calculate the contribution of the sample to the running *total*. After all samples are processed, the probability is then the *total* divided by the number of samples, see line 8. Finally, we scale the resulting probability up by the total data set size and return this value as the cardinality estimate.

The general workflow of our technique consists of (1) collecting a set S of samples, (2) determining the optimal bandwidths \mathcal{B} and (3) applying Algorithm 1 to estimate the cardinality of new queries. In the following we present the process of optimizing the bandwidths.

5 BANDWIDTH OPTIMIZATION

It is well-known [31] that the bandwidth of a kernel function has a crucial impact on the resulting cardinality estimate. A too small bandwidth leads to undersmoothing, a too large bandwidth to oversmoothing. The two edge cases are an infinitely small bandwidth that converges to sampling and an infinitely large bandwidth that converges to a uniform distribution. We thus take particular care of finding an optimal value. We distinguish between a global bandwidth for all samples and queries, and locally adaptive methods where the bandwidth is individually fitted to accommodate for sparser and denser regions of the data space.

5.1 Global

The computation of the optimal global bandwidth for a kernel function and a given data set is an optimization problem. We first formalize this problem and then present our optimization strategy.

5.1.1 Optimization Problem. We want to find a bandwidth h that minimizes the error of estimates for future queries on the given data set. As we do not know the future queries, we extract a set of training queries Q from the data set and minimize the error for these queries. Afterwards, we validate the performance against an independent set of test queries that we extracted from the data set beforehand. We formally define the optimization problem for a fixed kernel function as

$$\arg \min_h \text{Error}_X(h, Q), \quad (1)$$

where h is the bandwidth, X is the data set and Error_X a function that computes the error of the queries Q on X for the given bandwidth h .

We define an appropriate error measure for Equation (1) in two steps. First, we define an auxiliary function

$$\text{error}_X(h, Q) := \frac{\tilde{c}_h(Q) - c(Q)}{c(Q)}, \quad (2)$$

where $\tilde{c}_h(Q)$ is the estimated cardinality using bandwidth h and $c(Q)$ the actual cardinality of query Q on data set X . This measure differs slightly from the common relative error metric, as we do not take the absolute value in the numerator. This allows us to assess over- and underestimates separately. It returns values in the interval $[-1, \infty]$. Two values are of particular interest: -1 indicates that the estimator returns simply a result of zero even though there are results contained in the query. On the other hand, an error of zero indicates a perfect result: the estimated cardinality is equal to the true number of elements the query returns. There is no upper bound for our measure. However, one should notice, that a value of 1 means already an overestimation by a factor of 2.

To compute the error of a set of queries Q we combine the errors $\text{error}_X(Q)$ of the individual queries $Q \in Q$ using a measure $M : \mathbb{R}^{|Q|} \rightarrow \mathbb{R}_+$. M computes for a set of errors E a single value that is then subject to minimization. Two examples for M are the deviation of the median error from zero, and the sum of squared errors (LS for least squares):

$$M_{\text{median}}(E) := | \text{median}(E) |$$

$$M_{\text{LS}}(E) := \sum_{e \in E} e^2.$$

For $M \in \{M_{\text{median}}, M_{\text{LS}}\}$, the final optimization problem is defined as

$$\arg \min_h \text{Error}_X(h, Q) = \arg \min_h M(\{\text{error}_X(h, Q) \mid Q \in Q\}) \quad (3)$$

5.1.2 Optimization Strategy. The minimization of the error function (3) requires an efficient and robust optimization method. Figure 2 shows the relationship between bandwidth and error for an example data set. On the left-hand side of the plot we observe that starting from an infinitely small bandwidth results first underestimate the true cardinality. A higher bandwidth reduces the error to a certain degree. At some point the bandwidth over-smoothes the distribution, leading to very high overestimations. The right-hand side shows the mean squared errors. While the general trend of the error function is clearly visible, we can also

see that the results are noisy. This poses a difficult to find global optimum as the multitude of local optima has to be overcome. A method that has shown to be very effective in practice are Evolution Strategies.

An Evolution Strategy (ES) is a global numeric optimization approach inspired by the Darwinian theory of natural selection. We implemented the approach of Beyer and Schwefel [6]. Here, μ parents produce another set of λ offspring. From the thus obtained set of $\mu + \lambda$ individuals the best μ individuals are selected for the next generation based on a fitness function. An offspring is produced using a recombination of p parents followed by mutation. The evolutionary process is repeated until either a fitness threshold, a number of stall iterations without improvement, or a total number of iterations is reached.

In our case each individual represents a bandwidth h . For calculating the fitness, we use the error function from Equation (3) which we want to minimize. We tried different parametrizations and found the following to provide a good compromise between runtime and estimation errors: $\mu = 100, \lambda = 300, p = 2$, recombination via mean and mutation via a Gaussian distribution. We stop the optimization process after either 25 stall iterations or a given total amount of 1000 iterations is reached.

As the fitness function has no side-effects and only depends on the parameter h we can easily parallelize the evolutionary process by computing the score for different individuals on different threads. Because the evaluation of the fitness function is the most expensive part of the computation we can effectively scale up the throughput linearly in the amount of CPU cores.

We also exploit the fact that only a limited number of distinct distance computations are required. In the fitness evaluation for a given bandwidth h we need to compute a new estimate for each training query based on h . However, the distances of the query objects to the samples that give the interval for the integral in line 5 of Algorithm 1 remain constant. In our implementation we thus precompute these distances and store them in a matrix \mathcal{D} . In the iterations of the optimization process we then avoid redundant recomputations by performing simple look-up operations. The matrix \mathcal{D} is of size $|S| \cdot |O|$, where S is the set of samples and $O := \{x_Q \mid (x_Q, r_Q) \in Q\}$ is the set of distinct training query objects. \mathcal{D} is discarded after the optimization process is finished. It thus only influences the construction-time space complexity of our algorithm. Reasonable numbers are 10^2 distinct query objects and 10^4 samples as used in our experiments. This means \mathcal{D} typically requires only a few megabytes of memory.

5.2 Locally Adaptive

A fixed global bandwidth is usually insufficient for approximating the cardinality of small and large queries in dense as well as sparse regions. One possibility is to extend the bandwidth optimization process from the previous subsection to individual bandwidths per sample point. For the following reasons we refrain from this direction and rather focus on the balloon estimator [30].

In the Evolution Strategy we can extend the configuration to incorporate individual bandwidths. However, this leads to a very high-dimensional optimization problem as we potentially need to optimize hundreds or thousands of bandwidths simultaneously. Such an optimization may take very long to converge or get stuck in a local optimum of overall poor quality.

Another approach is to use coordinate search, where we optimize only one bandwidth at a time, keeping the others fixed. Here, we would initialize the N individual bandwidths h_i e.g.

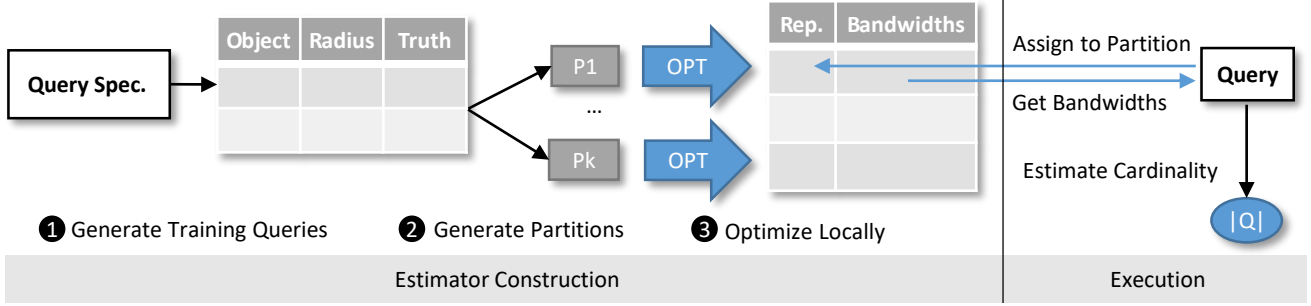

Figure 3: A general overview of the locally adaptive estimator construction and execution.

randomly and then optimize them one at a time in the order $i = 1, \dots, N, N - 1, \dots, 1$. We repeat this until no significant improvement is made in one full sweep. This approach, however, is also prohibitively expensive to compute.

We thus limit our investigation to the balloon estimator defined by the k^{th} -nearest neighbor estimator [23]. It chooses the bandwidth on basis of the evaluation point (query) and the surrounding sample points. In contrast to the traditional balloon estimator, we again use a set of training queries in the optimization process. Given a query $Q = (x_Q, r_Q)$ and the samples S we choose the bandwidth h as follows:

$$h = \mathcal{B}(\cdot, x_Q, r_Q) \propto \text{distance}(x_Q, \text{sample}_k(x_Q)), \quad (4)$$

where $\text{sample}_k(x_Q) \in S$ is the k^{th} -nearest neighbor of the query object x_Q in S , and \mathcal{B} the function returning the optimized bandwidth as introduced in Algorithm 1. We thus ignore the first parameter of \mathcal{B} and apply the same bandwidth to all samples in the final cardinality estimation of the query Q . Obviously, the distance to the k^{th} -nearest neighbor is smaller in denser regions than it is in sparser regions. This leads to the desired adaptive bandwidth.

Using the distance to the k^{th} -nearest neighbor directly, however, turns out to be insufficient. First of all, we need a linear scaling factor to transform the distance to a bandwidth. Furthermore, we incorporate the query radius into the bandwidth optimization as well. As our experiments will show, the optimal bandwidth varies for different query sizes (selectivity). However, we only know the radius at query time. The result size is precisely the value we want to estimate.

We can, however, distinguish differently sized queries by the relationship between the query's radius and the distance to the k^{th} -nearest neighbor sample. Here, the latter is an indicator of the density around the query object. We denote this relationship as

$$\rho(Q) = \frac{r_Q}{\text{dist}_X(x_Q, \text{sample}_k(Q))}. \quad (5)$$

It is an indicator for the cardinality of the query. If we fix the query radius, $\rho(Q)$ gets larger the smaller the distance to the k^{th} -nearest neighbor gets. This matches our intuition as this indicates the data space becoming more dense. On the other hand, if we fix the density in form of the denominator, a larger radius corresponds to a larger ρ value, indicating a larger cardinality.

For our extended balloon estimator called *BalloonEstimator⁺* (B^+ for short) we thus optimize the local bandwidth for a given query Q depending on $\rho(Q)$. Here, we again make use of the methods presented in the previous subsection. The optimization process consists of the following steps which are also presented in Figure 3:

1. Generate a set Q of training queries based on a query specification (e.g. m query objects with a set of target selectivities). This involves calculating for a given query object x_Q a radius r_Q and the true cardinality that fulfill the query specification.
2. Divide Q into k disjoint partitions $P_i \subseteq Q$ such that the intra-partition variance $\text{Var}(\{\rho(Q) \mid Q \in P_i\})$ is minimized.
3. For each partition P_i compute the optimal bandwidth h_{P_i} that minimizes $\text{Error}_X(h_{P_i}, P_i)$.

At query time we assign the query to a partition and use the optimized bandwidth.

In order to obtain the k partitions required in Step 2 we use *hierarchical* clustering with complete linkage based on ρ . We extract the k partitions from the dendrogram. For each partition we then compute the locally optimal bandwidth by means of an ES. Each partition is then identified by the mean ρ -value over all queries in the partition: $\bar{\rho}(P_i) = \frac{1}{|P_i|} \sum_{Q \in P_i} \rho(Q)$. Given a new query Q we first assign it to the nearest partition P^* by

$$P^* = \arg \min_{P_i} |\bar{\rho}(P_i) - \rho(Q)|.$$

We then use h_{P^*} as the bandwidth for the kernel functions when estimating the cardinality of query Q .

The depicted construction process of the B^+ estimator requires several distance computations and incurs some overhead in storage. For calculating the k -nearest neighbor when determining the ρ -value of the training queries we use the same matrix \mathcal{D} as for the actual bandwidth optimization. Storing the B^+ estimator requires storing for each cluster the mean ρ -value and the optimized bandwidth. This slightly reduces the amount of samples that can be stored with a given amount of space.

When estimating the cardinality for a given query Q , we induce some overhead with respect to a kernel estimator with a global bandwidth. Namely, we need to compute $\rho(Q)$ which includes finding the k^{th} -nearest neighbor sample. However, we calculate the distances of all samples to the query object anyway when calculating the estimation after the bandwidth has been determined. Thus, the additional overhead of the B^+ estimator only consists of finding the k -smallest element in the list of distances. We can efficiently determine this element while computing the distances using a bounded max-heap. Here, we always store the k smallest elements and larger elements are discarded. At the end the k -smallest distance is at the top of the heap. We then incorporate this distance in the calculation of $\rho(Q)$ and retrieve the bandwidth of the nearest partition. The remaining computations are identical to a kernel estimator with a global bandwidth.

6 EXPERIMENTAL EVALUATION

This section presents the results of our experimental study. First, we present the experiment setting, data sets and investigated methods. Then, we present the results of the experiments.

6.1 Setting

We implemented the kernel estimators and baseline algorithms in Java using embedding techniques and histograms from the XXL library [10]. All experiments were run on an Intel Core i7-4771 CPU and 16GB of RAM. We consider four real-world data sets which, together with our generated queries, are on our website¹.

Moby Word List (Moby) contains word lists in different languages². We used the German word list consisting of about 160 000 words and the Levenshtein distance [22] as a metric.

Protein Binding Sites (PBS) are taken from CavBase [29], a database of protein binding sites (PBS) from experimentally determined protein structures. In CavBase, currently 248 686 PBS are stored. Each PBS is described by a set of points in the 3-dimensional Euclidean space that model the shape of the protein. In addition to the coordinate, each point also carries a label specifying the physico-chemical property of that point. To compare pairs of PBS we use the measure presented in [13] which fulfills all metric properties.

Rea16 is a 16-dimensional vector-data set representing Fourier coefficients from CAD data. It contains 1.3 million points and is often used for benchmarking high-dimensional queries [5]. We use the Euclidean distance measure as metric.

Wikipedia (Wiki) is a data set consisting of 4.5 million Wikipedia articles represented by the article name and a short abstract. We used the data provided by the DBpedia project³. We removed articles that are only a disambiguation or a list of links to other articles. For easier syntactic comparisons we also removed all non-ASCII characters. The distance measure for this data set is based on the Jaccard coefficient of character shingles⁴ of length $k = 3$. The distance between two articles is computed by $dist(a, b) = 1 - \frac{|s_k(a) \cap s_k(b)|}{|s_k(a) \cup s_k(b)|}$, where a and b are articles and s is a function that computes the set of k -shingles of a short abstract.

We generate our test queries uniformly at random from the data set at hand. For this, we select 100 items as query objects and remove them from the data set. In particular we remove these items from the data set before optimizing the kernel bandwidths on a different set of training queries. We then choose the minimum radius around these items such that at least 0.01%, 0.1% and 1% of the data set are contained in the query. This radius varies depending on the density at the particular query object. The training queries are generated in the same fashion as the test queries. Note that it is not always possible to create a query from a data object that contains exactly the desired amount of data. Especially for discrete distance measures, many objects share the same distance to a reference object. Also note that by generating queries this way, they follow the distribution of the data. This means that it is more likely for a query to be placed in a more dense region of the data space. However, this is no undesired effect, since this approach intuitively matches real-world query patterns [17]. In contrast to vector spaces it is not possible to uniformly sample queries from a domain for metric data (e.g. of

newspaper articles). We are thus forced to limit our investigation to queries drawn uniformly from the data items.

In our experiments we compare the estimated cardinality for a given query with the actual cardinality – the closer both values, the better the estimator. We use our error measure from Equation (2) again. Recall that we use this slight variation of the common relative error to capture under- and overestimations individually.

For measuring the build time of the individual estimators we use wall-clock time. Note that we parallelized the Evolution Strategy and used all 8 threads of the machine. For our kernel-based approaches we measure only the time for creating the estimator and not for generating the training queries as, in practice, they can e.g. be obtained from historic queries or the current workload.

In addition to our kernel estimators we consider spatial histograms as a baseline method for cardinality estimation. For metric data, the spatial histograms require an embedding into a vector space. We use the following popular measure to assess the quality of the resulting embeddings:

$$STRESS_1 = \left(\frac{\sum_{i < j} (dist_{\chi}(x_i, x_j) - dist_E(y_i, y_j))^2}{\sum_{i < j} dist_{\chi}(x_i, x_j)^2} \right)^{\frac{1}{2}}, \quad (6)$$

where $dist_E$ is the Euclidean distance. It measures on a relative scale how well distances are preserved by the specific embedding. According to the literature [19] a value greater than 0.2 is already considered as a low-quality embedding.

We evaluated the performance of different kernels with optimized bandwidths. Even though the concrete choice of kernel function is considered to be insignificant in the literature [8], we found differences among the optimization results. We consider Cauchy, Epanechnikov, Exponential and Gauss kernels.

We now describe the estimators we used in our experiments. All of them are given 0.1% of the total data set size in memory to allow a fair comparison across the data sets of varying sizes. This size presents a reasonable value in big data scenarios and returned representative results in our experiments.

Sampling uses reservoir sampling to efficiently build a uniform random sample S of the data in one pass. The query is executed on the sample and the resulting cardinality $c_S(Q)$ is scaled up to return the estimated cardinality $\tilde{c}(Q) = c_S(Q) \cdot |X|/|S|$.

MSnd and R-Vnd use a MinSkew or R-V histogram, respectively. The parameter n indicates that the data was first embedded in an n -dimensional vector space using Landmark MDS. A distance query Q is then also embedded and becomes an n -dimensional query sphere \hat{Q} . For estimating the cardinality we calculate the volume $V_I(\hat{Q}, B)$ of the intersection between \hat{Q} and histogram bucket B and sum up the fractional bucket counts:

$$\tilde{c}(Q) = \sum_B V_I(\hat{Q}, B) \cdot count(B).$$

For $n > 2$ we use a Monte Carlo simulation for V_I , as it is more efficient than an analytical solution.

Global size uses a kernel estimator with the Cauchy kernel function and a global bandwidth optimized by means of an Evolution Strategy, as described in Subsection 5.1, with 100 individuals. We use M_{median} as defined in Section 5. The parameter *size* gives the cardinality of the training queries: $S \hat{=} small \hat{=} 0.01\%$, $M \hat{=} medium \hat{=} 0.1\%$, $L \hat{=} large \hat{=} 1\%$, $MIX \hat{=} X \hat{=} mixed \hat{=} SUMUL$. The query objects are selected uniformly at random.

B⁺k,n uses a kernel estimator with the Cauchy kernel and locally optimized bandwidths as described in Subsection 5.2 using

the same measure as *Global* on the *MIX* training queries. The parameter k expresses that the k^{th} -nearest neighbor is used and n defines the number of clusters.

6.2 Estimation Quality

We now present the results of our experiments of the described estimators on the introduced data sets. We visualize the estimation errors in terms of boxplots.

6.2.1 Baseline Algorithms. Figure 4 shows the estimation errors of MinSkew and R-V histogram for the individual data sets and a query size of 1%. We embedded all data sets into 2, 3, 4, 5, 6 and 7 dimensions using Landmark MDS with 10 landmark points. We can immediately see very large estimation errors. Using a higher target dimension for the embedding leads to lower estimations. However, this does not lead to good estimates. In contrast, the very high estimates turn into zero-estimates ($error = -1$) for higher dimensions.

Figure 5 shows the stress induced by the embedding. Overall, the embeddings are of poor quality with stress values above 0.2 as indicated by the dashed line. We observe that, in general, the stress decreases with the number of used dimensions. For PBS we notice a slightly worse embedding for higher dimension. This reveals a weakness of the Landmark MDS embedding. Only the landmarks profit directly from the higher degree of freedom in a higher dimensional vector space. They are properly embedded using an MDS that minimizes the stress. The remaining elements

Figure 6: Influence of the choice of kernel function on the Moby data set for a query size of 0.01%.

are only embedded with respect to the landmarks, not with respect to the other objects. Thus, a higher dimensionality does not necessarily guarantee a better embedding.

In addition to the poor embedding quality, the spatial histograms suffer from the curse of dimensionality. This leads to an overall performance degradation with an increasing dimensionality. The vector space becomes sparse leading to almost empty buckets or queries that intersect with no buckets at all. This is apparent as the high overestimations induced by the embedding turn into zero-estimates for higher dimensions. We conclude that spatial histograms are not a reliable choice for cardinality estimation in metric spaces. For the vectorial Rea16 data set in the original 16-dimensional vector space (omitted in Figure 4 due to lack of space), nearly all queries return an estimate of zero. This motivates the idea of using distance-based approaches on high-dimensional data in order to counter the curse of dimensionality.

Figure 4 also shows the performance using a random sample for estimating the cardinality. The resulting cardinality on the sample is scaled up by the constant factor $|X|/|S|$, where S is the sample and X the data set. If the sample is large enough with respect to the query size it reflects the data distribution well and estimates become accurate. However, if the sample is small or the query highly selective, errors increase dramatically. Estimates are either zero because no sample is contained in the query, even though there are qualifying items in the underlying data set. Or, estimates are very high because by chance a sample was included and then scaled up by a large factor. This results in a median of -1 and a very high maximum error.

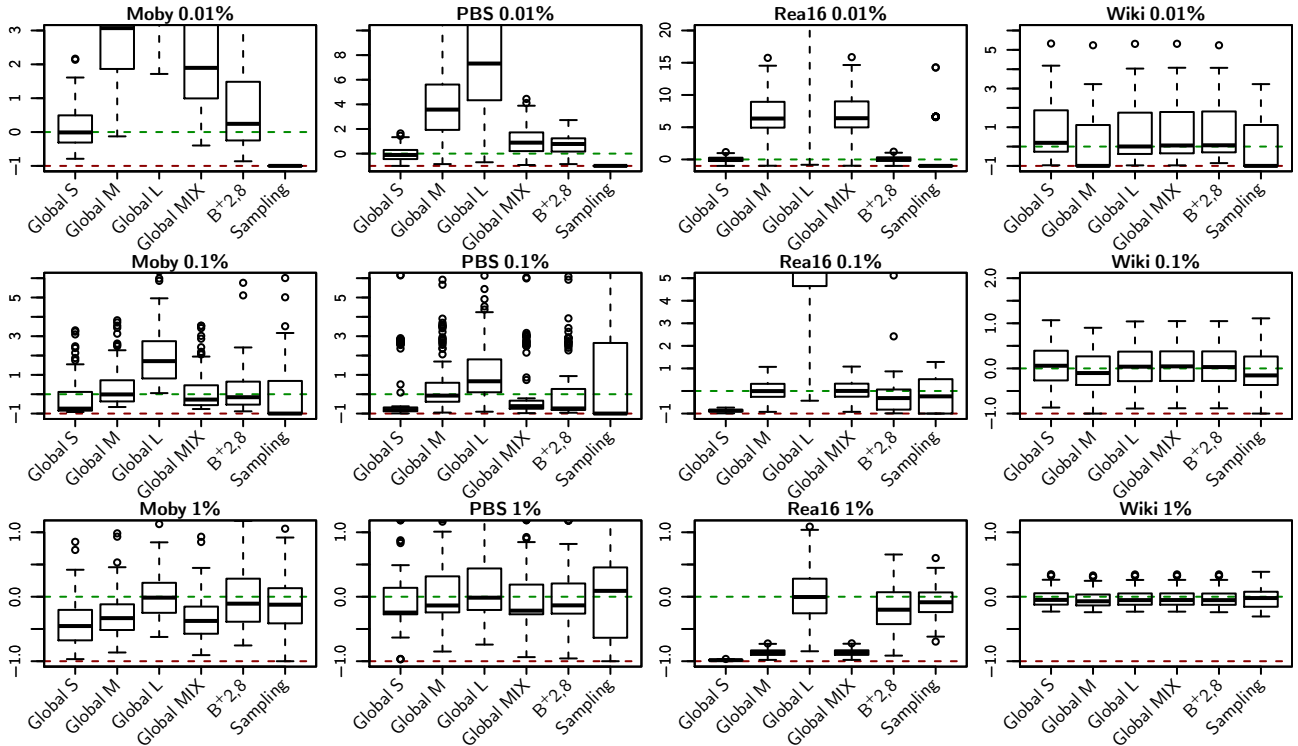

Figure 7: Estimation errors of the kernel estimators with global and local optimized bandwidths for different query sizes.

6.2.2 Kernel-Based Techniques. Figure 6 exemplifies the performance of different kernel functions using an optimized bandwidth as described in Section 5. It is apparent that different kernel functions lead to a different estimation accuracy. However, our experiments confirm that the selection of the bandwidth has a much greater impact on the performance than the choice of the kernel function. As the Cauchy kernel gave the overall best performance in our experiments, we limit our following presentation to this kernel. The reason for its superior performance is that its distribution is more heavy-tailed than that of the other kernels. In contrast to, e.g., the Gaussian kernel, the density does not decrease exponentially in the distance from the mean. This allows the kernel to distribute its weight more effectively.

Figure 7 shows the estimation errors of the kernel estimators with globally and locally optimized bandwidths. We also report the statistics in Tables 2-5 at the end of the paper. In contrast to sampling the kernel estimators are able to give reasonable cardinality estimations also for very selective queries. In particular they overcome the problem of either zero estimates or very high overestimates. For the global bandwidth optimization we generated training queries of different cardinality. In Figure 7 the labels *S*, *M*, *L* and *MIX* indicate the target query size for the bandwidth optimization process.

Kernel estimators optimized for a specific query size give good results on new queries of equal size. This proves that the bandwidth generalizes well from training to test queries. However, estimators optimized for small queries tend to underestimate the cardinality of larger queries. The optimal bandwidth for larger query sizes also leads to overestimates for smaller queries. Optimizing the bandwidth for all query sizes at the same time leads to a bandwidth that is not optimal for any of the query sizes. This result shows that a global bandwidth is not sufficient for applications where queries vary greatly in size.

The *BalloonEstimator*⁺ (B^+k, n) uses the same set of training queries, but computes a set of optimal bandwidths. The concrete bandwidth for a given query is chosen based on the local density and the query radius. We restrict our results to the setting $k = 2$ and $n = 8$ that gave slightly better results than for other settings.

Figure 8 displays how many results of good quality are produced by sampling and $B^+2, 8$, respectively. It confirms the results indicated by the boxplots that the kernel approach outperforms sampling for small queries. The plot shows the percentage of estimates within the error bounds given by the x-axis. Thus, it begins with all estimates with error zero, meaning perfect results. It then gradually increases the bounds uniformly in both directions, thus accumulating more results. The x-axis ends with all queries of errors in the interval $]-1, 1[$, as we consider greater errors as a failure of the estimator. Accordingly, we can see the number of estimates not fulfilling our requirements by the height of the plot. For all data sets the smallest queries show no results for sampling with absolute errors below 1. $B^+2, 8$ on the other hand is able to produce high quality results within the shown interval. Moreover, the shape of the curve is very consistent between the different query sizes and data sets, indicating the robustness of the approach. Sampling shows step-wise increments when new sample points are incorporated into the estimate.

The concrete choice of n and k is subject to optimization. We report one setting ($k = 2, n = 8$) that worked for all our data sets. There is a general tradeoff between the number of clusters (improving the estimation quality) and the required space (worsening the quality). In general, we observed in our experiments that large values for n and k do not improve the performance. Overall we conclude that the *BalloonEstimator*⁺ presents a significant improvement over the global bandwidth approach.

Figure 8: The plotted lines display the number of estimates with absolute errors within the bounds, given by the x-axis.

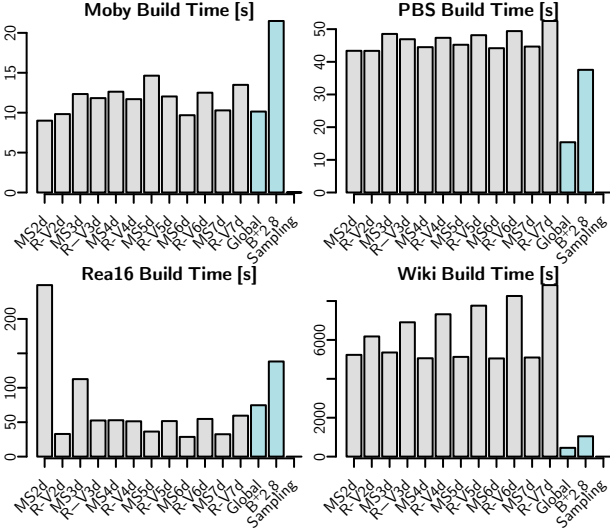

Figure 9: The build time of the estimators in seconds.

6.3 Runtimes

The efficiency of an estimator is the second criterion for assessing its performance. We first discuss the theoretical complexity of the construction of our B^+ estimator. Then, we present our empirical findings of the build and query time of all investigated methods.

6.3.1 Construction Complexity of the B^+ Estimator. The time complexity of the construction of our B^+ estimator is determined by (1) the cost C_P for creating P partitions of the training queries and (2) the cost C_{ES} of executing the ES which is dominated by evaluating the fitness of the individuals. All other operations are negligible because they cause only constant overhead.

The number of partitions P is defined by the user. The cost for partitioning the training queries Q using hierarchical clustering is dominated by the construction of the dendrogram which requires $C_P = O(|Q|^2)$ time.

The fitness evaluation of a single individual requires calculating the cardinality estimate for each training query in Q by incorporating the contribution of all samples S . We denote this cost as $c_{eval} = O(|Q| \cdot |S|)$. Given the number of iterations I , the number of parents μ and the number of offspring λ the cost for

executing the ES is $C_{ES} = O((\mu + I \cdot \lambda) \cdot c_{eval})$. As we execute one ES for each of the P partitions, the final time complexity is $O(|Q|^2 + P \cdot (\mu + I \cdot \lambda) \cdot |Q| \cdot |S|)$.

The time complexity depends on the number of iterations I of the ES. The termination condition is a given number of stall iterations \bar{I} and thus depends on the fitness development of the individuals. We can consider I as a random variable. For $\bar{I} = 25$, we observed the following number of iterations in our experiments: min. 79, 1st quantile 86, median 89, mean 93.57, 3rd quantile 101 and max. 136. Note that we also limit the ES to at most 1 000 iterations which gives an upper bound on the runtime.

6.3.2 Empirical Findings. Figure 9 shows the build times of the estimators from Subsection 6.2. The spatial histograms show a more or less constant construction time, regardless of the dimension. Sampling is the cheapest estimator to construct as it only requires a single scan of the data set. In comparison, our kernel-based techniques take more time to build. As our B^+ estimator performs multiple bandwidth optimization for the different query partitions, its runtime exceeds the global bandwidth approach. However, the required time for construction is still very reasonable in practical applications, especially as the estimator has to be built only once which makes the query response time much more crucial. We observed a very quick convergence of the Evolution Strategy in our experiments, where an optimum was usually found within very few iterations. We report the average build time for the different used configurations. The bandwidth optimization was performed in parallel, while the spatial histograms were constructed on a single thread. As the ES is very easy to parallelize, we can thus improve the construction time using more CPU cores. We also want to emphasize that a stochastic approach is only one method to bandwidth optimization. If another method turns out to be more efficient in this regard, it does not lower the accuracy of a kernel estimator. However, the build time is already very reasonable for practical scenarios. For Moby and PBS the construction of our estimator took less than a minute and for Rea only slightly more than two minutes. This means the overhead of constructing the estimator while importing the data into a database is insignificant. On the Wiki data set the construction was significantly slower with ~17 minutes. This has two reasons: The first is that the estimator size is much larger, as we choose it in relation to the data set size in our experiment. The second reason is that the distance computations

Table 1: Mean query times of the estimators in ms.

are the most complex of all data sets. This is also visible in the high construction times of the spatial histograms.

Table 1 shows the query response times of the cardinality estimation. The spatial histograms suffer from slow response times for dimensions greater than 2 which is amplified by the more complex calculation of the sphere-bucket intersection. For some experiments the time gets close to zero as no intersecting buckets were found due to the exponentially increasing vector space. Sampling, again, has the benefit of being very fast, as only few distance calculations are necessary. The kernel estimators additionally need to compute an integral for every sample point which results in a longer execution time. However, as reflected by the query times, this turns out to be insignificant overhead in comparison to the distance computations. The B⁺ estimator is also very efficient. Our experiments confirm that the determination of the appropriate bandwidth induces only very little overhead. In conclusion kernel-based cardinality estimation is an efficient method with effectively zero overhead in comparison to sampling in practical applications. The only reason to use sampling is its low cost for computing the estimator.

6.4 Impact of Estimator Size

The estimator size limits the number of samples used for calculating the cardinality estimate and thus impacts the quality of the estimates. We expect that a larger estimator size leads to overall better estimates. For estimator sizes of 0.05%, 0.1%, 0.2% and 0.4% of the total data set size we measured the performance of the estimators in 10 runs using different samples. In each run we, again, measure the error of 100 test queries. We compute the trimmed mean of the thus generated 100 error values with a ratio of 10% to accommodate for outliers. Figure 10 shows boxplots of the trimmed means for our B⁺2,8 estimator and pure sampling with a query selectivity of 0.01%. For both estimators we observe an overall improvement of the estimates with greater estimator sizes. Our B⁺2,8 estimator is able to already give good results when given only a very limited amount of space. The improvements for larger estimator sizes are relatively small for all data sets. In contrast, we can see that sampling benefits much greater from more available data. It starts with very bad results for such selective queries with a median of zero when only few sample are used. Overall we observe a tendency to underestimate while

the errors of our approach are more centered around zero. With greater estimator size, sampling is able to catch up with our kernel-based approach for some data sets. However, small estimator sizes with respect to the total data set size are highly relevant in practical scenarios because the amount of data in databases is rapidly growing. This makes our estimator superior to sampling in practical scenarios.

7 CONCLUSION AND FUTURE WORK

We presented the first effective and efficient approach to cardinality estimation on metric data. Our approach is based on the application of kernel-density techniques to the one-dimensional distance function. We are able to outperform sampling which suffers from zero-estimates and large overestimates for small queries. Our approach is also superior to spatial histograms on embedded data which suffer both from the poor quality of embeddings and the curse of dimensionality. We presented approaches for determining the bandwidth of the kernel estimator globally and locally adaptive.

In our future work we will further investigate efficient local bandwidth optimization strategies. Furthermore, we will look into adapting our estimator to changing data and query workloads by performing the ES continuously in the background. We will also address the incorporation of query feedback into the estimation process.

ABSTRACT

Answering crucial socioeconomic questions often requires combining and comparing data across two or more independently collected data sets. However, these data sets are often reported as aggregates over data collection units, such as geographical units, which may differ across data sets. Examples of geographical units include county, zip code, school district, etc., and as such, they can be *incongruent*. To be able to compare these data, it is necessary to realign the aggregates from the source units to a set of target spatially congruent geographical units. Existing intelligent areal interpolation/realignment methods, however, make strong assumptions about the spatial properties of the attribute of interest based on domain knowledge of its distribution. A more practical approach is to use available reference data sources to aid in this alignment. The selection of the references is vital to the quality of prediction.

In this paper, we devise GeoAlign, a novel multi-reference crosswalk algorithm that *estimates* aggregates in desired target units. GeoAlign is adaptive to new attributes with need for neither distribution-related domain knowledge of the attribute of interest nor knowledge of its spatial properties in Geographic Information System (GIS). We show that GeoAlign can easily be extended to perform aggregate realignment in multi-dimensional space for general use. Experiments on real, public government datasets show that GeoAlign achieves equal or better accuracy in root mean square error (RMSE) than the leading state-of-the-art approach without sacrificing scalability and robustness.

1 INTRODUCTION

Data are often found in silos, created independently. For example, administrative agencies and governments collect a great deal of data about their domain, most of which are then published in aggregate form. The primary purpose of the data collection is administrative, and the choice of data representation and structure is made by each agency for its own purpose. These data can be invaluable for understanding many social issues, particularly in conjunction with other data sources. However, most administrative agencies are not concerned with interoperability with other agencies, therefore standardization is unlikely. On the other hand, agencies value the privacy of individual citizens, and do not want any benefits from public data release to hurt their primary administrative mission. Therefore, in many cases, they

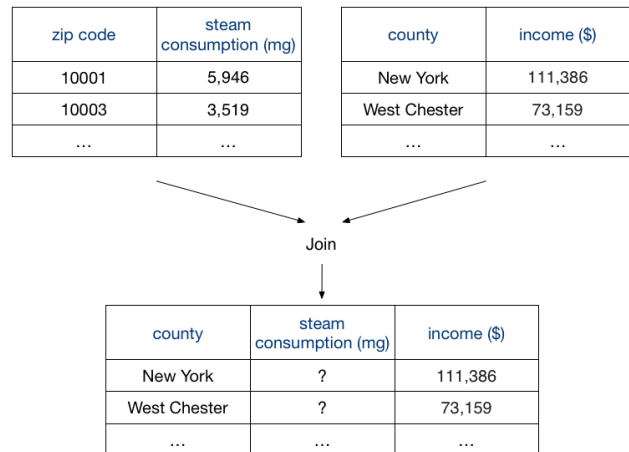

Figure 1: Join two tables for steam consumption (mg) and per capita income (\$) in New York State together by county.

will release data only in aggregate form. Similar reasoning applies in many other contexts as well. For example, Google Trends data is aggregated by geographical unit and time period, to avoid disclosing information about individual queries.

Data integration [25, 34] has been extensively studied, since there is often great benefit from joining multiple data sets. The bulk of the work on this topic addresses structural discrepancies, through schema mapping [2, 26, 42], and identification of individuals across data sets, through entity matching [21, 29]. One challenge not addressed in data integration is the case of data reported as aggregates over incompatible geographical/temporal units. This is a practical problem faced by government data center, NGOs, social scientists, and the general public when trying to related socioeconomic data to drive decision making processes, approximately 80% of which are related to a geographical location [14]. Even if the intention of joining such aggregated data based on their spatial or temporal properties seems to be the reasonable action of practice, these aggregates cannot easily be realigned accurately.

Motivating example. Let us consider two tables shown in Figure 1 – one table has the steam consumption amount aggregated by zip code and the other has the per capita income reported by county. A sociologist wants to study the correlation of energy consumption with income in order to plan for future energy supply arrangement. Valuable insight could be obtained by joining these two tables. However, this is not straightforward since the data are reported on incompatible aggregate units, since one zip code may

intersect several counties and one county may contain or overlap with multiple zip codes.

This challenge can be addressed by realigning one or both data sets to a common geographic type (target type) before performing the join. Let the intended target type be county, by which the per capita income is already reported. However, we only know the steam consumption amount by zip code, and have to estimate the number for each county. This estimate is obtained as a form of interpolation. Finding a good estimate of steam consumption per county is the challenge we need to address.

This problem of estimating aggregate values for geographic areas arises in many contexts, and has been extensively studied. *Areal Interpolation*, in Geographical Information Systems (GIS), is the process of aligning an attribute from one areal unit system (the source type of a set of polygons) to another spatially incongruent system (the target type of another set of polygons) [12, 22, 23, 31, 33]. It is more commonly known as *crosswalk*, or the *modifiable areal unit problem* in socioeconomic fields. If the attribute is uniformly distributed in space, then the interpolation can be performed in a straightforward way based on area. For example, if 70% of the area of a zip code lies in county A and 30% in county B, then we could estimate that 70% of the crimes reported in the zip code occurred in county A and the remaining 30% in B.

This uniform distribution assumption or homogeneity assumption rarely holds in practice. If we know something about the distribution, that can be taken into account in the interpolation. For example, if we know that more crimes occur in densely populated urban areas than in sparsely populated rural areas, we can take this into account. The mathematics can be tricky depending on exactly what we know about the distribution of the attribute of interest, so there has been a stream of research in the literature towards solving the problem based on different assumptions. We discuss this more in the related work.

In the data integration scenario, we often do not know much about an attribute of interest. Therefore, we may be unable to develop good rules for how it should be distributed. Even so, we can do better than make an unrealistic uniformity assumption, if we have access to additional data. In particular, if we can find a *reference* attribute, for which we know the detailed distribution, we can use it to perform a crosswalk from source units to target units of aggregation. For example, we may have detailed distribution available for population, with fine granularity aggregates giving us the population in every intersection of county and zip code. If we believe the crimes are distributed similarly to population (or at least more similarly to population than to area), then we can exploit our knowledge of population distribution to estimate the desired aggregates for number of crimes. In particular, consider a zip code with a population of 25,000 people. Suppose this zip code intersects two counties A and B, with the population in the intersections being 10,000 and 15,000 respectively. Suppose that we know there were 100 reported crimes in this zip code last year. We can estimate that 40 of these crimes occurred in county A and 60 occurred in county B, following the same ratio as the population. This approach makes no assumptions about the probability distribution of the reference attribute or the attribute of interest. It can work well if the attribute of interest is distributed similarly to the reference attribute. To the extent the distributions differ, the estimates will be off.

In this paper, our goal is to solve this data alignment problem through the use of more data. We often may have access to

more than one candidate reference attribute, each with its own distribution. We may not have domain knowledge enough to understand which reference is most similar to our variable of interest. Even if we found the best reference, its distribution may still not be close enough. Is there some way we can combine the information in the multiple reference attributes to do better? And at the same time, more adaptively predicts the estimates to new attributes of interest than using a single reference.

In this paper, we develop `GeoAlign`, a technique that does just this. The idea is to weight their relative contributions to the final estimate so that the most similar reference attributes have the greatest impact on the estimate.

The intellectual contributions of the paper are as follows:

- We define the general aggregate interpolation problem over unaligned partitions in one or more dimensions, which is an important problem in data integration (§2).
- We propose `GeoAlign`, an adaptive multi-reference crosswalk algorithm that solves the areal interpolation problem by realigning aggregates from source units to target units by learning distribution similarities between the attribute of interest and the reference attributes (§3). We show that `GeoAlign` can be used not just in two-dimensional maps but also for spaces with arbitrary numbers of dimensions.
- We evaluate the performance of `GeoAlign` against real data from `data.ny.gov` and Esri data in 2-dimensional space. These experiments show that `GeoAlign` outperforms the state-of-the-art single reference crosswalk approach in accuracy (§4). It is, at the same time, efficient, scalable and robust to noisy references even when limited references are available.

We then survey related work in areal interpolation (§5) before we conclude with future work (§6).

2 PROBLEM STATEMENT

In this section, we first introduce the terms we use throughout this paper before we formally define the aggregate interpolation problem in multi-dimensional space. We then illustrate, with examples, the aggregate interpolation problem in 2-D and in other dimensions.

2.1 Preliminaries

In Geometry, an n -dimensional universe $\Omega \subset \mathbb{R}^n$ can be partitioned into some *unit system* γ^y composed of a set of *units* $U^y = \{u_1^y, u_2^y, \dots\}$, where $\forall u_i^y \in U^y, u_i^y \subset \mathbb{R}^n$. Units in U^y satisfy

$$\forall u_i^y, u_j^y \in U^y, i \neq j, u_i^y \cap u_j^y = \emptyset, \quad (1)$$

that is any pair of units in U^y is disjoint with each other since they have no spatial overlap in n dimensions. Suppose that an attribute of interest α_x exists, then we denote its *aggregate vector* as $a_x^y = [a_x^y[1], a_x^y[2], \dots, a_x^y[|U^y|]]$ such that $a_x^y[i]$ is the aggregate of α_x in the i th unit of U^y .

As an example in 2-D space, in the universe of New York State Ω , county partitions compose a unit system γ^y . They share no areal intersection such that they are spatially incongruent with each other. Steam consumption, which is the attribute of interest α_x , has its data in Figure 1 collected from such a set of county units U^y . Another possible unit system is zip code partitions. We can view the steam consumption column in the table as its aggregate vector a_x^y for the county unit system. Each entry of

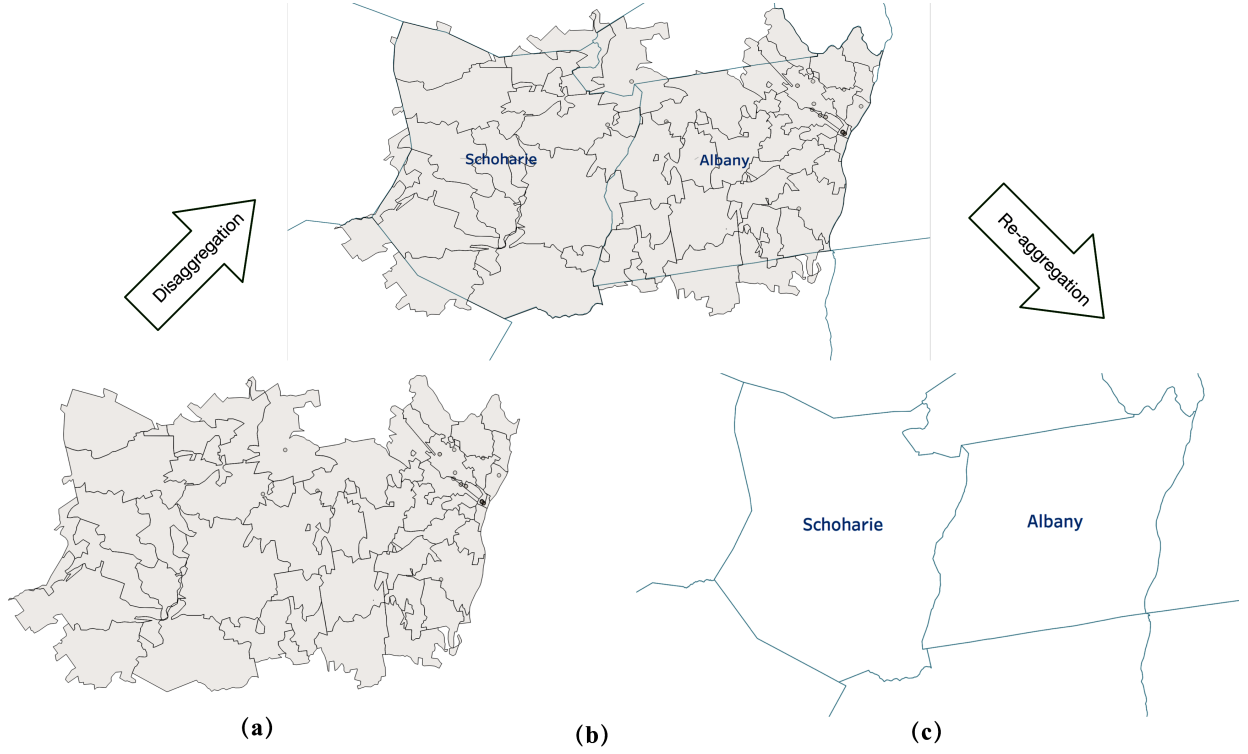

Figure 2: Examples of units in the partial map of New York State for aggregate interpolation: (a) zip code units (source units), (b) zip code and county intersection units and (c) county units (target units).

the vector represents the amount of steam consumption in some county.

2.2 The Aggregate Interpolation Problem

We define the following terms for the aggregate interpolation problem in \mathbb{R}^n :

- $U^s = \{u_1^s, u_2^s, \dots\}$, source units of the source unit system γ^s in the universe Ω .
- $U^t = \{u_1^t, u_2^t, \dots\}$, target units of the target unit system γ^t in the same universe.
- $a_o^s = [a_o^s[1], a_o^s[2], \dots, a_o^s[|U^s|]]$, aggregate vector of the objective attribute α_o in source units. $a_o^s[i]$, the i^{th} aggregate of a_o^s , is collected from source unit u_i^s .
- $a_o^t = [a_o^t[1], a_o^t[1], \dots, a_o^t[|U^t|]]$, aggregate vector of the objective attribute α_o in target units. $a_o^t[j]$, the j^{th} aggregate of a_o^t , is collected from target unit u_j^t .

Given U^s, U^t and a_o^s , aggregate interpolation approximates a_o^t as $\hat{a}_o^t = [\hat{a}_o^t[1], \hat{a}_o^t[2], \dots, \hat{a}_o^t[|U^t|]]$.

Aggregate Interpolation Problem in 2-D When it comes to a 2-dimensional space \mathbb{R}^2 , units are *simple polygons* consisting of straight, non-intersecting edges forming a closed path by pairwise join. A unit in 2-dimensional space can be denoted by

$$u_i = (V_{u_i}, E_{u_i}) \text{ where } |V_{u_i}| = |E_{u_i}| = n_i, \quad (2)$$

where V_{u_i} is a set of vertices in \mathbb{R}^2 and E_{u_i} is a set of edges connecting the vertices in V_{u_i} such that every vertex is shared by exactly two edges. Then, u_i is the closed area formed by connecting n_i vertices in V_{u_i} by n_i edges in E_{u_i} .

This problem is referred to as the *areal interpolation* problem in the GIS community. The 2-dimensional space is the map; and the

unit system, also recognized as feature layer in GIS, is composed of partitions delimited by boundaries of some geographic type. Some of the most widely used geographic types in demographic data are county, zip code, and more. For instance, as shown in Figure 2, U^s is the feature layer for zip code in (a); U^t is the other feature layer for counties in (c). Given the aggregates of steam consumption in zip codes a_o^s shown in Figure 1 from the motivating example, the aggregate interpolation problem in 2-D approximates the steam consumption in counties, \hat{a}_o^t .

Aggregate Interpolation Problem in other dimensions In the 1-dimension setting of the problem, units are *intervals* or *line segments* between two points such that

$$u_i = [u_{i_1}, u_{i_2}], \quad (3)$$

where u_{i_1} and u_{i_2} are two points on the real line \mathbb{R} . We may illustrate the problem as interpolation of population histogram aggregates for two sets of age intervals as depicted in Figure 3. In this case, we can treat the set of narrow bins of age in (a) as U^s , the set of wide bins of age in (b) as U^t , for the same range of age as the universe of interest Ω . Given the population histogram for narrow age bins, a_o^s , the aggregate interpolation problem in 1-D predicts the population histogram for wide age bins \hat{a}_o^t .

Unit system overlapping also exist in 3-D or higher dimensions. One example is 3-D GIS data, such as the distribution of disease, evaluated for cubic units of different size scales. Another example is the data collected for 4-D space (3D) and time systems, such as environmental exposures, crosswalked to another system incongruent in both space and time units. For both cases, areal interpolation is the bridge to map the data across unit systems to enable side-by-side comparison with data from incompatible units.

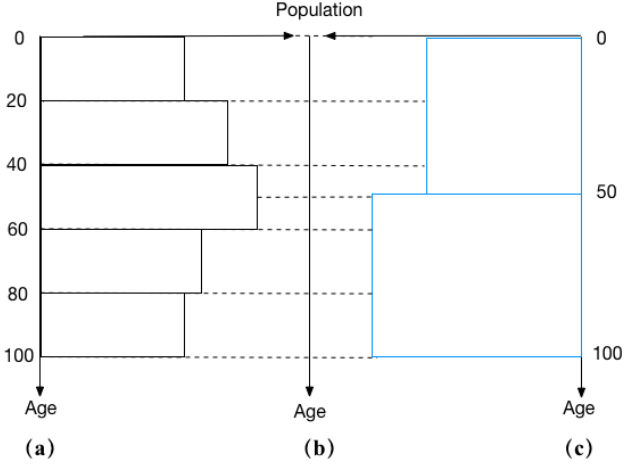

Figure 3: Realign population histogram in two sets of age intervals by transforming aggregates from (a) narrow bins to (c) wide bins. The dotted lines separate the age range into a set of tentative intersection units as in (b).

3 AGGREGATE INTERPOLATION BY GEOALIGN

In this section, we first introduce some additional definitions and notations used throughout the rest of the paper and a general two-step solution solving the aggregate interpolation algorithm. We then lay the groundwork for the assumptions made by GeoAlign before exploring the details of the algorithm.

3.1 GeoAlign preliminaries

Before introducing the general steps to solve the aggregate interpolation problem, we further define the set of *intersection units* for the intersection unit system γ^{st} as $U^{st} = \{u_1^{st}, u_2^{st}, \dots\}$, where $\forall u_k^{st} \in U^{st}, u_k^{st} \subset \mathbb{R}^n$. Each intersection unit is a subregion within some source unit and some target unit, that is

$$\forall u_k^{st} \in U^{st}, \exists u_i^s \in U^s \wedge u_j^t \in U^t, u_k^{st} \subseteq u_i^s \text{ and } u_k^{st} \subseteq u_j^t. \quad (4)$$

It can be thus deduced that $|U^{st}| \geq \max(|U^s|, |U^t|)$.

The aggregate vector of the intersection units for some attribute α_x is denoted as $a_x^{st} = [a_x^{st}[1], a_x^{st}[2], \dots, a_x^{st}[|U^{st}|]]$.

In the simplest case, the intersection units are the n -dimensional spatial intersections of source and target units. For instance, for the areal interpolation problem in Figure 2, U^{st} is the set of intersection areas between zip codes and counties in (b); and for the histogram realignment problem in Figure 3, U^{st} is the set of age intersection intervals between source and target bins. More fine-grained partitions of intersection units may be introduced if necessary when disparate spatial properties of the attribute in these partitions are introduced by auxiliary data.

Assume that the probability density function of attribute α_x for γ^{st} is a piecewise function, denoted as

$$f_x^{st}(z) = \begin{cases} f_x^{st}[1](z) & , z \subset u_1^{st} \\ f_x^{st}[2](z) & , z \subset u_2^{st} \\ \dots & \\ f_x^{st}[|U^{st}|](z) & , z \subset u_{|U^{st}|}^{st} \end{cases} \quad (5)$$

is known, then its aggregate in the source units and target units follows:

$$\begin{aligned} a_i^s &= \sum_{\forall u_k^{st} \in U^{st}, u_k^{st} \subseteq u_i^s} a_k^{st} \\ &= \sum_{\forall u_k^{st} \in U^{st}, u_k^{st} \subseteq u_i^s} \int_{z \subset u_k^{st}} f_x^{st}[k](z) dz, \end{aligned} \quad (6)$$

and similarly

$$\begin{aligned} a_j^t &= \sum_{\forall u_k^{st} \in U^{st}, u_k^{st} \subseteq u_j^t} a_k^{st} \\ &= \sum_{\forall u_k^{st} \in U^{st}, u_k^{st} \subseteq u_j^t} \int_{z \subset u_k^{st}} f_x^{st}[k](z) dz. \end{aligned} \quad (7)$$

Alternatively speaking, the aggregate in each source/target unit is equivalent to the sum of aggregates of all intersection units within it.

Two-step Approximation. We use a two-step solution to solve the aggregate interpolation problem for objective attribute α_o . In our solution, we first compute the approximate a_o^{st} (a_o^{st} is the aggregate vector for the intersection units). We then aggregate these approximate intersection unit aggregates to determine the approximate target unit aggregates. The two steps in our solution are described below:

- (1) **Disaggregation:** Split the aggregates in each source unit to its intersection units. Mathematically speaking,

$$\hat{a}_o^{st}[k] = \mathcal{B}(a_o^s[i], \dots), \text{ s.t. } u_k^{st} \subseteq u_i^s, \quad (8)$$

where the disaggregation function $\mathcal{B}(a_o^s[i], \dots)$ computes the approximated $\hat{a}_o^{st}[k]$ of $a_o^{st}[k]$. Note that \dots denotes the ancillary data that contribute to the approximation. Some of the most commonly used ancillary data are shape files of u_i^s and u_k^{st} , etc. More advanced approximation function may use external ancillary data. For instance, the distribution of a reference attribute that is positively related to the distribution of α_o .

- (2) **Re-aggregation:** Aggregate the approximated intersection unit aggregates for the target unit they reside in, or equivalently

$$\hat{a}_o^t[j] = \sum_{\forall u_k^{st} \in U^{st}, u_k^{st} \subseteq u_j^t} \hat{a}_o^{st}[k]. \quad (9)$$

General Solution Properties. Regardless of the types of ancillary data available, some constraints are widely adopted in the existing two-step approximation solutions. We name two of them here.

One of these constraints is the *volume preserving* property [31, 46]. This property ensures that every source aggregate is preserved by the total of approximated aggregates in its intersection units, or

$$a_o^s[i] = \sum_{\forall u_k^{st} \in U^{st}, u_k^{st} \subseteq u_i^s} \hat{a}_o^{st}[k]. \quad (10)$$

The property is improving the estimation in that greater fidelity is given to the approximation in the intersection units, which propagates to a more accurate estimation in target units. It has been shown experimentally that methods following the volume preserving property make comparatively better predictions [31].

Homogeneity is also often used to compensate for the absence of information. Mathematically, for some attribute α_x , its probability density function in a given unit is constant. In other words,

its aggregate on any sub-unit of the given unit is proportional to the area of the sub-unit. However, the assumption of homogeneity is rarely met in the real world [49].

3.2 GeoAlign Assumptions

We often have access to multiple reference attributes, no one of which perfectly matches the objective attribute we wish to estimate. It would appear advantageous for us to use all of them instead of using a single reference attribute as the current extensive approaches described above. To this end, we propose GeoAlign, an aggregate interpolation algorithm that realigns aggregated data by learning from a combination of reference attributes to best predict the actual aggregates of the objective attribute in target units. GeoAlign leverages the advantages of extensive approaches and is, at the same time, robust to various objective attributes.

An intuitive idea could be to model the objective attribute aggregates as a function of multiple reference attributes aggregates in source units, evaluate coefficients with estimation methods and substitute reference attributes in target units for prediction. However, this is not applicable for the aggregate interpolation algorithm since training samples (objective attribute aggregates in source units) and test samples (objective attribute aggregates in target units) are not randomly drawn from the same population and the test samples are constrained by the training samples.

To address the linkage between two sets of samples and to account for the scale variations of reference attributes, in GeoAlign, the realignment of the objective attribute is related to that of the reference attributes through a statistical model for re-aggregation. In order to make the problem tractable, we assume that different attributes are independent across source units, and that every attribute is correlated in its distribution between source and target units. We will loose the independence assumption of references later as shown in experiments in §4.4.2.

3.3 Disaggregation Matrix

Since we study the partition of aggregates in intersection units, in the disaggregation step, $\mathcal{B}(a_o^s[i], \dots)$ can be reformulated as

$$\hat{a}_o^{st}[k] = \frac{\omega_o^{st}[k]}{\omega_o^s[i]} a_o^s[i]$$

subject to $\sum_{\forall u_k^{st} \in U^{st}, u_k^{st} \subseteq u_i^s} \omega_o^{st}[k] = \omega_o^s[i],$ (11)

where $\frac{\omega_o^{st}[k]}{\omega_o^s[i]}$ is the share of aggregate in the k -th intersection unit ($\omega_o^{st}[k]$) over that in the i -th source unit ($\omega_o^s[i]$) it resides in. Intuitively, the re-aggregation step sums up the weighted share of all intersection units in all source units that overlap with the target unit. Alternatively speaking,

$$\hat{a}_o^t[j] = \sum_{\forall u_i^s, u_i^s \cap u_j^t \neq \emptyset} \frac{\sum_{\forall u_k^{st} \subseteq u_i^s \cap u_j^t} \omega_o^{st}[k]}{\omega_o^s[i]} a_o^s[i].$$
 (12)

Rather than approximating a_o^{st} in the disaggregation step, we can instead infer $\frac{\omega_o^{st}[k]}{\omega_o^s[i]}$, $\omega_o^{st}[k]$ or $\sum_{\forall u_k^{st} \subseteq u_i^s \cap u_j^t} \omega_o^{st}[k]$. This choice often depends on the type of ancillary data available. The most widely used ancillary data is the true disaggregation of a reference attribute between source and target units. For instance, for the population reference mentioned in the introduction, the population aggregates in intersection units of counties and zip codes. We denote the *disaggregation matrix* of some attribute

Table 1: Notations in §2 and 3

Notation	Description
Ω	an n-dimensional universe of interest
γ^y	a unit system in Ω , for example γ^s at source level
$U^y = \{u_1^y, u_2^y, \dots\}$	the set of units in γ^y
α_o	the objective attribute
$A_r = \{\alpha_{r_1}, \alpha_{r_2}, \dots\}$	the set of reference attributes
$\alpha_x \in \alpha_o \cup A_r$	an attribute of interest
$a_x^y = [a_x^y[1], a_x^y[2], \dots, a_x^y[U^y]]$	the aggregate vector of α_x in units of U^y
f_x^y	the probability density function of α_x for γ^y
$\mathcal{B}(a_o^s[i], \dots)$	the disaggregation function
ω_x^y	the weighted share vector of α_x for γ^y
α_x^y	the normalized α_x^y
$DM_x^{y_1, y_2}$	the dimension matrix of α_x , where $DM_x^{y_1, y_2}[i, j]$ is the aggregate of α_x in the intersection of $u_i^{y_1}$ and $u_j^{y_2}$
$\beta = [\beta_1, \beta_2, \dots, \beta_{ A_r }]$	weights computed from Equation (15)

α_x between two unit systems γ^{y_1} and γ^{y_2} as $DM_x^{y_1, y_2}$, where $DM_x^{y_1, y_2}[i, j]$ is its aggregate in the intersection area of $u_i^{y_1}$ and $u_j^{y_2}$. For γ^s and γ^t ,

$$DM_x^{s, t}[i, j] = \sum_{\forall u_k^{st} \subseteq u_i^s \cap u_j^t} a_x^{st}[k] \quad (13)$$

The disaggregation matrix of the reference attribute between source and target units is often wrapped up in a crosswalk relationship file. When the disaggregation matrix of only one reference attribute α_r is available, we can substitute $\sum_{\forall u_k^{st} \subseteq u_i^s \cap u_j^t} \omega_o^{st}[k]$ for $DM_r^{s, t}$ to complete the approximation of the objective attribute in target units. This type of method is named as the *dasymetric method* [32, 33, 48]. A special case of it is the areal weighting method [30], using the disaggregation matrix of area as the reference. Dasymetric methods are widely employed in socioeconomic data realignment by general users [10].

Since we only consider the disaggregation matrix between source and target units, from now on, we use DM_x for $DM_x^{s, t}$.

3.4 GeoAlign Algorithm

In the real world, the disaggregation matrix of more than one references attributes is often available. GeoAlign is a volume-preserving method that leverages the distribution similarity of the objective attribute with reference attributes at the source level and predicts the dimension matrix of the objective as a weighted combination of the dimension matrices of the references. We will first extend some of the notations in Section 2, and then describe our proposed algorithm in detail.

Notation. Let $A_r = \{\alpha_{r_1}, \alpha_{r_2}, \dots\}$ be the set of reference attributes available. The aggregate vectors of these reference attributes in source units are represented as $a_{r_1}^s, a_{r_2}^s, \dots, a_{r_{|A_r|}}^s$, where $a_{r_k}^s = [a_{r_k}^s[1], a_{r_k}^s[2], \dots, a_{r_k}^s[|U^s|]]$ for the k th reference attribute. Similarly, the aggregate vectors of these reference attributes in target units are represented as $a_{r_1}^t, a_{r_2}^t, \dots, a_{r_{|A_r|}}^t$, where $a_{r_k}^t = [a_{r_k}^t[1], a_{r_k}^t[2], \dots, a_{r_k}^t[|U^t|]]$.

Figure 4: GeoAlign interpolation for the objective steam consumption data in Figure 1 from zip codes to counties using two reference attributes: population and accidents, in three steps: weight learning, disaggregation and re-aggregation.

We assume that the ancillary data available is the disaggregation matrix of all the reference attributes. We denote the disaggregation matrix of the k th reference attribute as DM_{r_k} .

To avoid variation in scale, we normalize the objective attribute and the references at the source level, adjusting their values measured on different scales to a notionally common scale. This is reasonable in two ways. First, GeoAlign is dependent on the distribution similarity between the objective attribute and the references across source units rather than their actual value similarity. Second, GeoAlign jointly considers the similarity of the objective with multiple references. The magnitude of the references should not be a contributing factor.

The normalized $a_{r_k}^s$ is denoted by $a_{r_k}^{s'}$ for $k = 1, 2, \dots, |A_r|$, and is computed as $a_{r_k}^{s'} = a_{r_k}^s / \max_{i, i \in |U^s|} a_{r_k}^s[i]$, $a_{r_k}^{s'}[i] \geq 0$.

The aggregate vector of the objective attribute in source units a_o^s is also normalized similarly, and is denoted as $a_o^{s'}$.

GeoAlign Steps In the disaggregation step, GeoAlign computes \widehat{DM}_o , which is the estimated weighted dimension matrix of the objective attribute. Our intention is to best predict \widehat{DM}_o , and at the same time, preserve its volume preserving property. We propose

$$\widehat{DM}_o[i, j] = \begin{cases} \frac{\sum_{k=1}^{|A_r|} \beta_k \times DM_{r_k}[i, j]}{\sum_{k=1}^{|A_r|} \beta_k \times a_{r_k}^s[i]} \cdot a_o^s[i], & \sum_{k=1}^{|A_r|} a_{r_k}^s[i] \neq 0 \\ 0, & \text{otherwise} \end{cases} \quad (14)$$

where $\beta = [\beta_1, \beta_2, \dots, \beta_{|A_r|}]$ is the learned weight vector and $\sum_{i=1}^{|A_r|} \beta_i = 1$.

Our preliminary experiments lay the ground work of our assumption such that the higher the similarity between two attributes at the source level, the more likely their distribution in the intersection level are similar. We can thus express the objective attribute as linearly associated with the reference attributes for both aggregate vector in source units and disaggregation matrix. The weights are obtained by solving a constrained linear

least squares programming problem with objective function:

$$\begin{aligned} & \min_{\beta} \frac{1}{2} \|A\beta - \mathbf{b}\|^2 \\ & \text{subject to } \sum_{k=1}^{|A_r|} \beta_k = 1 \\ & \text{where } \beta_k \geq 0, \text{ for } k = 1, 2, \dots, |A_r| \end{aligned} \quad (15)$$

where A is the column-wise concatenation of $a_{r_k}^{s'}$ for $k = 1, 2, \dots, |A_r|$ and \mathbf{b} is $a_o^{s'}$. Instead of computing \widehat{DM}_o by directly applying the weights to DM_{r_k} s, we adapt it to the scale of reference attributes and insert back the weights to Eq. (14) to get an adjusted \widehat{DM}_o .

The approximated disaggregation matrix of the objective attribute satisfies the volume preserving property such that

$$\widehat{DM}_o[i, j] \geq 0 \quad \text{and} \quad \sum_{j=1}^{|U^t|} \widehat{DM}_o[i, j] \approx a_o^s[i]. \quad (16)$$

The estimated aggregates of the objective attribute in target units are computed in the reaggregation step as

$$\widehat{a}_o^t[j] = \sum_{i=1}^{|U^s|} \widehat{DM}_o[i, j] \quad (17)$$

Following the pseudocode in Algorithm 1, we further illustrate the algorithm by the motivating example in Figure 1, with the steps depicted in Figure 4. Assume that GeoAlign is crosswalking the steam consumption objective from zip codes to counties. Moreover, assume that the aggregate vectors, $a_{r_1}^s$ and $a_{r_2}^s$, and the disaggregation matrices, DM_{r_1} and DM_{r_2} , for two reference attributes, population and accidents, are readily available. Maximizing the distribution similarity across units between the normalized objective, $a_o^{s'}$, and the normalized references, $a_{r_1}^{s'}$ and $a_{r_2}^{s'}$, the objective attribute is first optimized as a weighted combination of the references at the source level (zip code level). The weights, β_1 and β_2 , are then reassigned to the disaggregation matrices of the references DM_{r_1} and DM_{r_2} , and adjusted to predict an approximated disaggregation of the objective \widehat{DM}_o . The approximated disaggregation matrix is eventually re-aggregated

Algorithm 1: GeoAlign

Input: aggregate vectors of reference attributes in source units $a_{r_1}^s, a_{r_2}^s, \dots, a_{r_{|A_r|}}^s$; corresponding disaggregation matrices $DM_{r_1}, DM_{r_2}, \dots, DM_{r_{|A_r|}}$; and the aggregate vector of the objective attribute in source units a_o^s .

Output: estimated aggregates of the objective attribute in target units \hat{a}_o^t

- 1 **Step 1. Weight Learning:** Compute weights, β , by solving the least squares problem in Equation (15)
 - 2 **Step 2. Disaggregation:** Compute the estimated weighted disaggregation matrix of the objective attribute, \widehat{DM}_o , using Equation (14)
 - 3 **Step 3. Re-aggregation:** Re-aggregate to estimate the aggregates of the objective attribute in target units, \hat{a}_o^t , using Equation (17)
-

to derive an approximate of the objective at the target county level (\hat{a}_o^t).

It can be easily shown that GeoAlign is applicable to any dimension since the algorithm involves no dimension dependent information or computation. Rather, the only information needed is the true partition of reference attributes in source and target intersection units regardless of dimension or dimension-related information, such as spatial correlation for geospatial data. Alternatively, if true partition of references in finer granularity is available, the data can be aggregated to the level of source and target intersection as a reference attribute.

4 EXPERIMENTAL EVALUATION

We evaluated the feasibility of the GeoAlign algorithm from two crucial aspects: whether the algorithm can correctly complete the realignment task (effectiveness), and whether the runtime of the algorithm is fast enough (efficiency). Additionally, we consider runtime scalability when larger datasets are involved and the robustness of the algorithm when low quality or limited reference attributes present.

We compare the performance of GeoAlign with that of areal weighting method [31] and dasymetric method [32, 33, 48] that utilizes three reference attributes separately.

4.1 Experimental Setup

We developed the GeoAlign algorithm in Python. All experiments were performed on a 2.3 GHz Intel Core i7 with 8 GB memory and a 7200 rpm SATA disk.

We evaluated GeoAlign for 2-D areal interpolation. We used county and zip code as the two geographic types of interest, and focused on data from two different universes, New York State and the United States. Most of the New York State data are collected from `data.ny.gov`, populated in tabular form. Three population level demographic datasets have been used as reference data for the single crosswalk algorithm, namely the population data from United States Census Bureau [4], the aggregated USPS residential address data and the aggregated USPS business address data [41]. In addition, we also selected five large individual level datasets (The New York State Restaurants dataset is generated by selecting unique restaurants in the Food Service Inspections dataset) with geographic information and aggregated their number of records for the intersection area of the two geographic types to form

their disaggregation matrices [5–8]. Thus we obtained a total of eight reference datasets with accurate distributions by zip code and by county, and their disaggregation matrices from zip codes to counties.

Besides the three population level Census data, which cover the entire nation including New York State, other data for the United States were collected from Esri, where the Maps and Data group provides publicly available geocoded GIS data. Six individual level GIS data [15–20] were aggregated based on their geospatial information for zip code and county levels and their intersections using ArcGIS Pro [27]. We also computed the area of units at these three levels, which is later used as the reference attribute by the areal weighting method, yielding 10 datasets in total for the universe of the United States.

There are more datasets with attributes for which the aggregate vectors are available for both zip code and county for New York State or for the United States. However, we did not use them as reference attributes due to two reasons. First, it was not clear whether these aggregates are accurate or approximate. In §4.4.1, we further discuss the impact of the reference approximates on the prediction. The other reason is that several attributes do not have their disaggregation matrices publicly accessible and such attributes cannot be used as reference attributes. In case of limited reference attributes, we show in §4.4.2 that GeoAlign makes reasonable predictions even when the references are poorly selected.

Since the number of datasets with accurate disaggregation matrix is limited, we adopted the cross-validation evaluation method that deals with the problem well. We conducted two series of experiments, one for each universe. More specifically, for each universe, we picked one of the datasets as the test dataset, in turn, and used the remaining datasets to develop crosswalks in GeoAlign whose combined weighted performance is then evaluated for the test dataset. The performance of GeoAlign is compared with the base-line single reference crosswalk method that redistributes by a disaggregation matrix of some known attribute. More specifically, GeoAlign is compared with the areal weighting method and the dasymetric algorithm referencing the three population level datasets. Note that when one of the population reference datasets or the area dataset is used as the test dataset, the performance of both methods referencing this dataset is not evaluated.

4.2 GeoAlign Effectiveness

To evaluate the effectiveness of GeoAlign, we adopted root mean square error (RMSE) as the evaluation criterion that computes the deviation of estimated aggregates from true aggregates of the attribute in counties. To ease the comparison across datasets of heterogeneous scales, in Figure 5, we show the RMSE normalized by the mean of the measured data (NRMSE).

The NRMSE of GeoAlign is compared with that of the dasymetric method using three population level datasets and the areal weighting methods for both New York States (Figure 5a) and the United States (Figure 5b), using eight and ten datasets respectively. The performance of areal weighting method is not shown in the figure since it makes poor predictions for all test datasets: over 15 times of the NRMSE of GeoAlign for New York State experiments and over 50 times of the NRMSE of GeoAlign for the United States experiments.

The NRMSE of GeoAlign is less than 0.13 for New York State experiments and less than 0.26 for the United States experiments.

(a) New York State

(b) the United States

Figure 5: GeoAlign prediction performance (NRMSE) compared with dasymetric methods. Since a better prediction yields a lower NRMSE, GeoAlign is making comparable or better predictions than the dasymetric methods for tests in New York State and the United States.

Though three dasymetric methods have comparable error on most datasets, for these datasets, GeoAlign is making equal or better predictions. It should also be noted that no one of these three methods is predicting uniformly well for all datasets as GeoAlign does, in whichever universe. For instance, the dasymetric method referencing the population data presents much higher error than the other methods when predicting for attorney registration and USPS Business Address counts for counties in New York State; all three dasymetric methods fail in accuracy for both area and USA uninhabited places datasets in the United States.

Except the USPS business address dataset, the rest three are individual level datasets with limited number of observational units that are sparsely distributed in the universe. Also, they do not align well with demographic attributes as those in the areal weighting and dasymetric methods. We observe that GeoAlign accounts for sparsity and heterogeneous distributions with flexibility.

4.3 GeoAlign Efficiency and Scalability

We evaluated the efficiency of GeoAlign in terms of algorithm runtime. Apart from the horizontal efficiency comparison across cross-validated tests for a given universe, we also considered the scalability of GeoAlign runtime. This is realized by comparing GeoAlign efficiency vertically across the universes of different scales.

In addition to New York State and the United States, new universes were selected as a set of states whose boundaries are congruent with any other state in the universe. The selection is a greedy process that ensures the states in a universe are tightly connected from a geospatial perspective. These four new universes include Mid-Atlantic division and Northeast region defined by Census Bureau, states contained entirely in the Eastern Time Zone and all states excluding the ones in the Census West Region (non-West). They form a spatial coverage hierarchy preventing the inter-state influence of randomly selected universes.

Moreover, for factor control purpose, instead of collecting more datasets for new universes, for each universe, we subset the ten datasets covering the United States, keeping the entries collected from units within the universe as inputs.

To avoid random error, we averaged the runtime across ten trials for the cross-validated experiments in each universe.

Experimental results show that GeoAlign runtime is stable across experiments for the same universe. This is consistent with our claim that the complexity of GeoAlign is not related to the magnitude of the count data. The majority of the runtime, over 90%, is spent on computing the disaggregation matrix after the weights are estimated. Note that the aggregate vectors of the objective attribute in source geographic units has the same size for all the different datasets (the size is $|U^s|$). Similarly the aggregate vectors of the reference attributes in source geographic units are all of the same size (all of size $|U^s|$), the aggregate vectors of the reference attributes in target geographic units are all of the same size (all of size $|U^t|$). Further, all the disaggregation matrices are all of the same size as well. The reason for the minor difference in GeoAlign runtime for different datasets is because of the difference in the number of non-zero entries in the disaggregation matrix, which is stored as sparse matrix, of reference attributes. For the disaggregation matrix, sparse datasets, such as cemeteries, have less non-zero entries, while dense datasets, such as population, have more non-zero entries. Matrix operations involving sparse matrices are influenced by this factor in SciPy package.

As for cross-universe comparison, we plotted GeoAlign runtime versus the number of zip codes (source units) and the number of counties (target units) in Figure 6. These two plots show that GeoAlign is fast: it runs for less than 0.15 second even for cross-walk between 30238 zip codes and 3142 counties in the United States universe. They also prove the linear relationship between GeoAlign runtime with the number of units in source and target levels since the dominating disaggregation matrix construction operation is linearly related to these two factors.

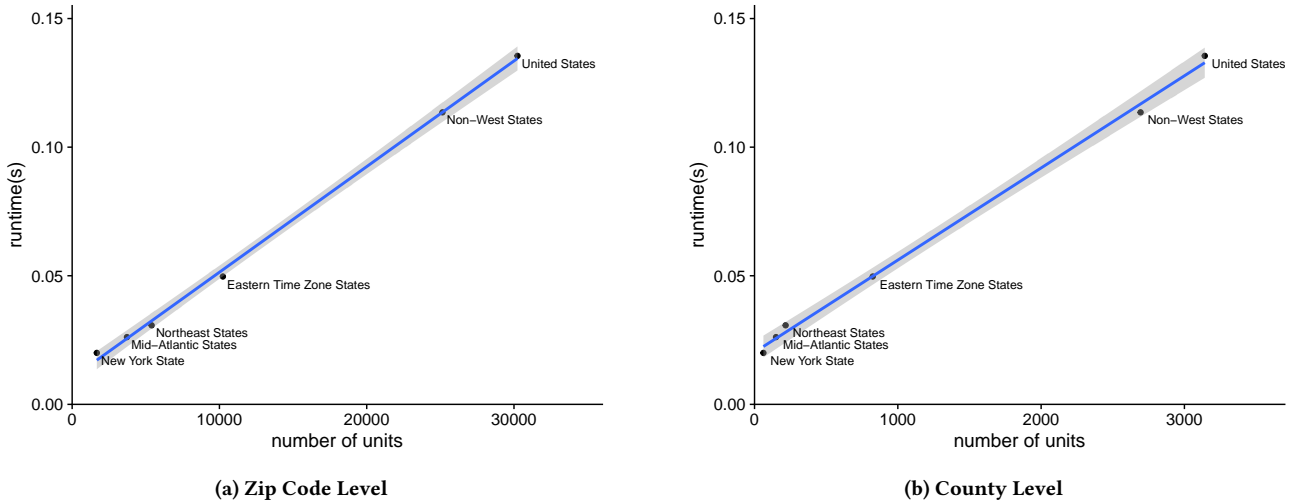

Figure 6: GeoAlign runtime scales linearly with respect to the number of units in source level and target level

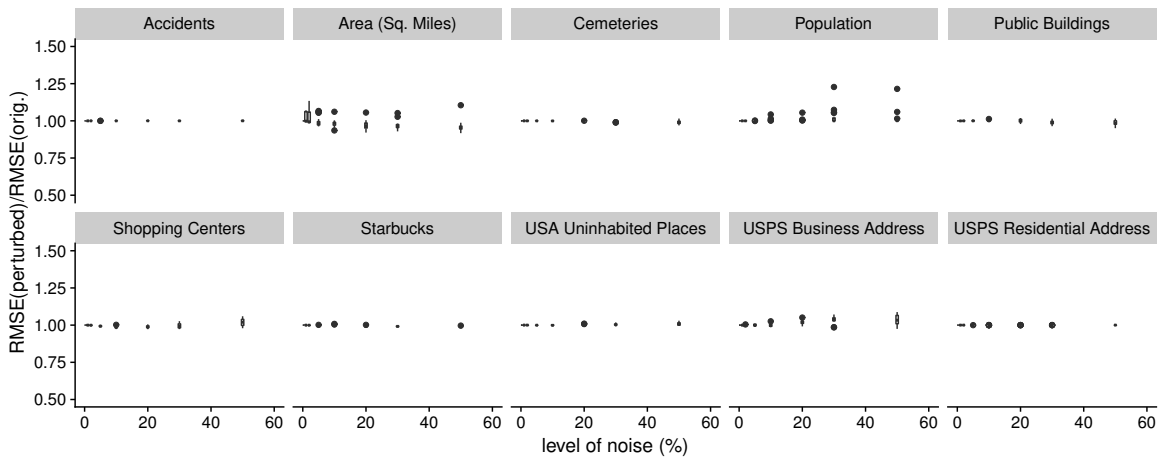

Figure 7: When noises are introduced in references, the prediction deviation is evaluated as the ratio of the RMSE using the perturbed references to the RMSE using the original references. The closer the ratio is to 1, the more invariant GeoAlign is to reference noises. For up to 50% level of noise, most experiments have the prediction deviation around 1 indicating the robustness of GeoAlign to noisy references.

4.4 GeoAlign Robustness

As mentioned earlier in §4.1, during the reference attribute collection process, we encountered two difficulties: the undetermined accuracy of reference attributes at the source level, and the limited availability of datasets with disaggregation matrix. We conducted two series of experiments evaluating the robustness of GeoAlign with respect to these two problems respectively.

4.4.1 Inaccurate Reference Attributes. Public aggregated data can be derived in multiple ways. They can be aggregates of individual level data, approximates derived from some crosswalk algorithm, etc. Without the raw data and the transformation information available, the accuracy of these aggregates are unknown. It is thus hard to determine whether the data can be used as references.

To quantitatively evaluate the influence of the accuracy of reference attributes on GeoAlign, we artificially introduced "noise" to the reference attributes. We define *noise* as the deviation from the actual value. Noise is measured by "levels" such that a $x\%$ level of noise for y is $\pm x * y/100$. The noise-polluted y is thus

$(1 + x/100) * y$. For each of the ten cross-validated experiments in United States, we synthetically generated noisy reference attributes at the source level with 1%, 2%, 5%, 10%, 20%, 30% and 50% degrees of noises for all references. Each experiment is replicated 20 times to account for random error due to randomness of positive or negative noises. We quantify the prediction deviation as the ratio of the RMSE using perturbed noisy reference attributes to the RMSE using the original reference attributes. The closer the prediction deviation is to 1, the smaller the impact of the noises is. GeoAlign is making better prediction with the perturbed reference attributes if the ratio is higher than 1; whereas a less than 1 ratio indicates worse prediction with the perturbed reference attributes.

In Figure 7, we show the box plot of the prediction deviation with respect to different levels of noise. The prediction performance of GeoAlign is stable across experiments. For each experiment, GeoAlign is making robust predictions for all levels of noise. Though for the area and population datasets, higher levels

Figure 8: GeoAlign is robust to the choice of reference attributes. Though extra reference attributes do not create any loss, reference attributes with higher correlation with the objective are preferred.

of noise resulted in higher prediction error, the mean prediction deviation for these levels is still small (less than 1.1).

4.4.2 Limited Reference Attributes. In general, we cannot predict how many reference attributes will be available. We may have very few, or we may have very many. In the process of reference attribute selection, there are two questions to consider: whether GeoAlign can make reasonable predictions with limited number of reference attributes, and how to select the reference attributes when more than one is available.

To answer these two questions, we chose multiple subsets of reference attributes among all reference attributes and repeated the cross-validated experiments for datasets in the United States. The subset of reference attributes were chosen based on their relationship with the target attribute of each test dataset. We adopted the leave- n -out metric such that $n = 1, 2$ for reference attributes with the highest (or lowest) correlation with the target attribute at the source level. The NRMSEs of these four series of experiments are compared with experiments using all reference attributes in Figure 8.

For 7 out of 10 tests, GeoAlign is making robust predictions regardless of the subset of reference attributes used. As for the series of experiments leaving 1 or 2 least target-attribute-related reference(s) out, the performance of GeoAlign is almost identical to using all reference attributes. This is in accordance with GeoAlign’s ability of assigning little weights to reference attributes loosely related to the target attribute.

Leaving out the most target-related attributes out can have an impact on accuracy. This does impact three of our attributes: area, USA uninhabited places and USPS business address datasets. None of the references are closely related to the area and the USA uninhabited places datasets at the source level (correlations less than 0.25). Apart from the two references left out, the rest of the references have even lower correlation with the target attribute (less than 0.2 and 0.05 respectively). According to the assumption basis of GeoAlign, the distribution of the target attributes is thus poorly related to the distribution of these attributes, leading to increased prediction error. We also found that leaving out the reference most related to the target attribute has almost no impact on the prediction for the USPS business address dataset; while leaving out top two such references dramatically worsens the situation. Further analysis reveals that these two references are

highly correlated with each other at the source level ($\approx 96\%$), the weight assigned to the reference most related to the target attribute is reassigned to the other when the former is left out. This verifies that similar attributes at the source level are also similarly distributed in the intersection units, as the predicted disaggregation matrix of the target attribute is almost the same regardless of using the reference most related to the target attribute or not.

These experiments give us more insight into GeoAlign reference attribute selection. GeoAlign prefers reference attributes highly related to the target attribute at the source level. For reference attributes poorly related to the target variable, it is able to weigh their contributions accordingly. The reference attributes are not necessarily independent of each other and the reference attributes are not necessarily accurate at the source level. From the user’s perspective, GeoAlign is able to make reasonable predictions by simply given all available reference attributes.

5 RELATED WORK

In the GIS community, spatial interpolation has advanced from isoline mapping in cartography to data realignment in different units or grids for multivariate analysis in geographic research [3, 31, 38]. *Realignment*, *crosswalk*, or *regridding*, is commonly used today as a preprocessing step before further data analysis in physics and socioeconomics to interpolate spatial or temporal data distribution from one grid to another [28]. Since these data are either point or areal based, two categories of methods are proposed for these two types respectively.

Areal interpolation is a subset of the spatial interpolation problem that realigns aggregates. Early methods built upon point-based interpolation, such as point-in-polygon method, do not follow the volume-preserving property such that reconstruction of exactly the original aggregates of each source unit with the transformed value of each target unit is not possible [31, 44]. It has been shown that these methods are not comparable in approximation efficiency with those that do have the property [31, 47]. Later methods thus introduce the property and turn over to the area-based areal interpolation instead [12]. These approaches depend highly on the spatial properties of the data collection area and thus different forms of ancillary data are introduced ever since.

Areal weighting method, one of the early area-based areal interpolation method, makes use of the area ancillary data available in the form of disaggregation partitions between source and target units [13, 36]. This method is widely available in GIS software for general users nowadays. However, it assumes even distribution within units (homogeneity) whereas this assumption hardly stands in reality. Areal weighting has been extended by referring to other single known reference attributes, called dasymetric weighting [1, 24, 37, 43]. These methods are restricted by the assumption of proportionality of the objective attribute to the single reference attribute. Hence the selection of the reference attribute is vital to the prediction accuracy and the methods are not adaptive to different objective attributes.

The regression methods are later introduced as extensions to the dasymetric methods allowing for multiple auxiliary variables. In general, the regression methods involve a regression of the source level data of the objective attribute on the values of the references in target units. For this track of methods, more advanced techniques such as EM algorithm, Monte Carlo simulation, smoothing techniques [9, 11, 31, 45, 46, 48], etc., are introduced later in the literature. However, they make different assumptions of density distribution within units, some of the mostly used ones are Poisson distribution and binomial distribution, and their performances are rather assumption dependent [30] and auxiliary variable dependent. Recently, more complicated regression models [35, 39, 40] are developed based on domain knowledge such as spatial correlation. However, they lack general applicability to heterogeneous target attributes and are hard to implement for practitioners.

These approaches can also be categorized as extensive or intensive approaches based on their approximation target. Extensive approaches approximate a_o^{st} while intensive ones approximate f_o^{st} . Most approaches for solving the areal interpolation problem are intensive approaches that build spatial statistical models for f_o^{st} in the disaggregation step. These approaches, mostly developed in 2-D space, can be extended to higher dimensions, though these extensions are typically non-trivial. Other major limitations of intensive approaches include narrow scope of application and low robustness to heterogeneous objective attributes.

Current intensive approaches for areal interpolation are not generally applicable for aggregate interpolation due to three main reasons. First, integration of f_o^{st} is computable in 2-D, however, it is computationally intensive in high dimensions with complex f_o^{st} . Second, shape files are indispensable for intensive approaches, and the probability density function for each intersection unit, $f_o^{st}[k]$, is associated with the shape files of source and/or intersection units. Further, attributes in plain tables without handy shape files of target units typically fail re-aggregation. Even if shape files are available, some of them constantly change over time, resulting in approximation inaccuracies. Last but not least, these approaches are not easily approachable for general users, especially those with little technical proficiency in mathematics, statistics and GIS. The \hat{f}_o^{st} model is built upon the spatial knowledge of the objective attribute; however, this knowledge is not available for all users. Further, implementations of intensive approaches are not publicly available, making them even harder to use.

Another limitation of intensive approaches is that they are not adaptive to new attributes. \hat{f}_o^{st} models are attribute dependent since the true f_o^{st} models for two attributes can be very different. Another point to note is that these approaches make many

assumptions of f_o^{st} . For instance, the distribution model of each intersection unit, the choice of parameters for these distributions and so on. Any change in these assumptions may dramatically influence the accuracy of approximation in some target unit. What is worse, there is no efficient verification of whether they are appropriate or not.

Extensive approaches are more generally applicable than the intensive ones: they can be easily extended to high dimensions, need no unit shape files, and are easy to implement. However, existing extensive approaches make use of a single reference attribute and are still limited in robustness. When the objective attribute and the reference attribute does not share similar spatial distribution, the approximated result can differ substantially from the true aggregates in target units. Further, since they use the same reference attribute irrespective of the objective attribute, they are not adaptive to different objective attributes with heterogeneous spatial distributions.

6 CONCLUSIONS AND FUTURE WORK

In this paper, we formally define the problem of aggregate interpolation in multi-dimensional space and propose GeoAlign, an adaptive multi-reference algorithm that realigns aggregates better than state-of-the-art approaches for real socioeconomic datasets. Unlike existing areal interpolation algorithms, GeoAlign requires no knowledge of spatial properties or dasymetric maps of source and target units and is thus generally applicable for plain aggregate tables. Our experiments show that GeoAlign is making better predictions in a reasonably short time. Its runtime scales linearly with the number of units in source and target levels, and is robust to noisy references even when limited references are available.

A potential future direction is to extend this work into an automatic aggregate data integration system that joins multiple aggregate tables without user intervention.

ABSTRACT

The concept of similarity is used as the basis for many data exploration and data mining tasks. Nearest Neighbor (NN) queries identify the most similar items, or in terms of distance the closest points to a query point. Similarity is traditionally characterized using a distance function between multi-dimensional feature vectors. However, when the data is high-dimensional, traditional distance functions fail to significantly distinguish between the closest and furthest points, as few dissimilar dimensions dominate the distance function. Localized similarity functions, i.e. functions that only consider dimensions close to the query, quantize each dimension independently and only compute similarity for the dimensions where the query and the points fall into the same bin. These quantizations are query-agnostic. There is potential to improve accuracy when a query-dependent quantization is used.

In this paper we propose a Query dependent Equi-Depth (QED) on-the-fly quantization method to improve high-dimensional similarity searches. The quantization is done for each dimension at query time and localized scores are generated for the closest p fraction of the points while a constant penalty is applied for the rest of the points. QED not only improves the quality of the distance metric, but also improves query time performance by filtering out non relevant data. We propose a distributed indexing and query algorithm to efficiently compute QED. Our experimental results show improvements in classification accuracy as well as query performance up to one order of magnitude faster than Manhattan-based sequential scan NN queries over datasets with hundreds of dimensions.

1 INTRODUCTION

Nearest Neighbor (NN) searches over high-dimensional data are ubiquitous in information retrieval, machine learning, and multimedia data mining. These searches are often performed through k nearest neighbor (k NN) queries over multi-dimensional feature vectors. Spatial and multimedia objects can be represented as feature vectors characterizing their shape and/or content. Social network data objects, for instance can be represented by links with other data objects, history actions, preferences, etc. Application domains such as spatial data-bases[8], computer vision [5], multimedia and social network applications [29] can all benefit from a more efficient method for finding nearest neighbors in high dimensional spaces.

However, due to the rapid advancements in data generation and collection, it is increasingly challenging to process similarity searches in a rapid and meaningful way on these larger and more complex datasets. Existing methods for finding nearest neighbors

using tree-based indexing for spatial data [36] and low dimensional data [13, 23, 24], suffer from the curse of dimensionality when applied to high-dimensional spaces. Moreover, not only processing time degrades, but also the ability to characterize similarity using a distance function for high-dimensional spaces is greatly reduced[3]. The reason is that distances between data points in high-dimensional spaces, are usually very concentrated around their average [7]. This makes it difficult to distinguish between the closest and furthest data points [3].

To overcome this limitation, localized distance functions [1, 37, 39] have been proposed in the literature. These functions only consider dimensions that are close to the query point to characterize similarity providing a better distinction between closer and further points and often improving the accuracy of the results. The IGrid index [1] efficiently supports the computation of a partial distance called PiDist and its performance scales well for high dimensional data. IGrid pre-process the data and define equi-populated partitions (bins) over each dimension independently. The points in these partitions are then mapped to buckets and only the points that fall into the same bucket as the query point are considered similar for that dimension. The points with the largest cumulative similarity are then retrieved after all dimensions have been processed. As stated in the paper, the accuracy of the results are affected by the binning strategy and the number of bins used.

In this paper, we expand on the ideas proposed in [1, 15] and define a query-dependent quantization strategy that further improves the accuracy of the results. The main idea is to use the query itself to determine a range for which the points falling within are considered similar. Note that considering a fixed interval around the query value for each dimension is not a viable option. Since the distribution of each attribute varies, a small interval could yield empty bins, while a large interval could include all the points. Determining the range needs to consider the data values in the attribute. We want to define a bin for each dimension where the number of points is roughly the same for each dimension. This novel function, called Query dependent Equi-Depth (QED) quantization, can be used with traditional distance functions (e.g. Euclidean, Manhattan) to improve their accuracy in high-dimensional spaces. In order to efficiently support QED over big-data, we design a distributed indexing and efficient query algorithm. The proposed approach includes the usage of compressed bitmap-based indexing and low level parallel bitwise operations.

Our approach does not require any pre-computations for quantization, or excessive storage or memory. On the contrary, the index requires less storage than the data itself. The index and query algorithms are designed for parallelism and can run on centralized systems as well as cluster systems. In this work we evaluate the distributed indexing and query processing on a Spark cluster, however it is suitable for other distributed environments as well. With QED quantization, as shown in our performance evaluation we observe an improvement in query time of up to one

order of magnitude when compared to Sequential Scan on high dimensional data.

We also evaluated the kNN classification accuracy of the proposed QED quantization on a set of nine high-dimensional datasets and observed an average improvement in accuracy of 2.4% for Manhattan distance and 10.95% for Hamming distance when using QED quantization.

The primary contributions of this paper can be summarized as follows:

- We present a bitmap-based, distributed index for answering similarity searches and nearest neighbor queries. The cumulative distance is computed in parallel through an optimized distributed aggregation that uses task mapping by slice depth at its core.
- We formalize the cost for the distributed aggregation and optimize the partition size to balance the memory shuffling and parallel processing trade-off.
- We propose a novel Query dependent Equi-Depth quantization (QED) for improved similarity searches. This dynamic quantization not only improves accuracy but also execution time because it reduces the amount of data processed by only considering, for each dimension, the closest points to the query.
- We introduce a power function using the number of tuples and the number of dimensions as a heuristic to determine the number of points that are considered similar in each dimension and empirically evaluated it.
- We evaluate the kNN classification accuracy of QED on a number of labeled real datasets and the performance of the proposed index and query algorithms in a distributed setting.

The rest of the paper is organized as follows. Section 2 presents related work on NN searches. Section 3 describes the index structure, the proposed quantization, and the parallel query optimization for similarity searches. Section 4 provides an experimental evaluation of QED over a Spark/Hadoop cluster. Finally, conclusions are presented in Section 5.

2 RELATED WORK

This section presents related work for high-dimensional similarity searches and nearest neighbor queries. The most recent exact nearest neighbor searches are using localized similarity functions. While some of the most recent approximate nearest neighbor searches use hashing or product-quantization techniques.

2.1 High-dimensional Similarity using Localized Functions

As described in [37], for high-dimensional applications where human cognition is the target judge of object similarity, it is more important to closely match a subset of attributes rather than provide some least total distance measurement over all the attributes. The similarity function, called Dynamic Partial Function (DPF) [37], considers only the smallest N distances between all dimensions to compute the similarity. Since the method is so sensitive to N , the k-N-match problem is introduced in [37] and the authors propose the use of a frequent k-N-match algorithm, where the most frequent k objects appearing in the k-N-match solutions for a range of N values. It is worth noting that DPF is not a distance since the triangle inequality does not hold.

In [1], quantization was used to create equi-populated partitions for each dimension to bound the worst case performance

of the query. Quantization has been widely used to improve the accuracy of classifiers and clustering algorithms as it reduces the noise of the data and simplifies the models. Supervised methods use the class label and a training dataset to make an informed decision about the optimal split points. Unsupervised methods rely solely on the statistics collected about the data. Examples of unsupervised methods are equi-width (divide into intervals of the same length) and equi-populated or equi-depth (divide into intervals with the same number of data objects). Examples of supervised methods are entropy-Minimum Description Length Principle (MDLP) [9], chi-merge [25], class-attribute interdependent maximization (CAIM) [26], and Class-attribute Contingency Coefficient (CACC) [38], among others. A detail survey of quantization methods can be found in [11].

After quantization, each attribute is represented using discrete values and points are considered “close” if they fall into the same bin. Hamming distance is the preferred distance metric for discrete domains and is defined as:

$$\text{Hamm}(x, y) = \sum_{i=1}^d \begin{cases} 0 & \text{if } x_i = y_i \\ 1 & \text{otherwise} \end{cases}$$

where x and y are the high-dimensional quantized vectors, d is the number of dimensions and x_i denotes the value of x for dimension i . The evaluation of the Hamming function produces discrete values in the range $[0, d]$. This is a source of ambiguity when defining similarity as the distance score is the same for an increasing number of nearest neighbors. To break these ties a weighted hamming distance function can be used. `PiDist` [1] computes the normalized Manhattan distance over the continuous values for the dimensions where the two points fall into the same discretization range. When equi-populated ranges are used, the attribute is forced to follow a uniform distribution and the distance between the continuous values is used to capture similarity.

`PiDist` is defined as:

$$\text{PiDist}(X, Y, k_d) = \left[\sum_{i \in S[X, Y, k_d]} \left(1 - \frac{|x_i - y_i|}{m_i - n_i} \right)^p \right]^{\frac{1}{p}}$$

where k_d is the number of splits for each dimension, $S[X, Y, k_d]$ is the set of dimensions for which the two objects lie in the same range, and m_i and n_i are the upper and lower bounds of the corresponding range in dimension i .

This function accumulates benefit for each attribute for which a data object maps to the same quantization as the query object. It does not differentiate between data and query objects that do not map to the same quantization. Therefore, a data point is not excessively penalized for a few dissimilar attributes.

2.2 Approximate nearest neighbor searches

Given the difficulty of answering exact nearest neighbor searches, approximate nearest neighbor searches were introduced to solve the NN problem in high dimensional spaces [10, 12, 20–22]. Local Sensitive Hashing (LSH)[12] hashes the data so that similar items fall into the same buckets. However, data sets are typically not distributed uniformly over the space, and as a result, the buckets of LSH are unbalanced, causing the performance of LSH to degrade. Data Sensitive Hashing (DSH) [10] aims to keep the buckets balanced with the help of a new hash family, while preserving the nearest neighbor relations.

Hashing techniques require the pre-computation of the hash tables without prior knowledge of the query. The accuracy of a similarity search is determined by the number and the quality of

Tuple	Raw Data		Bit-Sliced Index (BSI)				BSI SUM		
	Attrib 1	Attrib 2	Attrib 1		Attrib 2		sum[2]	sum[1]	sum[0]
			$B_1[1]$	$B_1[0]$	$B_2[1]$	$B_2[0]$			
t_1	1	3	0	1	1	1	1	0	0
t_2	2	1	1	0	0	1	0	1	1
t_3	1	1	0	1	0	1	0	1	0
t_4	3	3	1	1	1	1	1	1	0
t_5	2	2	1	0	1	0	1	0	0
t_6	3	1	1	1	0	1	1	0	0

Figure 1: Simple BSI example for a table with two attributes and three values per attribute.

the hash functions along with other tuning parameters. A higher number of hash functions can result in higher a probability of grouping similar objects together, however this can also result in a significant storage overhead. Moreover, with addition of new data, the hash index has to be re-computed. While QED uses some of the same concepts by projecting data into smaller ranges, it does not come with the storage overhead required by the hash index, and uses the query directly for data projection. Moreover, QED is an exact similarity function.

We compare QED against a distributed LSH¹ implementation and show that QED could present advantages in terms of smaller index size, and better accuracy for some applications.

3 DISTRIBUTED QED FOR HIGH DIMENSIONAL SIMILARITY SEARCHES

Consider a relation R and query vector Q . Every object in R is represented by m attributes or numeric scores. The query vector $Q = \{q_1, \dots, q_m\}$ is also represented by m values. The task is to find the k most similar objects to Q in R . This k nearest neighbor (k NN) query can either compute the similarity between each data object and the query and retrieve the k objects with the highest score or, inversely, compute the distance between each object and the query and retrieve the k objects with the smallest distance.

In high dimensional spaces however, many distance functions such as Manhattan and Euclidean metrics are not as effective and the quality of the answer returned by the k NN query degrades. The reason these functions are directly affected by the dimensionality of the data lies in the fact that the dominant components are the dimensions for which two points are farthest apart. With higher dimensionality, the probability of having high discrepancies between two points in at least one dimension increases. The authors of [1, 3] show that for L_p -norm distance functions, the averaging effects of the different dimensions start predominating with increasing dimensionality. To prevent this, the authors of PiDist [1] show that imposing a proximity threshold for each dimension, beyond which the degree of dissimilarity is not relevant, could improve accuracy in nearest neighbor and similarity searches.

They achieve this by quantizing the indexed space into a fixed number of bins which are either equi-width or equi-depth (equi-populated). These quantizations are performed over the dataset without considering the query points. Even when a query point lies close to the boundary of a bin, only the points within the bin are considered for computing the similarity. In this section we describe a novel equi-depth quantization method that considers the query value for defining the bin boundaries and it is done on-the-fly during query execution.

3.1 Bit-sliced indexing

In order to efficiently support QED over large datasets, we design a distributed indexing and efficient query algorithm. The proposed approach includes the usage of compressed bit-vector indexing and low level parallel bitwise operations. As shown previously [16, 18], this setup can leverage SIMD instructions and use the processing hardware more efficiently, for arithmetic operations.

Bit-sliced indexing (BSI) was introduced in [30], and it encodes the binary representation of attribute values with binary vectors. Therefore, $\lceil \log_2 values \rceil$ vectors, each with a number of bits equal to the number of records, are required to represent all the values for a given attribute.

Figure 1 illustrates how indexing of two attribute values and their sum is achieved using bit-wise operations. Since each attribute has three possible values, the number of bit-slices for each BSI is 2. For the sum of the two attributes, the maximum value is 6, and the number of bit-slices is $\lceil \log_2 6 \rceil = 3$. The first tuple t_1 has the value 1 for attribute 1, therefore only the bit-slice corresponding to the least significant bit, $B_1[0]$ is set. For attribute 2, since the value is 3, the bit is set in both BSIs. For example, the addition of the BSIs representing the two attributes is done using efficient bit-wise operations. First, the bit-slice $sum[0]$ is obtained by XORing $B_1[0]$ and $B_2[0]$: $sum[0] = B_1[0] \oplus B_2[0]$. Then $sum[1]$ is obtained in the following way: $sum[1] = B_1[1] \oplus B_2[1] \oplus (B_1[0] \wedge B_2[0])$. Finally $sum[2]$, which is the carry, is $majority(B_1[1], B_2[1], (B_1[0] \wedge B_2[0]))$, where $majority(A, B, C) = (A \wedge B) \vee (A \wedge C) \vee (B \wedge C)$.

BSI arithmetic for a number of operations, including the addition of two BSIs, is defined in [34]. Previous work [19, 33], uses BSIs to support preference and top k queries efficiently. BSI-based top k for high-dimensional data [16, 19] was shown to outperform current approaches for centralized and distributed query processing. In this work we adapt the distributed BSI query processing for NN queries. Furthermore, each individual bit-vector is compressed. The compression mechanism is described in section 3.6.

3.2 Query Dependent Equi-Depth Quantization

Further in this section we describe a novel function, called Query dependent Equi-Depth (QED) quantization, which can be used with traditional distance functions (e.g. Euclidean or Manhattan) to improve their accuracy in high-dimensional spaces. QED is implemented using a distributed bitmap-based index, and is designed with performance considerations in mind.

The main idea with localized functions is that for each dimension, if the data point has its respective dimension within threshold x then the distance to the query is considered for that dimension otherwise a dissimilarity penalty larger than x is assigned.

For this work, instead of directly specifying x , we consider parameter p as the minimum number of data points that should be contained within the query bin boundaries. Parameter p is

¹<https://github.com/mrsqueeze/spark-hash>

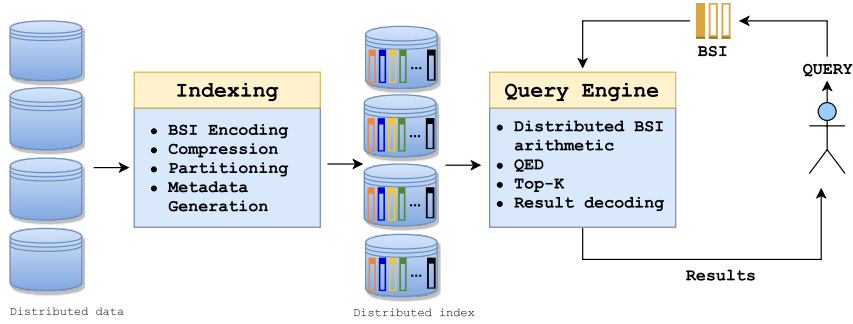

Figure 2: High level system overview

expressed as a percentage. Given the query value for dimension i , q_i , we find the $\lceil pn \rceil$ smallest distances to q_i and define a similar bin around the query point.

To illustrate the proposed dynamic quantization, consider a 1-dimensional dataset with values:

$$\{\{r1, 9\}, \{r2, 2\}, \{r3, 15\}, \{r4, 10\}, \\ \{r5, 36\}, \{r6, 8\}, \{r7, 6\}, \{r8, 18\}\}$$

and query $\{q, 10\}$. If using Manhattan distance, the distance between the data points and the query are:

$$\{\{r1, 1\}, \{r2, 8\}, \{r3, 5\}, \{r4, 0\}, \\ \{r5, 26\}, \{r6, 2\}, \{r7, 4\}, \{r8, 8\}\}$$

For QED, if parameter $p = 0.35$ (35% of the population), only the 3 points with the smallest distances, i.e. $\{r1, r4, \text{ and } r6\}$, will be considered according to their distance. The rest of the points will be given a larger penalty δ_i to characterize a large dissimilarity. This normalization of the larger differences gives point $r5$ a chance to make it as a NN in the cases where there are other many dimensions for which $r5$ is really close to the query.

The value of the penalty, δ_i , can be assigned a constant larger than the distances computed within the query-dependent interval for each dimension. In the case of PiDist, the penalty assigned to dissimilar points is 1 and the distance for similar points is normalized to less than 1. Another approach could be to make δ_i to represent a number larger than the largest distance between the query and the closest p elements in dimension i .

Equation 1 shows the Manhattan distance between a data point a and the query q after applying the QED quantization.

$$\text{QED}_{\text{Manhattan}}(a, q) = \sum_{i=1}^d \begin{cases} |a_i - q_i| & \text{if } a \in P_i \\ \delta_i & \text{otherwise} \end{cases} \quad (1)$$

Where P_i is the subset of points closest to the query in dimension i , and δ_i is the penalty for the points outside the similar range in dimension i .

Performing QED for kNN queries without an index would slow the execution time, as it needs to dynamically compute a range for each dimension based on the query, in addition to computing the distance. We choose to implement QED on top of a bit-sliced index because BSI provides a compact representation of numeric values and an implicit ordering of the values as the set bits in the most significant bit-slice represent the largest values. In the next section we show how using the BSI index can in fact improve the performance of the kNN query.

3.3 Distributed Bit-Sliced Index (BSI)

Figure 2 depicts a high level overview of the proposed system. There are two main components: the indexing module and the query engine. The indexing module encodes each attribute into a bit-sliced index (BSI), compresses and partitions them, and generates the metadata required by the query engine to ensure correctness of the execution plan. The query engine encodes the user query into a BSI, runs the distributed kNN query, and returns the k nearest neighbors to the query.

We support both vertical (a subset of the attributes) and horizontal (a subset of the rows) partitioning. Distributed query algorithms are developed to minimize shuffling, improve load balancing, and maximize cluster utilization. For this work, we use Apache Spark and its Java API to distribute the workload across the cluster.

3.3.1 Indexing. Let us denote by B_i the bit-sliced index (BSI) over attribute i . $B_i[j]$ is a binary vector containing n bits (one for each tuple), where j represents the j^{th} bit in the binary representation of the attribute value. j can hold a value between 0 and the number of slices s used to represent values from 0 to $2^s - 1$. The bits are packed into words, and each binary vector encodes $\lceil n/w \rceil$ words, where w is the computer architecture word size (64 bits in our implementation).

For every attribute i in R we create a Bit-sliced index B_i . The BSI index is then partitioned and distributed across the nodes of a cluster. The $BSIAttr$ class serves as a data structure for an atomic BSI element included in a partition. Each partition can include one or more $BSIAttr$ objects. A $BSIAttr$ object can represent all the attribute tuples (in the case of vertical-only partitioning) or only a subset (in the case of horizontal, or vertical and horizontal partitioning). Furthermore, a $BSIAttr$ object can carry all of the attribute bit-slices or only a subset of them. The $BSIAttr$ metadata generated includes information regarding the data type, encoding, number of slices, partition mapping. An example of attribute partitioning and use of metadata for partition mapping is shown in Figure 3.

We extended the BSI to handle signed numbers (both 2's complement and sign and magnitude) and represent decimal numbers using a fixed point format for each attribute. For every decimal BSI, the position of the decimal point is maintained as metadata for the attribute. To perform arithmetic operations between two attributes with different precision, namely a and b , where $a > b$, the decimal point for the second attribute is moved $(a - b)$ positions by multiplying the second attribute by the appropriate power of 10. Multiplication by a constant, as in this case, can be done efficiently by adding the logically shifted BSI to the original BSI for every set bit in the binary representation of the constant.

Figure 3: Example of vertical and horizontal partitioning of a BSI Attribute.

At query time, a BSI index is also generated for each partition using the attribute values in the query. Since the query value is constant, compressed bit-slices of all 0s or all 1s are used to generate a BSI with as many bits as objects in the partition in order support the bit-wise operations between the query and the *BSIAttr*. The hybrid query execution model [14] allows us to operate compressed and verbatim bit-vectors together and the results are dynamically compressed/decompressed as needed.

3.3.2 Query Engine. For developing the distributed algorithm we identified three main steps in the *k*NN query processing: compute the distance between the query *Q* and each *BSIAttr*, accumulate the partial distances for all dimensions, and retrieve the *k* closest points as the answer to the query. For an efficient execution of these three steps we are proposing a dynamic query aware quantization method called QED, and integrate it with algorithms for parallel execution of BSI arithmetic operations. In the following sections we describe in more detail the different components of the query engine.

3.4 Distributed *k*NN Query Processing

Most parts of the three-step process described earlier must be executed in parallel for achieving good scalability and performance. The computation of the absolute value of the difference between the query and each attribute BSI for *all* dimensions in parallel, aggregating all the distances into a single SUM_BSI also in parallel, and performing the top-*k* operation over the result BSI (can be executed in a single node or in parallel). We apply the same slice mapping distributed BSI aggregation developed for preferences queries [16]. This approach, described next, outperforms other parallel baseline implementations such as tree-reduction (adding pairs of BSIs together and using multiple reduce rounds) and its optimization Group Tree Reduction that reduces together groups of BSIs to reduce the number of rounds and the amount of data shuffled.

3.4.1 SUM_BSI Using Slice Mapping. It is true that the compact representation of the BSI makes the baseline implementations highly competitive versus their array counterparts. However, most of the performance gains, if not all, come from the reduced size of the BSI, and not necessarily because the algorithms are efficient. We propose an aggregation algorithm that promotes the bit-slices as the processing data units and applies the lessons-learned in computer arithmetic optimization to further improve

the performance of the parallel aggregation. The basic idea of this approach lies in the use of the bit-slice depth as the mapped key and implement a two-phase aggregation algorithm, shown in Figure 4. In the first phase, the slices are added by bit-depth, producing a weighted partial sum BSI. In the second phase, all the partial sums are added together in a method similar to a carry-save adder.

Consider a dataset where $m = 128$ attributes are added using 10-nodes. Let us now assume that each attribute’s value is within $1M = 2^{20}$, so every attribute i can be further partitioned into a set of 20 vertical bit-slices: $\{B_i[d] \mid 19 \geq d \geq 0\}$. In the proposed two-phase algorithm, the first task is to map all the bit-slices with the same depth (d) to a single node. Then addition is performed over 128 BSIs containing only 1 slice each, producing 20 partial sum BSIs. Each partial sum is in the range $[0, 128]$ and would require at most 8 slices. Next, these partial sums are added using their original depth d as their “weight.” For example, the partial sum for the bit-slices of depth $d = 2$ would have a weight of $2^d = 4$. Because the weight is always a power of 2, this weighting scheme can be done efficiently by bit-shifting. Since the BSIs are stored column-wise, this shift can be represented using an offset and never materialized.

It is also possible to perform the parallel aggregation using groups of bit-slices to reduce data shuffling. In the previous example, with a group size of $g = 2$, we could have slices 0 and 1 from all 128 attributes added together in the same node during the first stage. This ability to group the slices and divide the attributes (e.g., half of the depth 0 slices added in one node and the other half in another), allows us to balance the load and keep all the nodes busy longer.

For clarity in describing our algorithms, we use the example illustrated in Figure 4. In the first phase, every BSI attribute has its slices mapped locally to based on their depth d . The splitting of the BSI attribute in individual bit-slices allows for a finer granularity of the indexed data and for a more efficient parallelism during the aggregation phase. The pseudo-code of the mapping step is shown in the first Map() function of Algorithm 1. Every mapper has a *BSIAttr* (containing multiple slices) as input, and outputs a set of *BSIAttrs* that contain *one* bit-slice each. These bit slices are mapped by their depth in the input *BSIAttr*. Although there is an overhead associated with encapsulating each bit-slice into a *BSIAttr*, by creating a higher level of parallelism, we also achieve better load balancing and resource utilization.

Still in the first phase, the aggregation is done by the Reduce-ByKey() function of Algorithm 1. In this step, all the bit-slices with the same key (depth) are aggregated into a *BSIAttr*. Line 9 of Algorithm 1 performs the summation of two BSIs. We use the same addition logic as the authors in [35]. However, we achieve a parallelization of the BSI summation algorithm by splitting the *BSIAttr* into individual slices and executing their addition in parallel similarly to a carry-save adder. The offset of the resulting *BSIAttr*s are saved in the *offset* field of each *BSIAttr* object to ensure the correctness of the final aggregated result. The summation is optimized by aggregating the bit-slices on the same node first, then on the same rack, and then across the network. Thus, trying to minimize the network throughput. The aggregation by depth is done locally first.

After aggregating partial local results, the second phase initiates to complete the aggregation by depth through shuffling the partial sums and reducing by their depths. The final step of the aggregation is done by reducing all the BSIs (*pSum*) produced in

Figure 4: SUM_BSI Using Slice Mapping Example

the previous ReduceByKey() stage, regardless of their key. The final result ($attSum$) of this reduce phase is a single BSI attribute in the case of vertical only partitioning, or a set of BSI attributes, that should be concatenated, in the case of vertical and horizontal partitioning. Concatenation is straight forward, as each BSI in a partition has the same number of bits corresponding to the same rowIds.

3.4.2 Cost Estimations and Query Optimization. It is possible to estimate the complexity of the two-phase distributed aggregation and the expected amount of data shuffling. These estimations can help in choosing the most optimal partitioning strategies (group slicing) for the distributed aggregation, thus finding the best compromise between parallelism and the cost of network communication.

Note that the mapping in the first phase (Figure 4) does not produce any shuffling since it aggregates only the slices from attributes found on the same node. Data shuffling occurs twice in our two-phase aggregation. The first time is between the reducers of phase 1 and the mappers of the phase 2, and the second time data is shuffled between the mappers and reducers of the second phase. The amount of data shuffled depends on the number of nodes, partitions, tasks (or the number of attributes per task), and the number of slices per group. The number of slices per group can vary from 1 to s , where s is the highest number of slices per attribute in the dataset. In Figure 4 the slices are mapped into groups of one.

In order to determine the amount of data shuffled between the phase 1 and the phase 2, we should find first the number of outputs created by the reducers of phase 1. Given m attributes with s maximum slices per attribute, a attributes per node, and g slices per group, each node produces $\frac{s}{g}$ partial aggregations by depth. The size of each of these partial aggregations is in the worst case:

$$\lceil \log_2(g + a) \rceil \quad (2)$$

This represents the number of slices each partial aggregation by depth contains after the reduce phase 1. The total number of

slices shuffled at this stage is:

$$Sh_1 = \left[\left(\min \left(\left\lceil \frac{s}{g} \right\rceil, \left\lceil \frac{m}{a} \right\rceil \right) - 1 \right) \cdot \left\lceil \frac{m}{a} \right\rceil \cdot \lceil \log_2(g + a) \rceil \right] \quad (3)$$

Algorithm 1: Two phase distributed BSI aggregation by slice depth

```

Map(): //Map slices by depth
begin
  Input: RDD<BSIAttr> indexAtt
  Output: RDD<Integer, BSIAttr> byDepth
  int sliceDepth=0;
  while indexAtt has more slices do
    bsi = new BSIAttr();
    bsi.add(indexAtt.nextSlice());
    byDepth.add(new Tuple(sliceDepth, bsi));
    sliceDepth++;
  end
  return byDepth
end
ReduceByKey()://Reduce by depth - first reduce phase
begin
  Input: RDD<Integer, BSIAttr> byDepth1, byDepth2
  Output: RDD<Integer, BSIAttr> pSum
  pSum = byDepth1.SUM-BSI(byDepth2);
  return pSum
end
Map():
begin
  Input: RDD<Integer, BSIAttr> partSum
  Output: RDD<BSIAttr> pSum
  pSum = partSum._2();
  return pSum
end
Reduce(): //Second reduce phase
begin
  Input: RDD<BSIAttr> pSum1, pSum2
  Output: RDD<BSIAttr> sumAtt
  sumAtt = pSum1.SUM-BSI(pSum2);
  return sumAtt
end

```

The mappers of the second phase produce $\frac{s}{g}$ outputs, each with the size:

$$\lceil \log_2(g+a) \rceil + \lceil \log_2\left(\frac{m}{a}\right) \rceil = \lceil \log_2\left(\frac{(g+a)m}{a}\right) \rceil \quad (4)$$

The total number of slices shuffled between the mappers and reducers of the second phase is:

$$Sh_2 = \left(\left\lceil \frac{s}{g} \right\rceil - 1 \right) \lceil \log_2\left(\frac{(g+a)m}{a}\right) \rceil \quad (5)$$

The total amount of data shuffled is the sum of the results from Equations 3 and 5:

$$Sh = Sh_1 + Sh_2. \quad (6)$$

The amount of data shuffled decreases as g - the number of slices per group increases, or as a - the number of attributes per node increases. However, less data shuffling means a higher load on individual tasks. We further analyze the time complexity for each individual task, and its impact on the total query time in the two-phase distributed aggregation.

The cost of summing two BSI attributes is linear on the number of slices and the number of rows in the attributes. If v is the number of slices of the attribute with a higher number of slices, then the cost of adding the two attributes is equal to the cost of executing v bitwise logical operations between two vectors. Given that the number of slices per group is a constant, g is the number of slices for each depth-shifted attribute in the reduce phase 1. Adding all the depth-shifted attributes within one node has the following complexity:

$$T_1 = \sum_{i=1}^{\log_2 a} (g+i). \quad (7)$$

There are $\frac{m}{a}$ partial sums with the same key per task, to complete the aggregation of partial sums shifted by depth. Thus the cost of this aggregation is:

$$T_2 = \sum_{i=1}^{\lceil \log_2 m/a \rceil} (g + \lceil \log_2 a \rceil + i) \quad (8)$$

Finally, the cost of aggregating the partial sums shifted by depth into one final attribute, is given by:

$$T_3 = \sum_{i=1}^{\lceil \log_2 s/g \rceil} \left(g + \lceil \log_2 a \rceil + \lceil \log_2 \frac{m}{a} \rceil + i \right) \quad (9)$$

When taking into consideration the time complexities from Equations 7, 8, and 9, one must account for the different number of tasks executed in these three steps. For example, if T_1 has a weight of one, i.e. $W_{T_1} = 1$, then the number of tasks for T_2 and T_3 is different. For $W_{T_1} = 1$, the weight for T_2 is:

$$W_{T_2} = \frac{1}{\lceil \frac{m}{a} \rceil} \quad (10)$$

since there are fewer tasks for T_2 than T_1 by a factor of $\frac{m}{a}$. While the weight for T_3 is:

$$W_{T_3} = \frac{1}{\lceil \frac{m}{a} \rceil \lceil \frac{s}{g} \rceil} \quad (11)$$

In this case, there are s/g fewer tasks than in the previous step.

Using the time complexities discussed above, together with the data shuffle estimations, it is possible to find the optimum values for the number of slices per group (g) and the number of initial tasks/attributes per task.

3.5 QED over the distributed BSI

QED can be done gracefully with the BSI index without imposing any overhead when compared to the computation of the Manhattan distance without indexing, as shown in Algorithm 2. We operate on top of a BSI index representing the distance between the query and the data points in each dimension. Thus we define the penalty δ_i as the truncation of the most significant bits for the largest distances as depicted in Figure 5.

Algorithm 2: QED Quantization

Input: BSI A , int p
Output: BSI S

```

1 BitSlice penalty = ( $A[A.size - 2]$  XOR  $A.sign$ );
2 for ( $i = A.size - 2; i \geq 0; i--$ ) do
3   | penalty = (penalty OR ( $A[sSize]$  XOR  $A.sign$ ));
4   | if penalty.count()  $\geq n - p$  then
5     |   | sSize =  $i$ ;
6     |   | break;
7   | end
8 end
9 BSI  $S =$  new BSI(sSize);
10 for ( $i = 0; i < sSize; i++$ ) do
11   |  $S[i] = (A[i]$  XOR  $A.sign)$ ;
12 end
13 S.addSlice(penalty);
14 return  $S$ 
```

QED can be included in the calculation of the absolute value of the distance between query and each dimension as shown in Algorithm 2. In datasets with large attribute ranges, the output of Algorithm 2 is significantly smaller in size than the size of the actual distance measures, for most distributions. This is very important because the result of this operation is further processed to aggregate and rank similar objects. As a result of reducing significantly the output size of this step, the overall execution time of the k NN query is generally improved. The number of bit-vectors required to encode a difference attribute is equal to the number of bits required to encode the difference range. Where the difference range is the maximum difference between the query dimension and the same dimension of any of the $[pn]$ tuples, and their minimum difference.

In large datasets where the number of tuples is high, p should typically be small, and most of those p closest tuples are much closer than the attribute range. Thus the reduction in size of the result of Algorithm 2. A more detailed discussion on parameter p follows in section 3.5.1.

For a better understanding of Algorithm 2, we show how the distance BSI attribute between the query and the data points used in our previous running example is quantized using QED in Figure 5. For simplicity, all the distances are positive in Figure 5 (leftmost BsiAttribute). Starting from the most significant bit-slice, the bit-slices in the distance attribute are OR-ed until the count of set-bits in the resulting bit-slice (the penalty bit-slice) is equal or greater than $(n - p)$. At this point the bit-slices that were operated are dropped and replaced with one single penalty bit-slice.

The effect of this quantization is the identification of the furthest $(n - p)$ points from the query for one given dimension, and reducing their distance, while keeping an accurate distance for the close points. Hence avoiding over penalizing a point if only a few dimensions are far from the query.

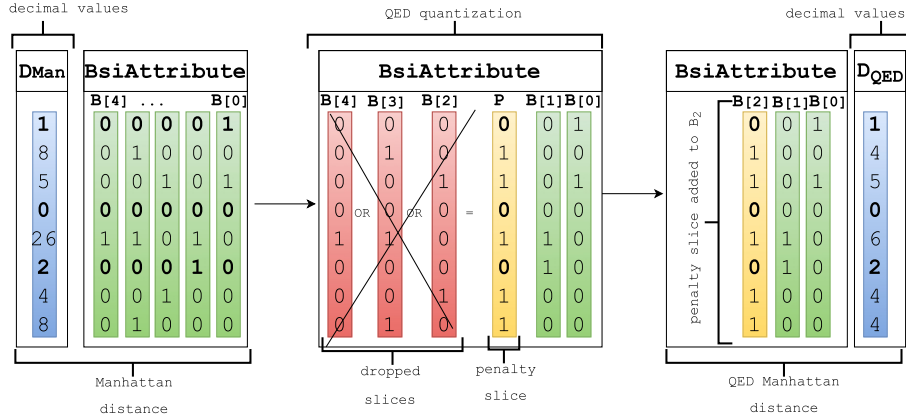

Figure 5: Query dependent Equi-Depth (QED) quantization with population range $p = 35\%$

Figure 5 and Algorithm 2 use Manhattan distance along with QED quantization. However it is also possible to use other distance metrics such as Euclidean or Hamming.

Equation 12 shows the Hamming distance between a data point a and the query q after applying the QED quantization.

$$\text{QED}_{\text{Hamming}}(a, q) = \sum_{i=1}^d \begin{cases} 0 & \text{if } a \in P_i \\ 1 & \text{otherwise} \end{cases} \quad (12)$$

Where P_i is the subset of points closest to the query in dimension i .

3.5.1 Estimating parameter p . The main idea of QED is to use the query itself for determining a range in which the points falling within are considered similar. Determining this range needs to consider the data values in the attribute. Thus we want to define a bin for each dimension where the percentage of points p in each bin is roughly the same for each dimension. We define p as a fraction of the total number of rows n in the dataset.

The value of p is directly influenced by the data dimensionality and the total number of rows in the dataset. Intuitively, for large datasets with a large number of tuples, p should be small, as even a small p would represent a large number of candidate points. Conversely, as the number of dimensions increases, p should also increase to prevent all the tuples from being penalized in many dimensions.

Inspired by the Pareto principle [31], where only the vital few produce the majority of results, we define the power function given in Equation 13 as a heuristic to estimate p :

$$\hat{p} = \left(\frac{m}{m+n} \right)^{\frac{1}{\lg(n)}} \quad (13)$$

For this power distribution, we use the number of attributes, m , as the scale, and the number of tuples, n , to derive the shape. We made the power function $\frac{m}{m+n}$ to guarantee a number less than 1.

Figure 6 shows the estimated values of p for four datasets with 1M, 10M, 100M, and 1B tuples as the number of attributes increases. We empirically evaluated this estimations over two large datasets and observed that the estimations for p were at or near the point with maximum accuracy for the task of k NN classification.

3.6 Bitmap Compression

For further optimization, in our setup, we apply compression to each individual bit-vector, when suitable [14]. Most types of

Figure 6: Estimated values of parameter p for maximizing accuracy of the k NN query results with QED

bitmap (bit-vector) compression schemes use specialized run-length encoding schemes that allow queries to be executed without requiring explicit decompression.

Word-Aligned Hybrid Code (WAH) [40] proposes the use of words to match the computer architecture and make access to the bitmaps more CPU-friendly. WAH divides the bitmap into groups of length $w - 1$, where w is the CPU's word size. WAH then collapse consecutive all-zeros or all-ones groups into a fill word.

Recently, several bitmap compression techniques that improve on WAH by making better use of the fill word bits have been proposed in the literature [27, 41], and others. Previous work have also used varying segment lengths s within $s \leq w$ encoding [17].

In this work we use our recently proposed bit-vector compression scheme [14], which is a hybrid between the verbatim scheme and the EWAH/WBC [27] bitmap compression. This hybrid scheme compresses the bit-vectors if the bit density is below a user-set threshold. Otherwise the bit-vectors are left verbatim. In our experiments we begin with compressed bit-vectors if the compressed size for the bit-vector is 0.5 or smaller than the size of the uncompressed bit-vector. The query optimizer described in [14] is able to decide at run time when to compress or decompress a bit-vector, in order to achieve faster queries. We choose this compression scheme due to its capability of operating with denser bitmaps, which is the case for the bit-vectors inside the bit-sliced index, and it allows for uncompressed bit-vectors to be operated with compressed ones. Nonetheless, it is possible to

apply other compression models, such as the one proposed in [6]. The compression model is orthogonal to the contributions of this work.

4 EXPERIMENTAL EVALUATION

In this section we evaluate the proposed indexing, quantization, and distributed k NN querying algorithms in terms of classification accuracy and query performance. When evaluating the query speed of the k NN query with QED quantization, we set $p = \hat{p}$ as described in Equation 13. In our evaluations we use two distance metrics with QED: QED with Manhattan distance (QED-M), and QED with Hamming distance (QED-H).

4.1 Experimental Setup

We implemented the proposed index and query algorithms in Java, and used the Java API provided by Apache Spark to run our algorithms on an in-house Spark/Hadoop cluster. The Java version installed on the cluster nodes was 1.7.0_79, Spark version 1.6.1. and Hadoop version 2.4.0.

Our Hadoop stack installation is built on the following hardware: There is one Namenode (master) server (Two 6-core Intel Xeon E5-2420v2, 2.2GHz, 15MB Cache; 48 GB RAM at 1333 MT/s Max). The cluster also contains four Datanode (slave) servers (two 6-core Intel Xeon E5-2620v2, 2.1 GHz, 15MB Cache; 64 GB RAM at 1333 MT/s Max). As cluster resource manager we used Apache Yarn. The namenode and datanodes are connected to each other over 1 Gbps Ethernet links over a dedicated switch. Unless otherwise noted, we use all the available hardware resources in this cluster for running the experiments.

In our experiments we used a number of real datasets to evaluate the proposed indexing and querying. We used nine datasets from the UCI repository [4] for accuracy evaluation, and two larger datasets (HIGGS[2], and Skin Data [32]) were used on the Spark/Hadoop cluster for performance measurements. The number of dimensions in the datasets range from 19 to 279 and the number of classes from 2 to 24. The Skin-Images dataset contains integer numbers (image pixel values), while the other datasets contain real numbers. The details of the characteristics of the data and the class distribution can be found in Table 1.

Dataset	Rows	Cols	Classes
anneal	798	38	5
arrhythmia	452	279	13
dermatology	366	33	6
higgs	11M	28	2
horse-colic	300	26	2
ionosphere	351	33	2
musk	476	165	2
segmentation	210	19	7
skin-images	35M	243	2
soybean-large	307	34	19
wdbc	569	30	2

Table 1: Description of the characteristics of the real datasets used in the experiments.

4.2 QED Classification Accuracy

Classification accuracy is computed over the labeled data using the leave-one-out methodology as the number of correct classifications divided by the total number of tuples in the data set. Voting was used to decide the class for each data point. Table 2 shows the best classification accuracy when using k NN classification

Figure 7: k NN Classification accuracy as the number of nearest neighbors (k) increases for Horse Colic dataset. (Dataset: HorseColic, 300 rows, 26 attributes, 2 classes (99/201))

for each method. We vary the number of nearest neighbors used in classification $k = \{1, 3, 5, 10\}$, and report the best result for each distance function. For quantization, we apply Equi-width and Equi-Populated partitioning varying the number of bins/clusters from 3 to 20 $\{3, 5, 7, 10, 15, 20\}$. The same number of bins/clusters was used for all the dimensions. The only case where attributes could be quantized using a different number of bins/clusters than the one provided as a parameter was the categorical attributes with less categories than the number of bins/clusters provided. In that case each value was considered as a bin/cluster. For dynamic quantization we set p as a percentage of the number of rows. We vary $p = \{60\%, 50\%, 40\%, 30\%, 25\%, 20\%, 10\%, 5\%, \text{ and } 1\%\}$.

For each function metric we report the best result, and then the best accuracy for each dataset is highlighted in bold in Table 2. As shown in the table, QED is able to improve the results for Manhattan and Hamming in most datasets. QED using Manhattan is consistently better than Manhattan with no quantization (8/9) with up to 7.35% accuracy increase (2.4% on average). For Hamming distance, QED quantization outperformed no-quantization in 7/9 cases with up to 57.7% accuracy improvements (10.95% on average).

4.2.1 Evaluation of Parameter k . When using nearest neighbor searches for classification purposes, the number of neighbors considered is often crucial for the accuracy of the classifier. In this experiment we evaluate the effect of k (the number of nearest neighbors) when QED is used in k -Nearest Neighbor (k NN) classification.

Figures 7 and 8 show the classification accuracy for several distance functions as the number of neighbors k increases for two different datasets. In figure 7 for the Horse-colic dataset, the classification accuracy increases gradually for QED (QED-M with Manhattan distance, and QED-H with Hamming distance), while the other distance functions are more sensitive to the value of k . Regardless of the value picked for k , QED-H has the highest accuracy among the measured distance functions for k NN classification for this dataset.

As Figure 8 shows for the Arrhythmia dataset, QED-M (with Manhattan distance) has the highest accuracy. It is worth noting that while the accuracy performance for other distance functions decreases as k increases, classification accuracy for QED is not significantly affected.

4.2.2 Evaluation of Parameter p . The p parameter determines the number of tuples for each dimension to be considered similar for distance computation, while the other tuples get a dissimilarity penalty. Expressed as a percentage, p falls within the

Dataset	Euclidean	Manhattan	QED-M	Hamming			QED-H	PiDist/iGrid	
				NQ	EW	ED		EW	ED
anneal	.934	.939	.964	.986	.984	.980	.994	.990	.990

Table 2: Leave-one-out best classification accuracy using k -nearest neighbor ($k \in \{1, 3, 5, 10\}$) classification with different distance functions and quantization methods (NQ=No Quantization, EW=Equi-width, ED=Equi-depth, QED=Query-dependent Equi-depth). The best result for each dataset is highlighted in bold.

Figure 8: k NN Classification accuracy as the number of nearest neighbors (k) increases for Arrhythmia dataset. (Dataset: Arrhythmia, 452 rows, 279 attributes, 13 classes)

interval $(0, 1]$. If $p = 1$ then the results of the k NN query are the same for both QED-M and Manhattan distance. Clearly, the value of p affects the accuracy of the k NN query results.

In this experiment we vary the value of p from 0.01 to 0.6 and measure the k NN classification accuracy. We chose the two largest of the datasets: HIGGS and Skin-Images, as a higher number of data objects results in a more robust evaluation of p . The accuracy is reported after running 1000 queries obtained by random sampling. We compare the k NN classification accuracy results of QED against sequential scan Manhattan distance and a distributed implementation of Locality Sensitive Hashing (LSH).

The LSH implementation and parameter choice was largely based on the description in chapter 3 of [28]. The LSH number of bins was set to 10000, number of hash functions: 25, and the number of hash tables: 4. For all three methods 5 nearest neighbors were considered for classification.

Figures 9 and 10 show the k NN classification accuracy results as the value of parameter p varies. The filled marker is the p value computed using Equation 13 from Section 3.5.1, and in both cases it is at, or near the highest accuracy point.

4.3 Index size

Given the rapid advancements in data collection, not only the data becomes more complex and harder to analyze, but also its size requires more computational resources. As described earlier, we make use of the BSI index to represent data in a more compact form. A smaller index size should enable performance gains through less network shuffling, fewer CPU cycles required for processing, and less memory utilization and I/O.

Figure 9: The impact of the p parameter on k NN classification accuracy (Dataset: HIGGS, 11M rows, 28 attributes, 2 classes)

Figure 10: The impact of the p parameter on k NN classification accuracy (Dataset: Skin-Images, 35M rows, 243 attributes, 2 classes)

An important advantage of the BSI index is that it has a compact size. The compression comes not only from using a lower number of bit-slices per attribute than the number of bits used in a Long or Double data type, but also from compressing each individual bit-slice (where beneficial) using a hybrid bitmap compression scheme [14]. The compression of the bit-slices occurs only if it can improve the query performance.

Figure 11 shows the size of the BSI index in comparison with the size of the raw data, the LSH index, and the PiDist (10 and 20) index for the HIGGS and Skin Images datasets. Five LSH hash tables were generated using 25 hash functions and 10,000 bins. PiDist-10 refers to the PiDist index with the bin size of 10, while

Figure 11: Index sizes for the HIGGS and Skin-Images datasets.

PiDist-20 has the bin size of 20. These are some of the bin sizes that where shown to perform well in [1].

The Skin Images dataset has a higher compression ratio than HIGGS when compared to the raw data size. This is mostly due to the low cardinality of this dataset, which has RGB encoded pixel values. The HIGGS dataset requires approximately 60 slices per attribute to encode its values, while the Skin Images dataset only requires 8 bit-slices per attribute (values from 0 to 255).

Because the BSI index does not require accesses to the raw data, and due to its small size, it is possible to fit more information into memory and less network communication is required when the k NN queries are performed in a distributed setting.

4.4 Performance impact of data cardinality

Given that the BSI index is sensitive to data cardinality, we set up to measure the scalability of the QED quantization method when compared to running NN searches over the BSI index without QED quantization. We use the HIGGS dataset for this experiment as its data has high cardinality. We vary the number of bit-slices per attribute for indexing from 15 to 60. Note that while it is possible to encode any attribute with any number of slices, using less than $\lceil \log_2 c_i \rceil$ slices, where c_i is the attribute cardinality, results in a lossy compression where the values are approximated to some degree. This approximation however, could have little effect on the k NN classification accuracy depending on the dataset. The evaluation of the BSI approximation is left as a subject for future work.

The query time is reported in milliseconds per query, and was obtained by averaging the k NN classification query times over 1000 queries. As Figure 12 shows, with the increase in cardinality, the query speed degrades at a much slower pace for QED-M than BSI Manhattan (without QED quantization). As mentioned in the previous section when describing Algorithm 2, the performance improvements is largely due to a smaller output, independent of the attribute cardinality, and consequently less data shuffling and processing in the aggregation phase. Running the same queries with Manhattan distance without any indexing took approximately two seconds. Thus, the k NN query time using BSIs was two to five times faster than sequential scan, while QED-M achieved an improvement in performance of one order of magnitude.

4.5 QED query time performance

Many of the existing indexing techniques fail to run faster than sequential scan when tested against high dimensional data. Thus, the approximate nearest neighbor searches became a solution that improves on query time performance by trading off accuracy.

Figure 12: BSI Manhattan and QED Manhattan k NN query performance when increasing data cardinality (Datasets: HIGGS)

Figure 13: k NN query performance comparison. (Dataset: HIGGS, 11M rows, 28 attributes, 2 classes)

Figure 14: k NN query performance comparison. (Dataset: Skin-Images, 35M rows, 243 attributes, 2 classes)

We ran a total of 1000 k NN classification queries over the HIGGS and Skin Images datasets, with the configuration for LSH and PiDist described earlier. Figures 13 and 14 show the average query time per query in milliseconds. Because the number of nearest neighbors k in k NN classification applications is generally low, we set k in our query speed evaluations to 5 and do not vary it. Increasing k , however, doesn't impact the query performance in any significant way because the scores are computed for all the points in the dataset regardless of k . The best query times were achieved when using the QED quantization over the BSI index. The average query time for QED-M was only 14% of the average Sequential Scan query time for the HIGGS dataset. For the Skin Images data set the QED Manhattan query time was 20% of Sequential Scan query time.

5 CONCLUSION

In this work we described the indexing structure and the methods for on-the-fly Query dependent Equi-Depth (QED) quantization to improve high-dimensional similarity. The quantization is done for each dimension at query time and localized scores are generated for the closest $p\%$ of the points. A constant penalty is applied for the rest of the points. By normalizing the penalty for values outside the similarity range we are able to improve nearest neighbor searches in high dimensional spaces.

We evaluated the kNN classification accuracy of the proposed QED quantization on a set of nine high-dimensional datasets and observed an average improvement in accuracy of 2.4% for Manhattan distance and 10.95% for Hamming distance when using QED quantization.

The index structure and the query algorithms that support the kNN searches were designed with distributed processing in mind. We implemented several BSI arithmetic operations such as: addition with a constant, absolute value, and various transformation of the BSI attribute. The index can be partitioned vertically as well as horizontally and makes for a fine level of task granularity and load balancing. Because each dimension is indexed independently, this approach is also scalable for high dimensional data. We evaluated the scalability for datasets up to 243 dimensions on a Spark/Hadoop cluster. We also show that when using QED quantization, the kNN query performance is very robust and does not decrease significantly with the increase in data cardinality.

Due to a smaller index size, the ability to partition the index vertically and horizontally, and the fast bitwise operations, the BSI index proves to be a good data structure for performing distributed Nearest Neighbor searches with query aware quantization at run time. With QED quantization, in our performance evaluation we observe an improvement in query time of up to one order of magnitude when compared to Sequential Scan on high dimensional data.

As future work we plan to investigate further the penalty applied for dissimilar dimensions and under what conditions the normalization of the penalty or the distance would improve the accuracy of nearest neighbor searches. More work is also required in expanding the distance metrics for which the QED quantization can be applied.

ABSTRACT

Global-Scale Data Management (GSDM) empowers systems by providing higher levels of fault-tolerance, read availability, and efficiency in utilizing cloud resources. But, *at which datacenters should data be placed?* Current cloud providers offer tens of datacenters and hundreds of edge datacenters that are globally distributed all over the world. Unlike networks within a datacenter, the topology of the Wide-Area Network (WAN) is asymmetric and diverse—the latency connecting a pair of datacenters can be an order of magnitude larger than the latency connecting another pair. This makes placement a significant factor in performance. However, it is not only placement. The specifics of the transaction management protocol play a crucial role in deciding which placement is ideal. In this paper, we develop GPlacer, a placement optimization framework that embeds the transaction protocol constraints into an optimization to derive both the data placement and the transaction protocol configuration that minimize the overall transaction latency. In developing GPlacer, we discover counter-intuitive lessons about data placement and transaction execution practices. Our evaluation shows that applying these lessons in addition to known best practices generate deployments that reduce the average transaction latency by up to 68%.

1 INTRODUCTION

Internet applications strive for high-performance 24/7 service to clients dispersed around the world. Achieving this is threatened by complete datacenter outages; either planned or unplanned. To overcome these challenges, application services and their backend databases are increasingly being deployed on multiple datacenters spanning large geographic regions (*geo-replication*). F1 [29], Spanner [11], and Tao [8] are examples of deployed systems that are geographically replicated for fault-tolerance and performance reasons.

Moving to Global-Scale Data Management (GSDM), despite its benefits, raises many challenges that are not faced by traditional deployments. The large WAN communication latency is orders of magnitude larger than the traditional LAN communication latency. Figure 1 illustrates the latency difference between communication messages that occur within the same machine, among different machine in the same datacenter, or in multiple datacenters in different geographical regions. This large communication latency of the WAN motivates systems like Yahoo’s PNUTS [9], Facebook’s Tao [8] and others [17, 24] to trade off replica consistency and/or multi-row transaction support with high availability and scalability. However, enterprise applications and applications with complex and evolving schemas have more interest in data management systems that provide transactional

Figure 1: Latency of the Wide-Area Network Round-Trip Time communication (WAN RTT) compared to memory access latency [27] and network latency within the datacenter (local RTT).

ACID properties [5, 11, 30]. Application developers spend significant time to build transaction semantics and complex mechanisms, that are error-prone, on top of the eventual consistent datastores in order to handle stale data items and reason about inconsistency [11, 29]. Therefore, in the past few years, many solutions have emerged to provide strongly consistent transactions for geo-replicated databases [11, 16, 18, 21–23]. These solutions use different replication and isolation techniques in order to minimize the number of WAN messages required to achieve strong ACID transactional guarantees for geo-replicated databases, hence reducing the transaction latency.

Data placement is the problem of deciding the subset of datacenters to host a full or a partial replica of the data to achieve a certain objective such as minimizing the transaction latency, minimizing the deployment monetary costs, and any combination of these and other user-defined objective functions.

In this paper, we propose GPlacer; an optimization framework that solves the data placement problem. GPlacer embeds the commit protocol constraints into an optimization to derive both the data placement and the commit protocol configurations that minimize the overall transaction latency. In developing GPlacer, we discover counter-intuitive lessons about data placement and transaction execution practices. These lessons exploit the latency diversity and asymmetry of the WAN links and are widely applicable to Paxos-based commitment protocols [13, 21] and leader-based commitment protocols [5, 11]. GPlacer incorporates these lessons, the commitment protocol constraints, and the application requirements in an optimization to find the placement that minimizes the average transaction latency.

WAN links are diverse and asymmetric; a link connecting a pair of datacenters can be an order of magnitude larger than a link connecting another pair. Table 1 shows the average measured Round-Trip Time (*RTT*) between every pair of nine Amazon AWS datacenters in California (*C*), Oregon (*O*), Virginia (*V*), São Paulo (*SP*), Ireland (*I*), Sydney (*Sy*), Singapore (*Si*), Tokyo (*T*), and Seoul (*Se*). As shown, the average *RTT* between California and Oregon datacenters is 22ms while the average *RTT* between Singapore and São Paulo datacenters is 329ms. Therefore, the number of WAN messages required per transaction is not the only factor that dominates the transaction latency. Transaction latency is a product of both the transaction commit protocol, which

Table 1: The average RTT latencies between different datacenters in milliseconds and the standard deviation inside parentheses.

Figure 2: The average latency, of all the clients in 9 datacenters, to reach the closest quorum (2 out of 3) for all the possible $\binom{9}{3} = 84$ different placements sorted by latency.

controls the number of the WAN messages required per transaction, and the locations of the replicas, hence the placement, which controls the latency per a WAN message. To illustrate the placement effect on the average obtained transaction latency, we hold the following experiment. We equally distribute clients among the nine AWS datacenters. Three out of the nine datacenters are chosen to host a data replica. The time to reach the closest quorum, two replicas out of these three, is measured for all the clients for all the **possible placements** and the average latency is reported. Figure 2 shows the effect of only changing the placement on the average obtained latency for all the clients while fixing the protocol. As seen in Figure 2, changing only the placement while fixing all the other parameters (the protocol, the workload distribution, etc.) can lead to a significant change of 1.75x between the minimum and the maximum reported average latency. This latency difference amplifies for real workloads when transactions are executed in chains [20].

Unlike GPlacer that optimizes the placement for *multi-row transactional workload with strong consistency requirements*, many works focus on optimizing the placement for weaker consistency levels and single-row operations. SPANStore [33] develops an optimization framework to optimize the monetary cost of deploying a geo-replicated *key/value* store. This framework optimizes the total cost of processing, storage, bandwidth, and I/O and finds the placement that achieves the minimum overall cost while meeting the application requirements. Liu et al. [19], like SPANStore, optimize the deployment monetary cost. However, they consider cost savings exploiting resource reservation payment model instead of the pay-as-you-go payment model while avoiding over reservation. Ping et al. [26] propose the use of a utility function to derive a placement that achieves a balance between the availability and the speed of data access. Volley [4] analyzes data access logs and

generates a migration plan for data partitions to minimize the access latency.

Sharov et al. [28] optimize the placement for *strong consistent transactions* using *leader-based* protocols. Sharov assumes that a database is sharded into multiple *partitions* and each partition is **replicated** independently. Each partition has a **leader replica** that serializes all the transactions that span this partition to achieve isolation. This leader replicates the updates to a *majority quorum* of the partition replicas to achieve fault tolerance. Although they provide placements for strong consistent transactional workloads, their optimizations are tightly coupled with leader-based protocols and it does not apply to the many non-leader-based protocols that are widely used such as [6, 13, 16, 21, 25]. Also, their resulting optimal placement allocates all the partition leaders together in one datacenter. Placing all partition leaders in one datacenter introduces the risk of losing access to the entire data until the leaders are re-elected. In addition, the transactions that span a single partition might incur higher latency than the latency observed when the leader of each partition is placed closer to the clients that access this partition.

The rest of the paper is organized as follows. Section 2 explains the transaction model, the client requests, and the assumptions and limitations of application requirements. Although GPlacer can optimize the placement for different classes of commitment protocols, a Paxos-based protocol is used to explain the details of GPlacer. Section 3 formalizes the placement problem into an exhaustive search problem. Although the exhaustive search finds the optimal placement, it does not efficiently scale with the number of datacenters. Therefore, we introduce several placement heuristics that find sub-optimal placements while efficiently scale with the number of datacenters. Section 4 describes the counter-intuitive lessons learned during the development of GPlacer and their effect on the transaction latency. In Section 5, we evaluate the effect of the placement lessons on the transaction latency and the abort rate. We also evaluate the output and the performance of the proposed heuristics compared to the exhaustive search. In Section 6, we explain the changes that need to be done to extend GPlacer to optimize for other protocols. The paper is concluded in Section 7.

2 BACKGROUND

Global-scale placement is the problem of deciding which datacenters will store a full or a partial replica of an application’s data subject to a certain objective function. Objective functions can vary between minimizing the deployment monetary cost [19, 33] or minimizing the data access latency for a defined set of client operations [28]. Objective functions are always constrained by the application requirements (e.g., availability, upper bound access time, or bandwidth usage). In this section, we present our storage model and our assumptions about the workload distribution, the application requirements, and the objective function.

The universe of datacenters, denoted by DC , is defined as all the datacenters that can host an application¹ instance and/or a replica² of the database. We assume that the application is deployed on a subset of the datacenters $DC_{app} \subseteq DC$. The clients of the application are scattered around the globe and for simplicity, we assume that clients are collocated with their closest datacenter. The application is deployed in all the datacenters that have clients. However, these datacenters can be different

¹Application refers to the middle tier logic.

²Replica refers to a copy of the backend database.

Figure 3: The state-transition diagram of a distributed transaction adopted from [13].

from the datacenters that host replicas. $DC_{db} \subseteq DC$ is the subset of datacenters that host a database replica. We assume that the database is *partitioned* and all the partitions are *fully replicated* in DC_{db} .

2.1 The Transaction Management Protocol

The clients of the application access the globally-distributed storage by issuing transactions, which are collections of read and write operations followed by a commit or an abort. GPlacer considers transactions with *strong guarantees*, i.e., serializability [7]. Strong consistent transactions on globally-distributed data require more coordination than weaker forms of access like eventual consistency or single-key atomicity— thus making strongly consistent transactions more expensive. A strong consistency transactional interface is more natural to programmers and is required by many applications. Thus, we adopt such strong access semantics for GSDM as others did from both academia [16, 21] and industry [11].

We adopt the distributed transaction model proposed by Gray and Lamport [13]. Figure 3 shows the different states of a transaction and the corresponding execution phases. A client drives the execution of a transaction in three phases. The details of these three phases differ across different transaction management protocols. However, the abstract semantics behind these phases are the same for all the protocols that provide the same strong transactional guarantees. The three phases of a transaction are: the execution phase, the vote collection phase, and the apply phase.

During the execution phase, the transaction is in the working state when read and write operations are processed. We assume that writes are locally buffered at the client and the updates are sent to the data replicas in the second phase. This assumption is widely used in many geo-replicated transaction management protocols [11, 16, 21]. For a read operation, clients communicate with their read coordinator, r_c . r_c processes a read request and responds back to the client. The RTT between a client c and r_c is denoted by RTT_{c-to-r_c} and the time for r_c to process the read request is denoted by P_{r_c} . The total execution phase latency is denoted by $L_e = n_r \cdot (RTT_{c-to-r_c} + P_{r_c})$ where n_r is the average number of read requests per transaction. The transaction management protocol determines the values of n_r , RTT_{c-to-r_c} , and P_{r_c} . Some protocols assume that the client is the read coordinator. In such case, $RTT_{c-to-r_c} = 0$. Also, some protocols require that the client issues read requests one by one and others require that the client should batch all the reads in one request. The processing time P_{r_c} depends on how many replicas r_c should communicate with to serve a read request. In our model protocol, r_c has to communicate with a majority quorum to serve each read (we also consider read optimizations later in Section 2.2. As write requests are locally buffered, their effect on the execution phase latency is negligible. During the execution phase, a client might

decide to abort the transaction by simply moving the transaction to the aborted state. However, if the client decides to commit the transaction, the transaction is moved to the prepared state and the vote collection phase starts.

During the vote collection phase, the client sends the transaction’s details to the commit coordinator c_c which is responsible for coordinating with the other replicas to decide either to commit or to abort the transaction. Typically, the c_c uses either two-phase commit (2PC) with two-phase locking (2PL) [11] or quorum-based approaches (e.g., Paxos) with 2PL [21]. The vote collection phase can be mapped to the first phase of the 2PC or the first round of Paxos. The latency of the voting phase is denoted by $L_v = \frac{RTT_{c-to-c_c}}{2} + RTT_{c_c-to-p}$ where RTT_{c-to-c_c} is the RTT between c and c_c and RTT_{c_c-to-p} is the round-trip time between the c_c and the furthest participant p included in the voting process.

If the decision of the vote collection phase is to abort, the client is notified, the transaction is moved to the aborted state, the other participants are asynchronously updated, and the obtained locks are released. However, if the decision is to commit, c_c starts the apply phase by sending the apply message to all the participants. Upon receiving the apply message, the participants commit the transaction, release the locks, and respond back to the coordinator. c_c notifies the client and the transaction is moved to the committed state. The latency of the apply phase is denoted by $L_a = RTT_{c_c-to-p} + \frac{RTT_{c-to-c_c}}{2}$ as the apply phase takes a round of communication with the participants in addition to the time to inform the client about the decision. A transaction commit latency L_c is the time spent in the vote collection phase and the apply phase combined: $L_c = RTT_{c-to-c_c} + 2 \cdot RTT_{c_c-to-p}$. The transaction latency L_t is the time from the beginning till the end of a transaction: $L_t = L_e + L_c = n_r \cdot (RTT_{c-to-r_c} + P_{r_c}) + RTT_{c-to-c_c} + 2RTT_{c_c-to-p}$.

GPlacer optimizes the average overall transaction latency over all the clients in different datacenters. It is designed to optimize the placement for a wide class of transaction commitment protocols. In this paper, we focus on optimizing for multi-master Paxos-based protocols [13, 21] and for leader-based protocols [11] both on *partitioned fully replicated databases*. In multi-master Paxos, each replica can act as the commitment coordinator role and uses the two rounds of Paxos for both transaction isolation and replication. However, in leader-based protocols, a transaction can fall into one of two categories: single-partition transactions or multi-partition transactions. Single-partition transactions span only one partition and the isolation between transactions that span this partition is managed by the leader of this partition. Multi-partition transactions span multiple partitions and typically 2PC is used between the leaders of the partitions involved in a transaction to achieve isolation. In both categories, partition leaders replicate the updates of committed transactions to a majority quorum of their partition replicas using only the second round of Paxos.

In Section 3, we formalize GPlacer. We use Replicated Commit [21] as our protocol model where reads are served from a majority of the replicas and commits are done using the two rounds of Paxos for isolation and replication. In Section 2.2, we explain some commonly used optimization to reduce the execution phase latency. In Section 6, we explain how to extend GPlacer to optimize placement for leader-based protocols like Spanner [11].

2.2 Read optimizations

In this section, we present two widely-used read optimizations that are considered in GPlacer. A read request latency $L_r = (RTT_{c-t_0-r_c} + P_{r_c})$. The first optimization, **optimistic read**, aims to eliminate the read processing time P_{r_c} . The second optimization, **passive replica read** aims to eliminate the time to reach the coordinator $RTT_{c-t_0-r_c}$ and the processing time P_{r_c} by bringing a copy of the data to the client’s datacenter. We define two different types of replicas a datacenter can host: *active replica* or *passive replica*. An active replica contributes synchronously in the voting collection and the apply phases and can act the coordinator and the participant roles. However, a passive replica is a read-only replica. It is asynchronously updated after the transactions are committed.

Optimistic read aims to eliminate the read request processing time by optimistically reading data values from the closest active replica without any coordination with other active replicas. This optimization has been introduced before as early as in Postgres-R local reads [15] and as fast reads in Zookeeper [14]. Applying optimistic reads require validating the value read in the commit phase to guarantee the freshness of the optimistically read values in the execution phase. In Spanner [11], reads are served by the leader of each partition. However, optimistic reads can be beneficial by reading from the closest partition replica instead from the partition leader. In Replicated Commit [21], a client is required to read from a quorum of the replicas. Applying optimistic read reduces the read latency by reading from one replica instead of a quorum.

Passive replica read aims to completely eliminate the read latency by processing read requests from a local read-only replica or a **passive replica**. The reason behind this naming is that a passive replica does not participate actively in the commit decision. Therefore, adding more passive replicas does not affect the commit latency. However, these replicas need to be asynchronously updated which increases the bandwidth required per committed transaction. Also, having many passive replicas increases the deployment cost. Data read from a passive replica needs to be validated in the commit phase to guarantee freshness. If the data is frequently updated at the active replicas, the data values read from a passive replica will be stale which increases the transaction abort rate. The concept of passive replica read has also been introduced in [28] as *weak reads*.

GPlacer chooses the set of active replicas and the set of passive replicas. In addition, it assigns r_c and c_c for clients in every datacenter. Application requirements are given as inputs to the framework. GPlacer takes as an input the fault tolerance level f , the total number of replicas t , and the workload distribution. f determines the number of active replicas and t determines the number of passive replicas. The workload distribution determines which datacenters should have active replicas, which should have passive replicas, and which should not have a replica at all. GPlacer finds placements that optimize the overall average transaction latency for strongly consistent multi-row transaction workloads. However, systems that require non-transactional or weakly consistent operations can easily be tuned in GPlacer’s prototype but we do not discuss them since they were treated in previous works [4, 33].

3 FRAMEWORK FORMULATION

GPlacer finds the placement that minimizes the average transaction latency for partitioned fully replicated databases. As explained in Section 2, Paxos-based protocols use majority quorums for both transaction isolation and replication while leader-based protocols use majority quorums only for replication. Placement for Paxos-based protocols requires finding the subset of datacenters that should host replicas and the majority quorums used by the protocol. Leader-based protocols requires an additional step of placing the leaders of different database partitions on the replicas chosen in the first step. In Section 3.1, we formulate the placement problem into an exhaustive search model for Paxos-based protocols. This model evaluates all the possible placement combinations and returns one placement that achieves the minimum average transaction latency for a given workload. The model finds the placement $DC_{db} \subseteq DC$ and the majority quorums for each replica in this placement that optimizes the objective function. Although the model finds the optimal placement, due to the model complexity, it does not scale with the number of datacenters *when multiple cloud providers and edge datacenters are considered*. Therefore, in Section 3.2, we introduce two replica-placement heuristics to find placements that are close to optimal among hundreds of datacenters. The performance and the resulting placements of these heuristics are evaluated in Section 5.

3.1 Model formulation

The **inputs** of GPlacer fall into *two* categories:

- **Datacenter information:** this includes the number of datacenters $|DC|$ and the average RTT between every pair of the datacenters.
- **Application information:** this includes the number of datacenter scale outages f the deployment should tolerate and the application workload distribution. The workload distribution is denoted by c_i and represents the number of clients c at datacenter i .

The **outputs** of GPlacer include:

- The list of datacenters that should host a database replica.
- The read and the commit coordinator of clients at each datacenter. Clients at one datacenter share the same read and commit coordinators.

As the placement problem can be represented as an optimization model, we first implemented the placement model as an integer program and used the open source GLPK solver [2]. However, the solver could not efficiently scale with the number of datacenters. Many of the optimization constraints are conditional and to convert them to linear constraints, multiple binary output variables are introduced. The binary outputs and their related constraints are quadratic in the number of the datacenters $O(|DC|^2)$. In addition, GLPK solver introduced performance overhead. Therefore, to conduct a fair comparison with the replica-placement heuristics, we implement both the exhaustive search and the heuristics in Java. The **objective function** of the placement model is to minimize the average transaction latency of all the clients in all the datacenters. Algorithm 1 shows the details of the exhaustive search model.

Algorithm 1 evaluates all the possible subsets of the input datacenters of size $2f + 1$ and returns the one that minimizes the average transaction latency. The function *evalLat*, in line 3,

Algorithm 1 Evaluates all the possible placement combinations and returns the one that achieves the minimum average latency for given application requirements.

Input: $f, |DC|, RTT_{ij} \forall i, j \in DC$ and the Set $C = \{c_i \forall i \in DC\}$
Output: $DC_{db}, DC_{rc},$ and DC_{cc}

```

1:  $DC_{db}, DC_{rc}, DC_{cc} \leftarrow \{\}, minL \leftarrow MaxInt$ 
2: for each Set  $S \subset DC, |S| = 2f + 1$  do
3:    $l, S_{rc}, S_{cc} \leftarrow evalLat(S, RTT, C)$ 
4:   if  $l < minL$  then
5:      $minL \leftarrow l, DC_{db} \leftarrow S$ 
6:      $DC_{rc} \leftarrow S_{rc}, DC_{cc} \leftarrow S_{cc}$ 
7:   end if
8: end for

```

has different implementations based on the enabled read optimizations. When all the read optimizations are disabled, *evalLat* assumes that the read coordinator and the commit coordinator are collocated with the client who issues a transaction and reads are served from a majority quorum of replicas. However, if *optimistic read* is enabled, the read latency is updated to the RTT to the closest chosen replica from the client. Also, if *passive replica read* is enabled, the read latency is updated to zero as all the clients perform read operations from a local replica.

3.2 Replica-placement heuristics

Although Algorithm 1 finds the optimal placement among all the possible placements, it does not efficiently scale when the total number of the datacenters, $|DC|$, or the number of the replicas, $|DC_{db}|$, increases. Our experiments show that choosing 7 replicas out of 60 datacenters ($\binom{60}{7}$) takes 2 hours while choosing 7 replicas out of hundreds of datacenters (which is the case when we consider edge datacenters) could take years. Therefore, we present two replica-placement heuristics that efficiently find placements with sub-optimal average transaction latency. These replica-placement heuristics consider the *two main aspects* that affect the transaction latency; the latency between the clients and the replicas and the latency between the replicas each other. The running-time of these heuristics is polynomial in the total number of the datacenters. The performance and the resulting placements of these heuristics are compared to the exhaustive search results in Section 5.2.

The first replica-placement heuristic is shown in Algorithm 2. It uses an iterative greedy algorithm to choose the replicas. It starts with an empty set of chosen replicas $DC_{db} \leftarrow \{\}$, line 1, and at each iteration, it adds one replica to DC_{db} until $2f + 1$ replicas are chosen. The inner loop, lines 4-14, evaluates the effect of adding each unchosen replica to DC_{db} on the average transaction latency and the replica that achieves the minimum latency is added to DC_{db} , line 15. *evalLat* is the same evaluation function introduced in Algorithm 1 line 3. The intuition behind this heuristic is that choosing the best candidate at each step should lead to a solution that is optimal or close to the optimal.

The second replica-placement heuristic is presented in Algorithm 3. It is based on the K-Means algorithm. It assigns weights to every datacenter, initially equals to the number of clients in this datacenter; line 4. A datacenter weight is updated according to the number of quorums it participates at; line 13. Datacenter weights are iteratively updated and datacenters are sorted by their weights. The top $2f + 1$ datacenters are chosen to host replicas in lines 5 and 18. The algorithm evaluates the placement

Algorithm 2 Greedily adds one replica at a time achieving the minimum average latency at each iteration.

Input: $f, |DC|, RTT_{ij} \forall i, j \in DC$ and the Set $C = \{c_i \forall i \in DC\}$
Output: $DC_{db}, DC_{rc},$ and DC_{cc}

```

1:  $DC_{db}, DC_{rc}, DC_{cc} \leftarrow \{\}$ 
2: while  $|DC_{db}| < 2f + 1$  do
3:    $S \leftarrow DC_{db}, minL \leftarrow MaxInt, minDC \leftarrow \phi$ 
4:   for all  $dc \in DC$  do
5:     if  $dc \notin S$  then
6:        $S \leftarrow S \cup \{dc\}$ 
7:        $l, S_{rc}, S_{cc} \leftarrow evalLat(S, RTT, C)$ 
8:       if  $l < minL$  then
9:          $minL \leftarrow l, minDC \leftarrow dc$ 
10:         $DC_{rc} \leftarrow S_{rc}, DC_{cc} \leftarrow S_{cc}$ 
11:       end if
12:      $S \leftarrow S \setminus \{dc\}$ 
13:   end if
14:   end for
15:    $DC_{db} \leftarrow DC_{db} \cup \{minDC\}$ 
16: end while

```

in every iteration and stops when the average transaction latency converges. To avoid fast convergence to a local minimum, a minimum iteration count is required before terminating the algorithm; lines 1 and 7. The minimum evaluated placement is saved to make sure that the final placement does not achieve higher transaction latency than any placement that has been evaluated before.

Algorithm 3 Assigns weights to datacenters and iteratively chooses the top weighted $2f + 1$ to host replicas.

Input: $f, |DC|, RTT_{ij} \forall i, j \in DC, t$ and the Set $C = \{c_i \forall i \in DC\}$
Output: $DC_{db}, DC_{rc},$ and DC_{cc}

```

1:  $minIter \leftarrow t, iter \leftarrow 0$ 
2:  $DC_{db}, DC_{rc}, DC_{cc} \leftarrow \{\}$ 
3:  $l_{n-1}, l_n \leftarrow MaxInt$ 
4:  $Weights \leftarrow \{c_0, c_1, \dots, c_{|DC|}\}$  // Initialize weights with the
   number of clients at each datacenter.
5:  $DC_{db} \leftarrow top(sort(Weights), 2f + 1)$  // Sort on weights and
   choose a placement of the top  $2f + 1$ .
6:  $l_n, DC_{rc}, DC_{cc} \leftarrow evalLat(DC_{db}, RTT, C)$ 
7: while  $l_n < l_{n-1} || iter ++ < minIter$  do
8:    $l_{n-1} \leftarrow l_n$ 
9:    $NewW \leftarrow \{0, 0, \dots, 0\}$  // New Weights
10:  for all  $dc1 \in DC$  do
11:    for all  $dc2 \in DC$  do
12:      if  $dc2 \in nearestQuorum(dc1)$  then
13:         $NewW[dc2] += Weights[dc1]$ 
14:      end if
15:    end for
16:  end for
17:   $Weights \leftarrow NewW$ 
18:   $DC_{db} \leftarrow top(sort(Weights), 2f + 1)$ 
19:   $l_n, DC_{rc}, DC_{cc} \leftarrow evalLat(DC_{db}, RTT, C)$ 
20: end while

```

4 SURPRISING PLACEMENT LESSONS

During the development of GPlacer, we learned some counter-intuitive lessons about data placement that exploit the diversity

and the asymmetry of the WAN links to decrease the execution and the commit latencies, hence the transaction latency. (The transaction latency L_t is sum of the execution latency L_e and the commit latency L_c .) In this Section, we explain the details of these placement lessons and their effect on the transaction latency.

4.1 Request handoff

A client executes either read or commit requests. The latency of these two requests can be abstracted as the sum of: RTT_{c-to-c} , the round-trip time between the client and the request coordinator and L_p , the time for the coordinator to process the request.

Therefore, the request latency is mainly affected by the distance between the client and the coordinator, the distance between the coordinator and the participants, and finally the number of communication rounds required between the coordinator and the participants to serve the request. Different transaction management protocols choose the coordinator based on some intuitive heuristics. In [21], Mahmoud et al. assume that the *client* is the coordinator of a transaction. In Spanner [11], the 2PC coordinator is randomly chosen from the leaders of the partitions involved in a multi-partition transaction. In [23], Nawab et al. choose the coordinator to be the closest replica to the client. However, the choice of the coordinator can drastically affect the request latency. To illustrate this effect, we provide two examples of 2PC and Paxos deployments to show that carefully choosing the coordinator can save up to 48% of the average latency.

Two-phase commit: assume there are three data partitions X , Y , and Z deployed in three AWS datacenters in SP , V , and I respectively. Now, assume a client in datacenter I wants to commit a transaction t that updates the elements $x_1 \in X$, $y_1 \in Y$, and $z_1 \in Z$. The commit latency at any coordinator equals to double the RTT between the coordinator and the furthest involved partition leader. Therefore, if the client chooses the leader of partition Z in datacenter I to be the commit coordinator, the resulting commit latency is $2 \cdot \max(RTT_{IV}, RTT_{ISP}) = 2 \cdot 185 = 370ms$. Although the time between the client and the coordinator is neglected, the latency is still high because the coordinator is relatively far from SP . However, if the client chooses the leader of partition Y in datacenter V to be the commit coordinator, the resulting commit latency is $RTT_{IV} + 2 \cdot \max(RTT_{VI}, RTT_{VSP}) = 73 + 2 \cdot 121 = 315ms$ saving around 15% of the commit latency without modifying any constraint of the original 2PC protocol. Also, when datacenter V is the 2PC coordinator, the participant at datacenter I will be notified about the commit decision after $\frac{RTT_{IV}}{2} + \max(RTT_{VI}, RTT_{VSP}) + \frac{RTT_{IV}}{2} = 36.5 + 121 + 36.5 = 194ms$. The participant at datacenter I can directly inform the client with the decision saving around 48% of the latency obtained when I is chosen to be the coordinator.

Paxos: assume there are five replicas of the database in datacenters I , V , SP , O , and C as shown in Figure 4. A client in datacenter SP wants to commit a transaction which requires to execute the two rounds of Paxos to reach a consensus about the commit decision. The latency of the two rounds of Paxos equals to double the RTT between the coordinator and the furthest replica in the closest majority to the coordinator. Therefore, if the client in SP chooses the replica in SP to be the coordinator, the resulting commit latency equals to $2 \cdot \max(RTT_{SPSP}, RTT_{SPV}, RTT_{SPO}) = 2 \cdot \max(1, 121, 182) = 2 \cdot 182 = 364ms$. However, if the client in SP , delegates the coordination to the replica in V , the resulting commit latency will be $RTT_{SPV} + 2 \cdot \max(RTT_{VV}, RTT_{VI}, RTT_{VC}) =$

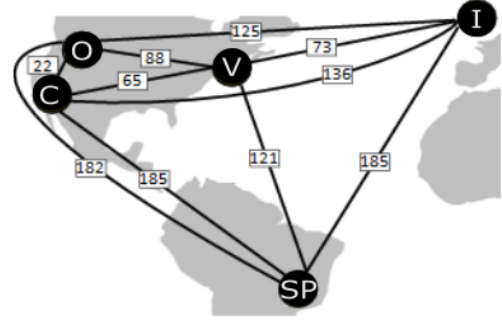

Figure 4: Five replicas of the database are deployed in datacenters I , V , SP , O , and C .

$121 + 2 \cdot 73 = 267ms$ saving around 26.6% of the commit latency obtained when SP is chosen to be the coordinator.

We presented a primitive version of the handoff idea in [34]. To generalize, for any request R from a client at datacenter A , it might be beneficial to handoff this request to a replica at datacenter B if the summation of RTT_{AB} and the time for datacenter B to serve this request L_B are less than L_A , the time to serve this request at datacenter A . In other words, request handoff from datacenter A to datacenter B is beneficial if $L_A > RTT_{AB} + L_B$. This optimization is widely applicable on different protocols and different request types.

4.2 Cover all the optimization aspects

During our SIGMOD demo [34], we ask the participants to place 5 data replicas in 5 out of the 9 datacenters shown in Figure 5. The participants are told that the data is fully replicated in the 5 chosen datacenters and the commitment protocol uses the two rounds of Paxos for isolation and replication and reads are served from the closest quorum. In addition, optimistic read and passive replica reads can be used and there is no restriction on the number of passive replicas that can be used. Finally, the workload at each site is represented by the number of blue clients at each datacenter and handoff can be used when possible.

When passive replica read is enabled and there is no restriction on the number of passive replicas assuming low contention, the commit latency contributes the most to the average transaction latency. As explained in Section 2, the commit latency is expressed as: $L_c = RTT_{c-to-c} + 2 \cdot RTT_{c-to-p}$.

Most of the demo participants tried to optimize the time to reach the commit coordinator c_c by placing the active replicas at the datacenters that have clients. Although this strategy is intuitive and reduces the time to reach c_c to zero, it does not find the placement that minimizes the overall average commit latency. This happens because the datacenters that have clients happen to be far from each other and the time to reach a quorum of participants is maximized using this strategy.

Figure 5 shows that the placement that minimizes the commit latency must consider all the optimization aspects of the commit latency. It places quorums of replicas close to each other (quorums are shown using the dotted curves) and uses handoff to handoff the commitment to replicas that can quickly form a quorum (handoff is shown using solid arrows). **Surprisingly, in this example, non of the chosen replicas are placed in datacenters that have clients.**

Figure 5: A placement scenario that shows the importance of considering different optimization aspects to minimize the average transaction latency.

5 EVALUATION

A performance evaluation study of the request handoff, the read optimizations, and the proposed heuristics is conducted in this section. In our study, we first evaluate the effect of the read optimizations and the request handoff on execution and commit latencies in Section 5.1. In Section 5.2, we evaluate the performance of the replica-placement heuristics introduced in Section 3.2. We compare the running time and the resulting placement latencies of these heuristics to the running time and the placement latencies of the exhaustive search algorithm in Algorithm 1.

5.1 Placement optimizations

5.1.1 Experimental setup. We use the placement scenario in Figure 4 to evaluate the effect of read optimizations and request handoff on the transaction latency. Request handoff exploits the diversity of the WAN links to decrease the transaction latency and this scenario shows a good example of this diversity, $RTT_{SPC} > 8RTT_{OC}$. Amazon EC2 machines in Ireland (*I*), Virginia (*V*), São Paulo (*SP*), Oregon (*O*), and California (*C*) datacenters are leveraged as infrastructure for our experiments. Larger machines are used in datacenters *C* and *O* so that we can measure the handoff effect without causing throttling in datacenters *C* and *O*. Compute optimized machines are used because computing is the main source of contention in our experiments. We use one compute optimized (c4.large) machine with 2 vCPUs and 3.75 GB of RAM in datacenters *V*, *I*, and *SP* while we use one compute optimized (c3.4xlarge) machine with 16 vCPUs and 30 GB of RAM in datacenters *C* and *O*. We assign active replicas to servers in *C*, *O*, and *V* while we assign passive replicas to servers in *I* and *SP*. These machines use HBase [3] as the underlying persistent data store. The average RTTs observed between different datacenters are shown in Table 1. The observed RTTs are sampled over 48 hours using AWS nano machines pinging each other. The data is fully replicated in all five datacenters and an optimistic Paxos-based concurrency control protocol is used. A transaction requires two majority rounds to commit and the read-set is validated at commit time. We implemented multiple versions of the protocol based on how read requests are processed in the execution phase. *Maj0* is conservative and requires read requests to be processed from a majority of the active replicas. *Maj1* implements the optimistic read optimization and requires read requests to be processed from one active replica. *Maj2* implements the optimistic read and passive replica optimizations and processes read requests from either active or passive replica. Transaction commitment is implemented the same way in all three versions.

The commit handoff optimization is applied on all three versions and it only changes the way a commit coordinator is chosen. For this, we implemented *Maj0h*, *Maj1h*, and *Maj2h* to apply the handoff optimization on the three protocol implementations. We compare the average obtained commit and transaction latencies for all the three implementations with and without applying the handoff optimization. In addition, we compare transaction throughputs and abort rates for all three implementations.

Dedicated client machines in each datacenter generate client workloads. Each client machine is configured with a read coordinator and a commit coordinator. Also, client machines execute a workload thread per client. Clients are uniformly distributed among the 5 datacenters in all the experiments unless otherwise stated. Client machines use YCSB [10] to generate workloads. Since YCSB is not designed to generate multi-record transactions, we use Transactional YCSB (T-YCSB) [12], an extended version of YCSB that generates multi-record transactions, for this purpose. T-YCSB generates transactions that consist of read and write operations on different data records followed by a commit. Each transaction is configured to have five operations. The ratio of read to write operations is 1:1 unless otherwise specified. Read and write operations choose a key from a pool of 50000 keys following a zipfian distribution. This small number of keys enables us to observe the performance of the system under contention. Each client can have only one outgoing transaction. Clients submit a new transaction as soon as they receive a decision for their outgoing transaction. Each experiment runs for 10 minutes.

5.1.2 Experimental results. Transaction latency. Active replicas are placed in only three datacenters *C*, *O*, and *V*. Therefore, a majority quorum consists of *two* active replicas. The *Maj0* implementation assumes that clients at each datacenter drive their transactions (no handoff). Also, it assumes that reads have to be processed from at least two active replicas and commits have to be accepted by and applied to at least two active replicas. *Maj0h* allows clients in *SP* to handoff their commit to *O* and clients in *I* to handoff their commits to *C*. *Maj1h* and *Maj2h* allow the same handoff plans while enabling optimistic reads in *Maj1h* and optimistic reads and passive replica reads in *Maj2h*.

Figure 6 shows the effect of increasing the number of clients from 10 to 200 on transaction latency. As a transaction requires two round trips to a quorum of two active replicas to commit, clients in *C* and *O* have their location as an advantage that they can always achieve lower transaction latency and higher throughput than clients in other sites as long as the number of clients is equal in all the datacenters. Therefore, to measure the effect of the placement optimizations on transaction latency in isolation from the throughput, we use the normalized transaction latency as a comparison metric between different implementations. The normalized transaction latency L_{norm} is the average of the average transaction latency in all the datacenters $L_{norm} = \frac{L_C + L_O + L_V + L_I + L_{SP}}{5}$ where L_i is the average transaction latency at datacenter *i*. As shown in Figure 6a, applying read optimizations in *Maj2* significantly enhances L_{norm} by 48% compared to *Maj0*. Also, the handoff in *Maj2h* enhances L_{norm} by 26% compared to *Maj2* leading to a total enhancement of 60% compared to *Maj0*. Increasing the number of clients beyond 100 (20 at each datacenter) causes throttling in server machines. This throttling leads to an increase in the overall transaction latency and a decrease in the benefit obtained from the applied optimizations. Figures 6b and 6c shows the effect of applying read optimizations and handoff on transaction latencies at *I* and *SP*

(a) Overall normalized transaction latency.

(b) Transaction latency in Ireland.

(c) Transaction latency in São Paulo.

(d) Transaction latency in California.

Figure 6: Transaction latency as number of clients increases. Figures 6a, 6b, 6c, and 6d share one plotting legend.

respectively. As shown, read optimizations and handoff together in *Maj2h* enhances transaction latency compared to *Maj0* by 62% and 68% in *I* and *SP* respectively. Also, handoff in *Maj2h* saves 30% and 38% of the transaction latency compared to *Maj2* for clients in *I* and *SP*. Figure 6d presents the effect of the placement optimizations on the transaction latency in *C*. As shown, read optimizations significantly reduce the transaction latency in *C* by 49% as reads are served locally. This applies until throttling happens. After throttling, the transaction latency in *C* increases for *Maj2* because serving reads locally in all the datacenters increases the frequency of the transactions that are ready to commit in the system causing more contention in datacenters *C* and *O*. The handoff slightly increases the transaction latency in *C* and its negative effect is negligible before the throttling happens.

Figure 7: Overall average commit latency as number of clients increases.

Commit latency. Figure 7 shows the effect of the placement optimizations on the overall average commit latency. While the normalized transaction latency is significantly enhanced by applying read optimizations, read optimizations negatively affect the overall commit latency. By reducing the execution phase latency, the number of active transactions that are ready to commit increases and leads to an increase in the commit latency. However, applying handoff enhances the overall average commit latency by 10 – 15% in *Maj0h*, *Maj1h*, and *Maj2h* compared to *Maj0*, *Maj1*, and *Maj2* respectively.

(a) Overall throughput.

(b) Throughput in Ireland.

(c) Throughput in São Paulo.

Figure 8: Throughput as number of clients increases. Figures 8a, 8b, and 8c share one plotting legend.

Figure 9: Overall abort rate as number of clients increases.

Throughput. The throughput, measured by number of operations per second, is presented in Figure 8. Figure 8a shows that applying read optimizations in *Maj1* and *Maj2* achieves 2x the throughput in *Maj0* until hitting the thrashing point (≥ 100 clients). After that, throughput is slightly higher in *Maj1*, *Maj2*, and *Maj1h* and about 8% higher in *Maj2h*. Throughput results in *I* and *SP* are shown in Figures 8b and 8c. These figures show a significant increase of 100% between *Maj0* and *Maj2h* in *I* and 170% between the same implementations in *SP*. Applying hand-off not only significantly benefits *I* and *SP* but also benefits the overall throughput.

Abort rate. The abort rates are shown in Figure 9. The abort rate is a result of many factors, such as the amount of contention, the number of concurrent transactions, the lifetime of a transaction, among others. As shown, the overall abort rate is below 1% for all six different implementations. However, we observed two important patterns that are worth analyzing. First, read optimizations increase the abort rate by 100% for some experiment runs. Obtaining the read-set from a local copy increases the chances of reading a stale value and hence increasing transaction aborts. However, these stale values has a small life-time as all the passive replicas are asynchronously updated. Second, handoff decreases the abort rate by 25–30% because a transaction’s lifetime is shortened by reducing the overall transaction latency and specifically the high latency transactions in *I* and *SP*.

5.2 Replica-placement heuristics

We evaluate the replica-placement heuristics in this section. This evaluation tries to answer two questions: *How fast can these heuristics find a placement? and how good is this placement compared to the optimal placement?* For that, we compare the performance and the resulting placements of the proposed heuristics in Algorithms 2 and 3 to the performance and the resulting placements of the exhaustive search in Algorithm 1 at scale. We assume that optimistic reads and passive replica reads are enabled. Therefore, we use commit latency as a comparison metric as the transaction execution latency is negligible when reads and writes are served locally and none of the replicas are overloaded with requests. The proposed heuristics and the exhaustive search programs are all implemented in Java which allows us to conduct a fair comparison. The exhaustive search algorithm evaluates all possible placement combinations and returns the placement that achieves the minimum average commit latency for a certain workload. Algorithm 2 introduces a greedy heuristic that adds one replica at a time achieving the minimum average transaction latency at each iteration. Algorithm 3 is inspired by the K-Means algorithm and it assigns initial weight to each datacenter equals to the number of clients at this datacenter. Weights are updated

based on the quorums a datacenter participates at and based on handoff.

Finding the optimal placement of five replicas within ten datacenters can be efficiently done. It requires the evaluation of only 252 different placements and the exhaustive search is sufficient in this case. However, in a more realistic setting, the number of datacenters around the globe, including edge datacenters, may easily exceed 4000 datacenters [1]. Also, it has been shown in [33] that it is economically efficient to deploy storage in datacenters of different cloud providers as non of them provides cheaper storage in all the deployment regions. To choose five datacenters out of 4000 datacenters requires to evaluate $8.5e+15$ different placements. To get a sense of the space size and the running time, we evaluated the exhaustive search algorithm and the heuristics proposed in Section 3.2 using different datasets.

First, we generate multiple datasets of datacenters *DC* distributed around the globe with randomly chosen round-trip time $0 \leq RTT \leq 500$ ms. We also make sure that the triangle inequality holds among any three datacenters such that $\forall A, B, C \in DC, RTT_{AB} + RTT_{BC} \geq RTT_{AC}$. Second, we distribute the workload around the generated datacenters with ratios between 0–10. We use the generated data as inputs to both the exhaustive search program and the placement heuristics. These experiments are run locally on an Intel Core i5-3210M CPU 2.50GHz with 8GB of RAM.

Running time. In this part of the evaluation, we answer the first question, namely *How fast can these heuristics find a placement?* Figures 10a and 10b show a running time comparison between the exhaustive search and the placement heuristics when the number of replicas are 5 and 7 respectively. As shown, the running time of the exhaustive search grows exponentially with the number of datacenters while the running time of both heuristics are negligible (< 1 second). Also, the exponential power significantly increases as the number of replicas required to be placed increases. This shows that it is infeasible to use the exhaustive search when the datacenter set size exceeds few tens.

Resulting placements. The second part of the evaluation answers the second question about the quality of the placements found by the proposed heuristics. We compare the commit latency of the resulting placement to the optimal commit latency of the resulting placement decided by the exhaustive search. Figures 11a and 11b show the relative commit latency of the heuristics compared to the optimal commit latency when the number of placed replicas are 5 and 7 respectively. In these figures, the optimal commit latency is represented by 1.0. A relative comparison of the commit latency is shown for both the placement heuristics and the best of the two heuristics as well. As shown, the best of the two heuristics is optimal in 70% of the cases and within 5%–11% of the optimal in the rest of the cases. As the running times of both heuristics is negligible, we can always run both the heuristics and choose the best placement out of the two results. Figure 11 suggests that neither heuristics beats the other in all cases.

6 GPLACER EXTENSIONS

In this section, we discuss how GPLacer can be extended to optimize the placement for leader-based protocols. In leader-based protocols, a transaction can fall into one of two categories: single-partition transactions or multi-partition transactions. Single-partition transactions span only one partition and the isolation between transactions that span this partition is managed by the

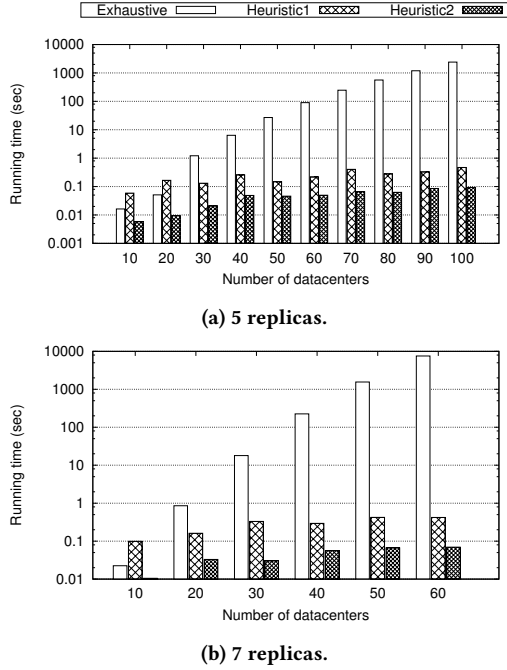

Figure 10: The running time (seconds), in log scale, of exhaustive search and placement heuristics as number of datacenters increases. Figures 10a and 10b show the running time when 5 replicas and 7 replicas are chosen respectively. Both figures share one plotting legend.

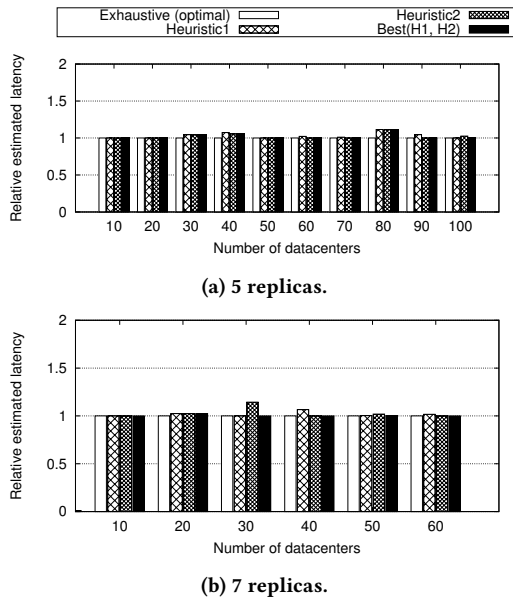

Figure 11: A comparison of the resulting commit latency of placements by exhaustive search and placement heuristics as number of datacenters increases. Figures 11a and 11b compare the estimated latency when 5 replicas and 7 replicas are chosen respectively. Both figures share one plotting legend.

leader of this partition. Multi-partition transactions span multiple partitions and typically 2PC is used between the leaders of the partitions involved in a transaction to achieve isolation. In both

categories, partition leaders replicate the updates of committed transactions to a majority quorum of their partition replicas using only the second round of Paxos.

The average transaction latency for leader-based protocols is affected by the following factors:

- The distance between the client and the partition leader
- The distance between the partition leader and its replicas
- The distance between different partition leaders involved in multi-partition transactions
- The percentage of multi-partition transactions P_{mp-txn} (how often 2PC is required to be executed)

The first two factors mainly affect single-partition transactions while the last two factors mainly affect multi-partition transactions. Finding the optimal placement for leader-based protocols can easily become impractical. Consider a database with p partitions and we want to place the leaders of these partitions on r replicas. There are r^p different placement combinations and finding the optimal placement by checking all the combinations is impractical. For example, if a database has 500 partitions and we want to place these partitions among 5 replicas. To find the optimal leader placements, 5^{500} different combinations need to be evaluated. Therefore, different heuristics are usually used to limit the search space.

6.1 Leader-placement heuristics

A solution that *considers all the optimization aspects* should adapt the placement based on the percentage of the multi-partition transactions P_{mp-txn} . Sharov et al. [28] place the leaders of all the partitions in one datacenter. Algorithm 4 implements the leader-placement heuristic introduced in [28]. It iterates over all the replicas, line 4, and evaluates the latency assuming that all the partition leaders are placed in the currently evaluated replica. The replica that achieves the minimum latency is returned. This heuristic optimizes the placement when P_{mp-txn} is high. However, when P_{mp-txn} is low, placing the leaders of all the partitions in one datacenter can hurt the performance in addition to introducing a single point of failure.

The second heuristic is to *independently* place the leaders of different partitions. For every partition, place its leader at the same datacenter where it is accessed the most. This heuristic optimizes the placement when P_{mp-txn} is low and partitions are mostly accessed from one datacenter.

Algorithm 4 Finds datacenter $dc_l \in DC$ that achieves the minimum average transaction latency assuming all the partition leaders are put together in one datacenter.

Input: $DC, RTT_{ij} \forall i, j \in DC$, and $c_i \forall i \in DC$

Output: dc_l

- 1: $dc_l \leftarrow \emptyset, l \leftarrow MaxInt$
 - 2: **for all** $j \in DC$ **do**
 - 3: $tempL \leftarrow 0$
 - 4: **for all** $i \in DC$ **do**
 - 5: $tempL+ = c_i \cdot (RTT_{ij} + q_j)$ // q_j is the time for replica j to reach its closest quorum from DC .
 - 6: **end for**
 - 7: **if** $tempL < l$ **then**
 - 8: $l \leftarrow tempL, dc_l \leftarrow j$
 - 9: **end if**
 - 10: **end for**
-

Placing all the partition leaders in one datacenter favors multi-partition transactions while independently placing them in multiple datacenters favors single-partition transactions. When the workload is a mixture of both transaction categories, both heuristics fail to optimize the placement. Therefore, we present a third heuristic that optimizes the placement when the workload is divided between the two categories. This heuristic uses GPlacer to find the set of $2f + 1$ datacenters that should host a replica DC_{db} according the workload distribution. Then it runs Algorithm 5 to independently place the leaders of each partition among the chosen replicas. The second heuristic independently places partition leaders in the universe of all datacenters DC while the third heuristic limits the placement to the set of datacenters that are chosen by GPlacer DC_{db} . In Section 6.2, we compare the resulting placements of the three heuristics.

Algorithm 5 Places the leader of each partition among the chosen replicas and closer to the clients who access this partition the most.

Input: DC_{db} , and $p_i \forall i \in DC$ and $\forall p \in P // P$ is the set of all partitions and p_i is the percentage of access for partition p from datacenter i .

Output: $\forall p \in P l_p$

- 1: **for all** $p \in P$ **do**
- 2: $i \leftarrow \max(\forall_{j \in DC} p_j)$
- 3: $l_p \leftarrow \text{nearest}(dc \in DC_{db}, i)$ // returns the nearest datacenter $dc \in DC_{db}$ to datacenter i .
- 4: **end for**

6.2 Leader-placement heuristics evaluation

We compare the expected average commit latency of the resulting leader placements using the three heuristics. The percentage of distributed multi-partition transactions is varied and the expected commit latency is calculated for the three heuristics. Before placing partition leaders in the third heuristic, we use the exhaustive search algorithm to find DC_{db} . Then, we use the heuristic to place partition leaders among the chosen replicas.

The commit latency of a single partition transaction is estimated as the RTT from the client datacenter to the partition leader datacenter plus the RTT from the partition leader datacenter to a majority of the partition replicas. The commit latency of a multi-partition transaction requires an addition 2PC between the involved partitions. In our evaluation, we assume that the 2PC added latency is negligible if all the involved partition leaders are placed together and two round-trips to all the partition leaders if they are not placed together. This assumption favors algorithm 4 over our proposed heuristic in algorithm 5.

Figure 12 shows the expected commit latency when the three heuristics are used to place partition leaders. The expected commit latency is shown in a log scale in the y-axis and the percentage of the multi-partition transaction is shown in the x-axis. In this scenario, clients are distributed among 10 datacenters and 5 datacenters host replicas for heuristic 3. A transaction has to be replicated to 3 replicas before it is committed. As heuristic 1 places all partition leaders in one datacenters, the average commit latency does not change with the percentage of multi-partition transactions. Therefore, the average estimated commit latency is a horizontal line. However, for heuristics 2 and 3, increasing the percentage of multi-partition transactions boosts the average commit latency as the cost of the 2PC between all partition leaders increases. Figure 12 suggests that heuristic 2 should be used to place

partition leaders as long as P_{mp-txn} is low (below 9%). Heuristic 3 should be used when $9\% < P_{mp-txn} < 25\%$ and heuristic 1 should be used if P_{mp-txn} is high (above 25%). Typically, the percentage of multi-partition transactions is $< 10\%$ [31, 32].

Figure 12: A commit latency comparison between leader-placement heuristics as the percentage of multi-partition transaction increases.

It is important to mention that the commit latency crossing lines between the three heuristics are different for different scenarios and estimates should be calculated a priori to decide which leader placement achieves the minimum commit latency for a given scenario. Our framework evaluates the outcomes of the three heuristics and chooses the placement that achieves the minimum latency.

7 CONCLUSION

In this paper, we address the data placement problem of geo-replicated databases with strong consistency guarantees. We present different placement optimizations to reduce transactions execution latency and commit latency. These placement optimizations are widely applied on different distributed transaction management protocols. Our evaluation shows that applying the read optimizations and the request handoff optimization could reduce transaction latency by 68% and increases throughput by 170%. To address the placement problem at scale, we propose different placement heuristics that can efficiently find sub-optimal placements within 5–10% of the optimal placements. Experiments show that these heuristics are able to scale without significantly reducing the quality of the resulting placements from the optimal placement. Finally, we discuss three partition leader placement heuristics to place partition leaders. Experiments show that non of the three heuristics is superior when the percentage of multi-partition transactions changes. Unlike in [28] which uses one heuristic to place partition leaders regardless of the percentage of multi-partition transactions, our framework switches between different heuristics when the percentage of multi-partition transactions changes.

ABSTRACT

Online analytics, in most advanced scientific and business applications, rely heavily on the efficient execution of large numbers of Aggregate Continuous Queries (ACQs). Incremental sliding-window computation is used in the state-of-the-art ACQ processing algorithms (*FlatFIT*, *TwoStacks*, and *DABA*) to avoid the re-evaluation of the aggregate value of the window from scratch on every update. *FlatFIT* and *TwoStacks* aim to increase throughput, and *DABA* to minimize latency, while all process invertible and non-invertible aggregates uniformly. In this paper, we propose a novel algorithm, *SlickDeque*, that distinguishes the execution between invertible and non-invertible aggregates and offers better throughput and latency for both types. In addition, our method requires less memory and efficiently supports *multi-ACQ* processing. We theoretically show the time and space complexity advantages of *SlickDeque* and experimentally validate them using a real workload. Specifically, our approach maintains 283% lower latency spikes on average while achieving up to 19% throughput improvement in a single query environment and up to 345% improvement in a multi-query environment over the state-of-the-art approaches along with requiring up to 5 times less memory.

1 INTRODUCTION

Motivation Data stream processing has gained momentum in many applications that require quick responses based on incoming high velocity data flows. A representative example is a stock market application, where multiple clients monitor the price fluctuations of the stocks. In this setting, a system needs to be able to efficiently answer analytical queries (e.g., average stock revenue, profit margin per stock, etc.) for different clients, each one with (possibly) different timing requirements. Efficient data stream processing is also important in monitoring applications in the fields of health care, science, social media, and network control.

Data Stream Management Systems (DSMS) [1–3, 22, 30] have been proposed as the most suitable systems for handling such data flows on-the-fly and in real time. In a DSMS, clients register their analytical queries on incoming data streams. These queries continuously aggregate streaming data, and as such they are called Aggregate Continuous Queries (ACQs). ACQs are typically associated with a *range* (r) and a *slide* (s) (also referred to as *window* and *shift* [15]), which can be either count or time-based. A slide denotes the period at which an ACQ updates its answer; a range is the window for which the statistics are calculated.

An ACQ requires the DSMS to keep state over time while performing aggregations. Normally, DSMSs only keep the window of the most recent data, and produce the answers by running aggregate queries over it. It has been shown that in sliding-window

stream processing, it is beneficial to use *incremental evaluation*, which involves storing and reusing calculations performed over the unchanged parts of the window, rather than performing the re-evaluation of the entire window after each update [10, 20]. Incremental evaluation typically runs partial aggregations on the data and produces the answer by performing the final aggregation over the partial results [18, 19].

Problem Statement Handling of aggregate operations that are both *invertible* and *non-invertible* proved to be essential in domains such as finance and science. *Invertible* operations include Sum, Product, Count, Average, and Standard Deviation, while *non-invertible* operations include Max, Min, Range, Alphabetical Max (for strings), ArgMax of Cosine, and ArgMin of x^2 . It was shown previously that *invertible* operations can be processed efficiently by maintaining a running Sum (or other aggregation), and invoking the inverse operation (such as Subtract) on every expiring tuple, however *non-invertible* operations require more effort to be processed efficiently and remain a challenge.

The current state-of-the-art solutions for processing ACQs, *FlatFIT* [26] and *TwoStacks* [28], aim to increase throughput and *DABA* [28], to minimize latency. These solutions process invertible and non-invertible aggregates uniformly, which negatively affects their performance with increasing workloads. To address the aforementioned shortcomings, in this paper we propose a novel solution named *SlickDeque*, which handles aggregate operations differently based on their invertibility property. The invertible operations are processed using *SlickDeque* (Inv), our new modified *Panes* (Inv) approach, while non-invertible ACQs are processed with *SlickDeque* (Non-Inv), our novel deque-based algorithm that intelligently maintains and utilizes intermediate partial aggregates allowing a greater level of reuse of previously calculated results. The separation based on invertibility leads to exceptional throughput and latency for both invertible and non-invertible operations in systems with heavy workloads.

We consider also *multi-query*, *multi-tenant* environments, where large numbers of ACQs with different ranges and slides operate on the same data stream, calculating similar aggregations.

Contributions We make the following contributions:

- We propose a novel solution for processing ACQs, *SlickDeque*, which processes invertible and non-invertible operations differently. *SlickDeque* is applicable for both single query and multi-query environments. (Section 3)
- We theoretically evaluate *SlickDeque* and show that it achieves better time and space complexities compared to the state-of-the-art *FlatFIT*, *TwoStacks*, and *DABA* solutions. To our knowledge, there are no prior algorithms that can achieve the same time and space complexities without loss of query generality in terms of supported aggregate operations. (Section 4)
- We experimentally evaluate *SlickDeque* based on a real dataset and show that it significantly outperforms state-of-the-art techniques in all tested scenarios by increasing the ACQ

Figure 1: Panes Technique

Figure 2: Paired Window Technique

throughput by up to 19% in a single query environment and by up to 345% in a multi-query environment, while maintaining 283% lower latency spikes on average and reducing memory consumption by up to 5 times. We also show that our approach becomes superior to the state-of-the-art approaches starting at window sizes as small as eight tuples with its benefits increasing rapidly, making *SlickDeque* widely applicable for processing *ACQs* in a variety of *DSMSs*. (Section 5)

2 BACKGROUND & RELATED WORK

In this section we briefly review the underlying concepts of our work, which are the incremental sliding-window computation techniques. These could be broadly divided into *partial aggregation* and *final aggregation*. We also review other related work.

2.1 Partial aggregation

Partial aggregation can be thought of as the buffering of partial results until the query result needs to be returned by the final aggregation. Since partial aggregation allows some buffering before the result needs to be processed by a more expensive final aggregator and each buffered partial can be reused multiple times as part of final aggregations, the use of the CPU and memory resources to maintain the partials can be amortized. The following techniques aiming to reduce the number of partials were proposed for partial aggregations.

Panes [19] was proposed as the first partial aggregation technique for processing *ACQs* efficiently. The idea behind it is to partition the incoming datastream into “*panes*” (we refer to them as *partials*), and maintain just one aggregate value for each partial. This way every incoming tuple will affect the aggregate value for just the current partial, and when the whole aggregate is due to be reported, the answer is assembled by performing the final aggregation over all the partials in the current window. Therefore, each new partial will be reused multiple times for different final aggregations. For example, in Fig. 1 partial *P5* is used 3 times as part of the final aggregations *F1*, *F2*, and *F3*.

Paired Window technique, or simply *Pairs* [18], was introduced to reduce by a factor of 2 the number of partials in a window in cases where the range is not divisible by the slide, reducing the

Figure 3: Cutty-slicing Technique

Figure 4: FlatFAT Technique

memory consumption and accelerating the final aggregations. As illustrated in Fig. 2, two fragment lengths are used, f_1 and f_2 , where $f_2 = range \% slide$ and $f_1 = slide - f_2$.

Cutty-slicing was proposed as part of the *Cutty* optimizer [8], and it starts each new partial only at positions that signify the beginning of new windows. This way the final aggregation can execute in the middle of the partial aggregation calculation by accessing the current value in the partial (Fig. 3). This reduces the number of partials per window by a factor of two compared to *Pairs* but it comes at a cost: additional punctuations have to be sent over the data stream to the execution module to indicate the beginnings of the new partials, which reduces the effective bandwidth of the stream and can slow down the system, especially if the workload includes a large number of queries with small windows.

2.2 Final Aggregation

The goal of final aggregation is to produce the result of a query by utilizing the partials. Initially it was performed by simply iterating over them and constructing the answer [18, 19]. For example the *Panes* technique (which we consider *Naive* in this work) in Fig. 1 performs a final aggregation *F1* by iterating over partials *P2*, *P3*, *P4*, and *P5*. Naturally, such a solution quickly became outdated due to the increasing workloads that created bottlenecks in the final aggregator. To improve this, several final aggregation techniques have been proposed [5, 21, 26–29, 31].

Panes (Inv) [19] (or *Panes* for Invertible (Differential) Aggregate Queries) was proposed to efficiently process invertible aggregates, and it works by maintaining a running aggregate (e.g. running Sum), and invoking the inverse operation (e.g. Subtract) on every expiring tuple. This algorithm (with minor differences) was also proposed as *R-Int* [5] and *Subtract-on-Evict* [28]. In this paper we extend this approach into *SlickDeque (Inv)*, which can do multi-query processing by maintaining a running aggregate for each query with a distinct range registered on the data stream.

Despite being very effective, *Panes (Inv)* is only applicable for invertible operations. In order to allow greater generality in query processing, the following techniques have been introduced.

FlatFAT [29] (or Flat Fixed-sized Aggregator) is a final aggregation approach which stores tuples in a pre-allocated pointer-less

Figure 5: B-Int Technique

tree-based data structure (Fig. 4), and was later extended [8] to allow partial aggregation and multi-query processing by allowing to store partial aggregates as tree leaves. Each internal node of the tree contains an aggregate of its two children. New partials are inserted into the leaves of the binary tree left-to-right. The leaves form a circular array, meaning that after inserting a value to the rightmost leaf, the next insert will go into the leftmost one. Each insert triggers the update procedure, which is performed by walking the tree bottom-up and updating all internal nodes. An example of an update operation on leaf 15 is illustrated with green squares in Fig. 4. The look-up of the answer in *FlatFAT* is performed by returning the root node value if a query requires the result for the maximum window, or by aggregating a minimum set of internal nodes that covers the required range of leaves. The example of answering a query with a range of 11 partials starting from leaf 15 is shown with red triangles in Fig. 4. **B-Int**[5] (or Base Intervals) is another final aggregation technique that uses a multi-level data structure that consists of dyadic intervals of different lengths. On the first level, the intervals are of a length of one partial, on the next level the interval length is two partials, on the third level the length is four partials, and so on. The top level has just one interval of the maximum supported range length. The whole data structure is organized in a circular fashion, so that the rightmost interval on any level is followed by the leftmost interval from the same level (Fig. 5). Similarly to *FlatFAT*, when producing the final aggregate, *B-Int* determines the minimum number of intervals needed to represent the desired range, and aggregates them. For example, in Fig. 5 *B-Int* aggregates all intervals marked with color to get the answer for the specified query range. Another tree-like approach similar to *FlatFAT* and *B-Int* is [6].

FlatFIT [26] (or Flat and Fast Index Traverser) was proposed with a goal of increasing the throughput of *ACQ* processing. *FlatFIT* achieves acceleration by dynamically storing the intermediate results and their corresponding pointers, which indicate how far ahead *FlatFIT* can skip in its calculation. It uses two circular arrays, *Pointers* and *Partials*, interconnected with their indices and a stack, *Positions*, for keeping indices that are currently processed. The *FlatFIT* algorithm is applicable in a multi-query environment, where it achieves a high throughput by allowing additional partial result reuse between all *ACQs* on the stream.

TwoStacks [28] was shown to also achieve a high throughput by using an old trick from functional programming to implement a queue with two stacks, *F* (front) and *B* (back), where all insertions push a value, *val*, and an aggregation, *agg*, of everything below it onto *B*, and evictions pop from *F*. When *F* is empty, the algorithm flips *B* onto *F*, making it a calculation heavy step that introduces latency spikes to processing. To produce the final aggregation, the tops of both the *F* and *B* stacks are aggregated.

DABA [28] (or De-Amortized Bankers Algorithm) was proposed as an alternative to *TwoStacks* that reduces the latency spikes

Figure 6: DABA Technique

Figure 7: Shared Processing

while maintaining high throughput. The algorithm uses a principle of the Functional Okasaki Aggregator to de-amortize the *TwoStacks* algorithm. *DABA* uses two queues, *vals* and *aggs*, as shown in Fig. 6 implemented as chunked-array queues with six ordered pointers which make up the *F* and *B* stacks similarly to *TwoStacks*. However after each insertion and eviction event, a function *fixup* is called which re-balances the pointers and fixes the consistency of the *aggs* queue.

Currently, neither *TwoStacks* nor *DABA* are known to support multi-query execution as opposed to the other above algorithms.

2.3 Shared Processing of ACQs

Since the *ACQs* are executed periodically (unlike one-shot queries), several processing schemes, as well as *ACQ* optimizers, take advantage of the shared processing of *ACQs* [8, 14, 18], which reduces the long-term overall processing costs by sharing partial results. To show the benefits of sharing in such scenarios, consider the following example:

Example 1 (Fig. 7) Assume two *ACQs* monitor Max stock value over the same data stream. The first *ACQ* has a slide of 2 tuples and a range of 6 tuples, the second one has a slide of 4 tuples and a range of 8 tuples. That is, the first *ACQ* is computing partial aggregates every 2 tuples, and the second is computing the same partial aggregates every 4 tuples. Clearly, the calculation producing partial aggregates only needs to be performed once every 2 tuples, and both *ACQs* can use these partial aggregates for their corresponding final aggregations. The first *ACQ* will then run each final aggregation over the last three partial aggregates, and the second *ACQ* will run each final aggregation over the last 4 partial aggregates. ■

Partial results sharing is applicable for all matching aggregate operations, such as Max, Product, Sum, etc. and for different but compatible aggregate operations, for example Sum, Count and Average can share results by treating Average as $\frac{\text{sum}}{\text{count}}$.

To determine how many partial aggregations are needed after combining *n* *ACQs* into a shared execution plan, we first find the

length of the new composite slide, which is the *Least Common Multiple (LCM)* of the slides of the combined ACQs (in Example 1 it is four). Each slide is then repeated $LCM/slide$ times to fit the length of the composite slide, and all slide multiples are marked within the composite slide as *edges*. If slides consist of several fragments due to the partial aggregation, all fragments are also marked within the composite slide as edges. The more common edges are present in the composite slide, the more partial aggregations can be shared.

In this work we combine all compatible ACQs into one shared plan to achieve maximum sharing, which, in a general case, provides the most computational resource savings. Although, in specific cases it was shown that aiming for maximum sharing is not always beneficial [13, 14, 24, 25].

2.4 Other Related Work

Work similar to sliding-window aggregation exists in *Temporal Database Systems*, which store the entire stream of tuples and allow aggregations over any continuous segments of the stream, which are called *Historical Windows*. In contrast, *DSMSs* generally support windows that end at or near the most recent results are referred to as *Suffix Windows* in Temporal Databases. In Temporal Databases, Red-black trees [17, 21], SB-trees, B-trees [31], and Skylines [23] are used for aggregations. Due to the tree-based natures of these algorithms their update complexities are $O(\log(s))$, where s is the size of the entire stream history.

Several approximate calculation approaches were proposed to save time and space by giving up accuracy [4, 7, 9, 11]. Our approach focuses solely on computing *exact* answers since it is crucial for many applications (e.g., financial, medical, etc.).

3 SLICKDEQUE

In this section we describe our new algorithm, *SlickDeque*, that significantly speeds up the final aggregation calculations in a sliding-window environment by employing different processing schemes for invertible and non-invertible aggregations.

3.1 Algebraic Properties and Assumptions

One of the important metrics that allows the evaluation of the difficulty of incremental evaluation of a particular query is the algebraic properties of the underlying aggregate operation. Based on classification from [12], all aggregate operations are divided into three broad categories: *distributive*, *algebraic*, and *holistic*.

- **Distributive** aggregation means that the aggregation for the set S can be computed from two of the same aggregations of subsets S_1 and S_2 , where subsets S_1 and S_2 were constructed by splitting S in two. For example, if we have a set of 10 numbers and the Sum of the first 7 is 20, and the Sum of the 3 remaining is 15, then we can get the Sum of all 10 numbers by adding 20 and 15. Therefore, Sum is a distributive aggregation.
- **Algebraic** aggregation means that the aggregation can be computed from a number of distributive aggregations, e.g., Average, which is calculated from Sum and Count. The list of common distributive aggregations includes Count, Sum, Sum of Squares, Product, and Max. By combining these distributive aggregations we can calculate some commonly used algebraic aggregations such as: Average (Count and Sum), Standard Deviation (Sum of Squares, Sum, and Count), Geometric Mean (Product and Count), and Range (Max and Min).

- **Holistic** aggregations are neither distributive nor algebraic, e.g., Median, Top-K, Quantile, Collect Distinct. Holistic aggregations are out of the scope for this work since they require specifically tailored algorithms which cannot be generalized.

In this paper we will focus on optimizing the distributive aggregations; calculating the algebraic aggregations follows trivially. Distributive aggregations can be further classified by their mathematical properties: *associativity*, *invertibility*, and *commutativity*. Below we provide brief definitions of these properties.

- An operation \oplus is *associative* if $x \oplus (y \oplus z) = (x \oplus y) \oplus z$ is true for all x, y, z .
- An operation \oplus is *invertible* if there exists an operation \ominus such that $(x \oplus y) \ominus y = x$ for all x, y , and \ominus is feasibly inexpensive.
 - Note: if operation \oplus is *non-invertible*, then $x \oplus y = z$, where $z \in \{x, y\}$. This is only true for **non-holistic** operations (which we target in this work).
- An operation \oplus is *commutative* if $x \oplus y = y \oplus x$ is true for all x, y .

Query Operation Assumptions In terms of query operation generality, our proposed approach, *SlickDeque*, is no different from the state-of-the-art approaches, which all support non-invertible and non-commutative operations while requiring the operations to be associative. In general, all operations that can be executed on a window of values are associative. The common non-associative operations such as subtraction ($x - y - z$), division ($x/y/z$), exponentiation (x^{y^z}), and some binary operations such as *NAND* and *NOR*, are generally impractical when executed on sets of values larger than two. The difference of our proposed *SlickDeque* approach is that it has separate processing algorithms for the invertible operations (e.g., Sum, Product, Count, etc.) and non-invertible operations (e.g., Max, Min, Range, Alphabetical Max (for strings), ArgMax of Cosine, ArgMin of x^2 , etc.), which allows us accelerated processing of both.

Window Structure Assumptions In *non-FIFO* window structures, the events of insertion and expiration are not synchronized, which can cause window overflow situations when there are not enough expiring tuples (or partial aggregates) to make room in the window for the insertions. All of the compared approaches, including ours, are able to handle such cases by performing dynamic resize operations. However in this paper we are focusing on the *FIFO* window environment which is the most common way to processing sliding-window aggregations in practice.

Arrival Order Assumptions Similarly, all of the aforementioned algorithms allow updates on multiple partial aggregates already stored within the window. However in this paper we focus on the classic streaming scenario when all new partial aggregates are processed by the final aggregator one-by-one as they become available. In such settings the arriving tuples have to be *in-order* or slightly *out-of-order*. As long as the *out-of-order* tuples are within the same partial aggregation, the final result will not be affected. If, however, some tuples fall outside of their partial, inconsistencies in the final result may arise. The mechanism that all systems uses to cope with such extreme situations is outside of the scope of this paper.

3.2 The SlickDeque Algorithm

In this subsection we provide the algorithm and implementation details for our approach followed by the clarifying examples. We

Algorithm 1 SlickDeque (Inv) Pseudocode

```
1: Input: A set of aggregate continuous queries  $Q$ , invertible aggregate
   operation  $\oplus$ , the initial value for  $\oplus$   $initVal$ , the inverse operation  $\ominus$ ,

16: while results are expected do
17:   length = sharedPlan.getNextPartialsLength()
18:   newPartial = partialAggregator.aggregate(length, PAT)
19:   for each ( $qR \rightarrow ans$ ) pair in answers do
20:     startPos = currPos -  $qR$ 
21:     if startPos < 0 then
22:       startPos += wSize
23:     end if
24:     ans = ans  $\oplus$  newPartial  $\ominus$  partials[startPos]
25:   end for
26:   queriesToAnswer = sharedPlan.getNextSetOfQueries()
27:   for each query  $q$  in queriesToAnswer do
28:     send answers.getVal( $q$ .range) as answer to  $q$ 
29:   end for
30:   partials[currPos] = newPartial
31:   currPos++
32:   if currPos == wSize then
33:     currPos = 0
34:   end if
35: end while
```

break down our algorithm description based on invertibility of the aggregate operator.

SlickDeque for Invertible Aggregates

For processing invertible aggregates we propose *SlickDeque* (Inv), a modified *Panes* (Inv) extended for processing multiple ACQs. Pseudocode for it is depicted in Algorithm 1. The algorithm consists of two major phases: *Preparation* and *Execution*.

The Preparation Phase given a set of queries, Q , and one of the partial aggregation techniques (PAT) discussed in Section 2.1 (e.g., *Pairs*) as an input, *SlickDeque* (Inv) builds a shared execution plan by executing the *buildSharedPlan* function (line 4). The *sharedPlan* is constructed as discussed in Section 2.1, and includes a full list of partials (or edges) augmented with their lengths and lists of queries to be evaluated for each partial. The *buildSharedPlan* function identifies the query with the longest range in terms of the number of partials, and saves the range as the member *wSize* of the *sharedPlan* (line 5). *wSize* signifies the necessary window length needed to process all input queries.

After generating the *sharedPlan*, *SlickDeque* (Inv) initializes its data structures: a circular array, *partials*, (line 6) and a map, *answers*, (line 7). The *partials* array is initialized to a length equal to *wSize*, and is used to store partial aggregates. The *answers* map maintains the mappings of all queries with unique ranges to

their current answers. Queries operating over the same range can share results even if they have different slides. Both the *partials* array and the values of the *answers* map are initialized (lines 8-13) with the initial value for the operation \oplus , *initVal*, supplied as input. For example, *initVal* is $-\infty$ for the Max operation.

The *currPos* variable signifies the current position within the *partials* array (line 14). It starts at 0 initially and increases to *wSize* - 1 during execution, after which it wraps back to 0. The arriving partial aggregates will be inserted into the *partials* array always at the *currPos*.

The Execution Phase is implemented as a loop that continuously returns all query results while they are expected. At the beginning of the loop (lines 17-18), *SlickDeque* (Inv) gets the next partial's length from the *sharedPlan*, and passes it to the *newPartial Aggregator* which uses the provided PAT technique to produce the *newPartial* value.

Next, *SlickDeque* (Inv) loops over all range-to-answer mappings ($qR \rightarrow ans$) in the *answers* map (lines 19-25). The loop starts by identifying the start position, *startPos*, for each mapping within the *partials* array from which the values need to be aggregated. *startPos* is identified by rewinding *currPos* back by query range, *qR*, length.

Since *SlickDeque* (Inv) only works for the invertible queries, it utilizes both the aggregate operation \oplus (e.g., Sum if query is seeking Sum), and an inverse operation \ominus (e.g., Subtract if the original operation is Sum). This way each answer, *ans*, is updated by executing the aggregate operation \oplus with the newly calculated *newPartial* value and the inverse operation \ominus with expiring *partials[startPos]* value (line 24).

Next, the answers to all queries scheduled at the current position need to be produced (lines 26-29). After receiving the *queriesToAnswer* (a subset of Q) from the *sharedPlan*, *SlickDeque* (Inv) loops over them while sending back the corresponding answers pulled from the *answers* map. Then, the *Partial* value is inserted into the circular *partials* array at *currPos*, and *currPos* is moved one position forward (lines 30-34).

The following Example 2 (illustrated in Fig. 8) should clarify the above algorithm. In order to make the explanation more intuitive we execute the two queries, Q_1 and Q_2 , on the same incoming datastream using two algorithms: *Naive* and *SlickDeque* (Inv), and we illustrate each step of their calculations side-by-side.

Example 2 Assume we have queries Q_1 and Q_2 , which are seeking the Sum over the ranges of 3 and 5 tuples, respectively, both with a slide of 1 tuple. The slide size is set to one tuple in this example for simplicity, which means that there is no partial aggregation and the answers to both queries need to be calculated after every new tuple arrival. Since the range of Q_2 is 5, which is greater than the range of Q_1 , and the slides of Q_1 and Q_2 are the same, the shared execution plan has a *wSize* of 5 tuples.

Both *Naive* and *SlickDeque* (Inv) algorithms use the *partials* array in order to maintain incoming partial aggregates (in this case just tuples). The difference is that *Naive* produces answers to queries by iterating over this array, while *SlickDeque* (Inv) utilizes the additional *answers* map (Introduced above).

In the *partials* array we mark the positions that have been modified by the algorithm in each step. The current position (*currPos*) at each step is bolded in Fig. 8 for convenience. The tuples enter the system in the order: 6, 5, 0, 1, 3, 4, 2, 7.

After the initialization in Step 0, in Step 1 the first tuple, 6, arrives. Both algorithms store the new tuple at the *currPos* in the *partials* array, and *Naive* iterates over indexes 3, 4, and 0 in order

Step	Naive	SlickDeque (Inv)	Answer

Figure 8: Example 2 processing of invertible aggregate queries Q1 and Q2 using Naive and SlickDeque (Inv) algorithms.

to answer $Q1$, and iterates over the entire array to answer $Q2$. Both answers in this case are 6.

SlickDeque (Inv) on the other hand in step 1 just updates all answers in the *answers* map by executing the operation \oplus (in this example it is Sum) with the newly arrived tuple 6 and the inverse operation \ominus (in this example it is Subtract) with values at indexes 2 and 0 in the *partials* array, which both are zeros. The updated answers are stored in the *answers* map.

In Step 2, the new partial, 5, arrives, and *Naive* iterates again over the past 3 tuples to answer $Q1$ and over the whole window to answer $Q2$, and sums up all of the values that were visited. The *SlickDeque* (Inv) algorithm on the other hand, is able to provide answers to both queries with just two operations each. It adds 5 and subtracts 0 from both answers in the map, making both 11.

Skipping ahead, in Step 4 *SlickDeque* (Inv) adds the new tuple, 1, to both answers, subtracts 6 from the answer to $Q1$ (since it is now out of range of $Q1$), and then subtracts 0 from the answer to $Q2$ (since 0 was in *partials*[3] in the previous step), returning 6 and 12 as answers to $Q1$ and $Q2$ respectively.

Skipping further, in Step 7 *SlickDeque* (Inv) adds 2 to both answers, and subtracts 1 from $Q1$'s answer (since it is now out of range for $Q1$) making it 9, and subtracts 5 from $Q2$'s answer (since 5 was in *partials*[1] in the previous step) making it 10. ■

Notice that in this example *Naive* had to execute a total of 48 Sum operations, while *SlickDeque* (Inv) executed a total of 32 operations (Sum and Subtract).

SlickDeque for Non-Invertible Aggregates

For processing non-invertible aggregates we propose a novel algorithm, *SlickDeque* (Non-Inv), which accelerates the processing of *ACQs* by intelligently maintaining and utilizing a deque data structure consisting of nodes allocated in chunks interconnected with pointers. For simplicity of explanation we assume

that each node is allocated on a separate chunk. The benefits of allocating multiple nodes per chunk are explained in Section 4.2. Pseudocode for *SlickDeque* (Non-Inv) is depicted in Algorithm 2, and similarly to *SlickDeque* (Inv) it consists of two major phases: *Preparation* and *Execution*.

The Preparation Phase Similarly to *SlickDeque* (Inv), the execution starts by building a *sharedPlan* by executing the function *buildSharedPlan* (line 4). It is constructed using one of the partial aggregation techniques as discussed in Section 2.1, and it includes a full list of partials augmented with their lengths and lists of queries that need to be evaluated for each partial. The query with the longest range in terms of the number of partials is identified and saved as the member *wSize* of the *sharedPlan*, signifying the necessary window length needed to process all input queries.

After generating the *sharedPlan*, *SlickDeque* (Non-Inv) defines node, *Node*, structure that has members *pos* and *val*, and initializes deque, *d*, composed of nodes, *Node*, (lines 6-7). *SlickDeque* utilizes the *currPos* variable to signify the sequential number of the current partial aggregate. It starts at 0 initially and increases to *wSize* - 1 during execution, after which it wraps back to 0.

The Execution Phase is implemented as a loop that continuously returns all query results while they are expected, and identically to *SlickDeque* (Inv), it begins by aggregating a *newPartial*. The if-statement on line 13 is removing the expired node (if present) from the head of the deque, *d*. The while-loop after that (line 16) is executing operation \oplus on two values: the value of the tail node and of the new partial. If the new partial is returned by the operation, the tail node is removed from the deque (it will never be a query answer), and the next one is tested, otherwise the loop stops. The new node is then added to the deque with *currPos* as the position and *newPartial* as the value (line 19).

Next, set *queriesToAnswer* (a subset of Q scheduled at this position) is accessed from the *sharedPlan*, and the answers for its queries are produced in the for-loop below. Naturally, when the *sharedPlan* was constructed, all queries in each *queriesToAnswer* set were ordered descendingly by their range. We utilize this ordering to answer all queries by looping over the deque only once, since the larger ranges always correspond to the deque nodes closest to the head. Therefore, the position *i* within the deque is defined outside the loop and initialized to the head of the deque (line 21).

The loop starts by identifying the *startPos* of the aggregation for each query, q , by subtracting q 's range from *currPos* (line 23). If *startPos* is negative it means that this range crosses a boundary between two windows, and thus the boolean *boundaryCrossed* is set to true and *startPos* is increased by the *wSize*. Otherwise *boundaryCrossed* is set to false.

Then, based on whether the current range crosses the window boundary or not, one of the two subsequent *Answer Loops* is executed (lines 29-39), iterating over nodes from the current position *i* until the answer node is identified based on the *pos* member of each node, and returned as an answer to the query, q . The next iteration (to answer the next query) will continue working from the position *i* forward, until all queries are processed. After returning all required answers the *currPos* is moved one position forward (lines 42-45).

The following Example 3 (illustrated in Fig. 9) should clarify the above algorithm. To make the explanation more intuitive we again execute the two queries $Q1$ and $Q2$ on the same incoming datastream using *Naive* and *SlickDeque* (Non-Inv), and illustrate each step of their processing side-by-side.

Algorithm 2 SlickDeque (Non-Inv) Pseudocode

```

1: Input: A set of aggregate continuous queries  $Q$ , non-invertible aggregate operation  $\oplus$ , and partial aggregation technique PAT
2: Output: Continuous answers to queries in  $Q$  according to their specifications.
3:           Phase 1 (Preparation)
4: sharedPlan = buildSharedPlan( $Q$ , PAT)
5: wSize = sharedPlan.wSize
6: Node with members pos and val
7: Deque d composed of nodes of type Node
8: currPos = 0
9:           Phase 2 (Execution)
10: while results are expected do
11:   length = sharedPlan.getNextPartialsLength()
12:   newPartial = partialAggregator.aggregate(length, PAT)
13:   if d.size > 0 AND d.front.pos == currPos then
14:     d.pop_front()
15:   end if
16:   while d.size > 0 AND d.back.val  $\oplus$  newPartial == newPartial do
17:     d.pop_back()
18:   end while
19:   d.push_back(new Node(currPos, newPartial))
20:   queriesToAnswer = sharedPlan.getNextSetOfQueries()
21:   i = d.firstNode
22:   for each query q in queriesToAnswer do
23:     startPos = currPos - q.range
24:     boundaryCrossed = false
25:     if startPos < 0 then
26:       startPos += wSize
27:       boundaryCrossed = true
28:     end if
29:     if boundaryCrossed == false then
30:       //Answer Loop 1
31:       while i.pos < startPos OR i.pos > currPos do
32:         i = i.nextNode
33:       end while
34:     else
35:       //Answer Loop 2
36:       while i.pos < startPos AND i.pos > currPos do
37:         i = i.nextNode
38:       end while
39:     end if
40:     send i.val as answer to q
41:   end for
42:   currPos++
43:   if currPos == wSize then
44:     currPos = 0
45:   end if
46: end while

```

Example 3 Assume we have queries $Q1$ and $Q2$, which are seeking Max over the ranges of 3 and 5 tuples respectively, both with a slide of 1 tuple. The slide size is again set to one tuple for simplicity, which means that there is no partial aggregation and the answers to both queries need to be calculated after every new tuple arrival. As before, the range of $Q2$ (5) is greater than the range of $Q1$ (3), and the slides of $Q1$ and $Q2$ are the same, the shared execution plan has a $wSize$ of 5 tuples.

While *Naive* uses the circular *partials* array to maintain the incoming partials (in this case just tuples), *SlickDeque* (Non-Inv) only utilizes deque in its operation. In both *partials* and deque we mark the positions modified in each step. The tuples enter the system in the same order as in Example 2: 6, 5, 0, 1, 3, 4, 2, 7.

After the initialization Step, in Step 1 the first tuple, 6, arrives. *Naive* stores it at the $currPos$ in the *partials* array, and iterates

Step	Naive	SlickDeque (Non-Inv)	Answer
0	partials [0 1 2 3 4] [-∞ -∞ -∞ -∞ -∞]	deque []	Q1 Q2 n/a n/a
1	partials [0 1 2 3 4] [6 -∞ -∞ -∞ -∞]	deque [0] [6]	6 6
2	partials [0 1 2 3 4] [6 5 -∞ -∞ -∞]	deque [0 1] [6 5]	6 6
3	partials [0 1 2 3 4] [6 5 0 -∞ -∞]	deque [0 1 2] [6 5 0]	6 6
4	partials [0 1 2 3 4] [6 5 0 1 -∞]	deque [0 1 3] [6 5 1]	5 6
5	partials [0 1 2 3 4] [6 5 0 1 3]	deque [0 1 4] [6 5 3]	3 6
6	partials [0 1 2 3 4] [4 5 0 1 3]	deque [1 0] [5 4]	4 5
7	partials [0 1 2 3 4] [4 2 0 1 3]	deque [0 1] [4 2]	4 4
8	partials [0 1 2 3 4] [4 2 7 1 3]	deque [2] [7]	7 7

Figure 9: Example 3 processing of non-invertible aggregate queries $Q1$ and $Q2$ using Naive and SlickDeque algorithms.

over the last 3 indexes (3, 4, and 0) to answer $Q1$, and over the entire array to answer $Q2$. Both answers in this case are 6.

SlickDeque (Non-Inv) places a new node with $pos = 0$ (which is $currPos$) and $val = 6$, at the head of the deque, and since its pos value is both within the last 3 and 5 positions from $currPos$, its val is returned as the answer to both $Q1$ and $Q2$.

In Step 2, the new partial, 5, is placed into the $currPos$, and *Naive* iterates again over the past 3 tuples to answer $Q1$ and over the whole window to answer $Q2$, and returns the Max value from all values visited, which is 6. Our algorithm on the other hand, places the new tuple 5 as a val of the new node (with $pos = 1$) at the end of the deque, and returns 6 (the val of the head node of the deque) as an answer to both queries.

Skipping ahead, in Step 4 *SlickDeque* (Non-Inv) removes the tail node of the deque since the newly arrived tuple, 1, is greater than 0, which is the val of the tail node, and adds the new node with $pos = 3$ and $val = 1$ at the end of the deque. Since $Q2$ has a larger range, it is scheduled to be processed first. Its $startPos$ is identified: $3 - 5 = -2$, and since -2 is negative, the window boundary is crossed. Therefore $startPos$ is moved to $-2 + 5 = 3$, and the *Answer Loop 2* is executed returning the val of the head node, 6. The $startPos$ of $Q1$ is $3 - 3 = 0$, and since 0 is not negative, the window boundary is not crossed. Thus, the answer is produced by iterating using *Answer Loop 1*, which returned 5, the val of the second node from the head.

Skipping further, in Step 6 *SlickDeque* (Non-Inv) removes the head node of the deque (with $pos = 0$ and $val = 6$) which expires at this step since the $currPos$ is 0. Also, since the newly arrived tuple, 4, is greater than 3, the last node of the deque is removed, and the new node with $pos = 0$ and $val = 4$ is added at the end

of the deque. Q_2 and Q_1 are then both processed by executing the *Answer Loop 2* and returning 5 and 4 respectively. ■

Note that this example also shows the advantage of *SlickDeque* (Non-Inv) over *Naive* by showing that *Naive* had to execute 48 Max operations total, while *SlickDeque* (Non-Inv) executed 11.

4 COMPLEXITY ANALYSIS

In this section, we calculate the time and space complexities of *Naive*, *B-Int*, *FlatFAT*, *FlatFIT*, *TwoStacks*, *DABA*, and *SlickDeque*. These are summarized in Table 1.

4.1 Time Complexities

We evaluate each algorithm’s time complexity in terms of the number of aggregate operations it performs per slide to return all query answers given a window size of n partial aggregates. This metric was chosen because the aggregate operations are (1) applied directly to the input data, (2) constitute the the bulk of all performed operations, and (3) their number correlates best with the actual query performance. In order to cover the entire complexity space, we calculate **amortized** complexities as well as **worst-case** complexities. Amortized complexities are important to us because they correlate with *ACQ* processing throughputs, while worst-case ones reflect possible latency spikes.

In addition to providing calculations for a **single query** environment (where only one query covering the entire window is executed each slide), we also evaluate a multi-query environment with the maximum number of queries (which we refer to as a **max-multi-query** environment). This way, a single query environment can be thought of as a **lower bound** of complexity per slide, while a max-multi-query environment (which executes all queries covering all possible ranges from 1 to the window length (n) each slide), can be thought of as the **upper bound**. It is clear that in most cases the complexity of the general case (with any other numbers of queries) lays between these bounds.

Naive has an exact time complexity (with matching amortized and worst cases) because it always executes the same number of operations per slide. In a single query environment, its complexity is $n - 1$ (asymptotically n) because it simply iterates over all n partials and aggregates them.

In a max-multi-query environment, *Naive* needs to return n answers each slide for ranges from 1 to n , yielding 0 to $n - 1$ operations, respectively. By summing up this arithmetic sequence we get $\frac{n^2}{2} - \frac{n}{2}$ (asymptotically n^2).

FlatFAT has an exact time complexity of $\log_2(n)$ in a single query environment since each new partial updates the binary tree in a bottom-up fashion from the leaf to the root. Since the number

of levels in a binary tree is $\log_2(n) + 1$, *FlatFAT* needs exactly $\log_2(n)$ operations to calculate the query answer. In a max-multi-query environment it is intuitive that the upper bound of the time complexity is $n \cdot \log_2(n)$, since *FlatFAT* needs to iterate over n different query ranges at each slide and each range would require $\log_2(n)$ operations at most to return the result. The exact complexity per slide can be produced by iterating over all possible ranges and summing their required numbers of operations, which equates to: $n \cdot \log_2(n) - \frac{3n}{2} + \frac{5\log_2(n)}{2} + \frac{5}{2}$. For simplicity, we use the asymptotic equivalent of this complexity: $n \cdot \log(n)$.

B-Int similarly to *FlatFAT* is of a binary nature, and is only different in how it handles updates and look-ups. In [29] *B-Int* has been shown to have the same asymptotic time complexity as *FlatFAT*, with *B-Int* being slower by a constant factor, which we confirm in this work as well.

FlatFIT executes different numbers of operations for different slides, unlike *Naive*, *FlatFAT*, and *B-Int*, which causes spikes in latency. The execution of *FlatFIT* follows a cyclical pattern which repeats every $n + 1$ slides, where n is the window size. In a single query environment, the so called *window reset* event happens once per such period and constitutes the worst-case complexity per slide. During the *window reset* the indexes of the entire data structure are updated in $n - 1$ steps. The *window reset* operation is surrounded by two slides that require just one operation, and the rest of the slides in a period require two operations each. By summing everything, we have the amortized complexity for the natural period of *FlatFIT*: $(n - 1) + 2(n - 2) + 2 = 3(n - 1)$, equating to $3n$ operations for the period of n slides, which in turn makes the amortized complexity asymptotically constant and equal to 3 operations per slide.

In a max-multi-query environment, *FlatFIT* keeps the data structure maximally updated by answering queries over all possible ranges each slide, which allows it to calculate the query answers with just one or zero operations each. Due to this, the *window reset* event happens only once at the beginning of the execution phase, and therefore in this scenario the operational complexity of the *FlatFIT* algorithm is not amortized and yields $n - 1$ operations per slide (asymptotically n).

TwoStacks also executes different numbers of operations for different slides, which introduces latency spikes similarly to *FlatFIT*. During insertions, each new partial is added to the *B* stack and one aggregate operation is performed to determine the new aggregate value of the entire stack *B*. After that, another operation is performed using the top values of both the *F* and *B* stacks to return the query answer, which makes the complexity of insertions 2 operations. The majority of evictions are free since they are done by just popping the node from the *F* stack. When *F* becomes empty, however, *B* is flipped onto *F* by popping values one-by-one from *B* and inserting them into *F* while performing one aggregate operation per insertion (to populate *agg* values on *F*). The flip procedure (n operations) clearly constitutes the worst-case complexity per slide. To calculate the amortized complexity we add all operations per one full iteration of the algorithm: n insertions (1 operations each), n queries (1 operation each), and one eviction that causes stack flip procedure (n operations), totalling $3n$ operations per n slides. Thus, the amortized complexity of the algorithm in constant and equals 3 operations per slide. *TwoStacks* does not currently allow multi query processing.

DABA was proposed to alleviate latency spikes in *TwoStacks* by making its worst-case time complexity constant (though it still performs different numbers of operations each slide). By doing

Table 1: Algorithmic Complexities

Algorithm	Time			Space	
	Single Query	Max-Multi Query	Max-Multi Query	Single Query	Max-Multi Query
	Amort			Worst	Single Query
Naive	n	n	n^2	n	n
FlatFAT	$\log(n)$	$\log(n)$	$n \cdot \log(n)$	$2n^{**}$	$2n^{**}$
B-Int	$\log(n)$	$\log(n)$	$n \cdot \log(n)$	$2n^{**}$	$2n^{**}$
FlatFIT	3	n	n	$2n$	$2n$
TwoStacks	3	n	—	$2n$	—
DABA	5	8	—	$2n$	—
Slick Deque	Inv	2	2	$2n$	n
	Non-Inv	<2	n^*	n	2 to $2n^*$

*the probability of these cases is negligible: 1 in $n!$.

**true only when n is a power of 2, otherwise $3n$.

that *DABA* sacrifices its amortized time complexity (and consequently its throughput). Per one full window iteration *DABA* executes 2 flip actions, n shift actions, and n evict actions (which all cost 0 operations), n shrink actions (costing 3 operations each), and also n insert actions and n answer look-up actions (cost 1 operation apiece), totalling $5n$ operations per n slides, which yields the amortized complexity of 5 operations. *DABA*'s worst-case complexity can be attributed to a step that performs the following sequence of actions: Evict, Flip, Shrink, Insert, Shrink, Query, which costs 8 operations total. Similarly to *TwoStacks* *DABA* does not currently support multi query processing.

SlickDeque for Invertible Operations has an exact time complexity of just 2 operations per slide in a single query environment, since after each arrival of the new partial aggregate, the query answer is updated twice: once by executing an aggregate operation with the incoming partial, and once by executing the inverse operation with the expiring partial. In a max-multi-query environment *SlickDeque* (Inv) has to perform $2n$ operations, since one aggregate operation and one inverse operation need to be executed on each of the answers to n queries, which makes the algorithm's exact time complexity $2n$.

SlickDeque for Non-Invertible Operations executes variable numbers of operations per slide. As opposed to *FlatFIT*, *TwoStacks*, and *DABA* which are input agnostic and have their worst-case steps executed periodically, *SlickDeque* (Non-Inv) depends on the input, and the probability of ever executing its worst-case step is minuscule as we point out below.

Intuitively, in the long-running environment with a non-infinite window, each partial can cause at most two operations: one when it is inserted (invokes its comparison with the tail of the deque), and one when it is deleted by another incoming partial (invokes comparison of the incoming partial with the next item on deque). Clearly, the only two situations when a partial performs less than two operations in its lifetime are (1) if it becomes the first element of the deque after its insertion (either by removing all other partials or by being inserted into an empty deque), or (2) if it expires before being removed by another partial. If both situations happen to the same partial it will be involved in 0 operations in its lifetime. Also, it is impossible to execute a full window iteration without hitting one of the two situations by one of the partials at least once, since we cannot have an element in a deque that would both not get removed by another incoming partial as well as not expired after a full window iteration. Thus, the amortized complexity of this algorithm depends on the input, however it is always less than 2 operations.

The worst time complexity of this algorithm happens when the input (except the last partial of the window) is ordered in the opposite way of the aggregate operator order, e.g., if Max is processed and the entire input is ordered descendingly, forcing the deque to fill up, after which the next input partial has the largest value so far. This causes the new element to perform n operations while deleting all nodes on the deque. Fortunately, such a situation is highly unlikely on most inputs (1 in $n!$ chance in the uniform case). Consider the state-of-the-art *DABA* algorithm that we showed to have a worst-case complexity of 8 operations. In order for *SlickDeque* (Non-Inv) to have a step with the same complexity there should be at least 9 ordered partials in the input. The probability of receiving 9 values ordered in a specific way in a row is 1 out of $9!$ (equals 362880), which is highly unlikely.

In a max-multi-query environment, to process all queries scheduled at a slide, the deque is traversed from the head while

answering each query. Clearly, if the number of nodes in the deque is smaller than the number of different queries to answer, some nodes will have answers to multiple queries. Thus, the worst case would again be when the input forced the deque to completely fill up, for which the probability is again 1 in $n!$. In such a case, iterating over the entire deque at each step will take n operations (and at worst 2 operations per step as shown in the single query environment), so the complexity of the worst-case becomes $2n$. In the best case, the deque would have only one node each slide that would answer all queries, which would make complexity just 2 operations total.

Summary The differentiated processing of invertible and non-invertible operations allows *SlickDeque* to utilize optimizations tailored towards each type that are not available in the general case. Thus, *SlickDeque* is superior in the time complexity for both invertible and non-invertible cases compared to all other algorithms. However, in the worst-case complexity per slide, theoretically *SlickDeque* has a small possibility (1 in 362880 based on the input) to be outperformed by *DABA*.

4.2 Space Complexities

Naive has the space complexity of n since it stores partials only once and does not keep any additional structures. This complexity stands despite the number of registered queries, since additional queries do not require any additional structures.

FlatFAT and **B-Int** both have the space complexity of $2^{\lceil \log(n) \rceil + 1}$. Due to their binary nature, they are more space efficient when the window size is a power of two, in which case they consume $2n$ of memory: n for all leaf nodes and $n - 1$ for all tree nodes above leaves. The first position within a flat array is normally left unused in order to simplify the addressing of nodes within the tree. In cases where the window size is not a power of two, *FlatFAT* and *B-Int* round it up to the closest power of two, which is mathematically expressed as: $2^{\lceil \log(n) \rceil}$. Therefore, the space complexity of these algorithms yields $2^{\lceil \log(n) \rceil + 1}$. The window rounding manifests the worst-case space complexity of $3n$.

FlatFIT needs two pre-allocated arrays of size n to operate and a stack that can grow up to 2 values total in a single query environment and in a max-multi-query environment. This results in an asymptotic space complexity of *FlatFIT* $2n$. However, in terms of space complexity, single query and max-multi-query environments do not bound *FlatFIT*. In a general case where we have more than one query and less than the maximum queries registered, the stack might have to store up to $n/2$ values (case with two queries) at most. However, each additional query (of a different range) after that cuts the maximum stack memory consumption in half. Therefore, if the number of queries is q , the space complexity of *FlatFIT* becomes $2n$ for $q = 1$ and $q = n$, and $2n + \frac{n}{2^{q-1}}$ for the rest of the possible values of q .

TwoStacks uses stack structures with nodes containing two values, however both stacks combined can never have more than n nodes total by the nature of the algorithm, which makes its space complexity $2n$.

DABA similarly to *TwoStacks* maintains the front and back stacks with nodes consisting of both values and aggregates, however it is implemented on top of the doubly linked list of chunks. The space complexity of *DABA* depends on the number of underlying chunks, specifically, having less chunks that are bigger in size saves space on pointers (left and right), but wastes space on over-allocations (periodically window slides between chunks during

the execution leaving up to two chunks' worth of space wasted). If the window is split into k chunks, then *DABA*'s space complexity is: $2n + 4k + 4n/k$. If we take a derivative with respect to k , equate it to zero, and solve for k , we conclude that the minimum space complexity for *DABA* is achieved by setting k to \sqrt{n} , and it equals $2n + 4\sqrt{n}$ (asymptotically $2n$).

SlickDeque for invertible operations stores partial aggregates similarly to *Naive*. In addition, it stores the answer for each query with a unique range, making its single query space complexity $n + 1$, and max-multi-query $2n$.

SlickDeque for non-invertible operations performs node allocations in chunks to reduce the space required by pointers similarly to *DABA*, causing an overallocation of up to two chunks' worth of space (at the beginning and at the end of the deque). The space complexity of *SlickDeque* (Non-Inv) does not depend on the number of registered queries, but depends on the input. In the worst-case, the input forces the deque to become full. In such a case, having n nodes with two values each, and k chunks with two pointers each, the space consumption becomes $2n + 4k + 4n/k$. By taking a derivative with respect to k , equating it to zero, and solving for k , we conclude that k should be set to \sqrt{n} to minimize the worst-case complexity, which becomes $2n + 4\sqrt{n}$ (asymptotically $2n$). Similarly to the time complexity, the chance of the worst-case happening in normal conditions is very low: just 1 in $n!$. In the best case, however, each incoming partial forces the deque to eliminate all of its nodes, making the space complexity constant (2).

Summary *SlickDeque* shows a clear advantage over the rest of the algorithms in terms of space complexity. *SlickDeque* (Inv) shares the space complexity of n with *Naive*, while the rest of the algorithms have a complexity of at least $2n$, and the complexity of *SlickDeque* (Non-Inv) is always less or equal than $2n$ (based on the input). This means that only *Naive* can possibly outperform it, however the probability of that happening is low (just 1 in $n!/2$), and even then, *Naive* is still not a feasible solution because of its high time complexity.

5 EXPERIMENTAL EVALUATION

In this section, we present our experimental evaluation that confirms the theoretical superiority of *SlickDeque* in practice, by comparing it to other final aggregation approaches.

5.1 Experimental Testbed

Platform In order to test the performance of our sliding-window aggregation technique, we built an experimental platform in C++ (compiled with G++5.4.1). Specifically, we implemented a stand-alone stream aggregator platform and programmed the *Naive*, *FlatFAT*, *B-Int*, *FlatFIT*, *TwoStacks*, *DABA*, and *SlickDeque* (Inv and Non-inv) algorithms within the same codebase, sharing data structures and function calls to enable a fair comparison. Although all of the compared algorithms can be easily ported to any commercial general purpose stream processing system, we chose to go with a stand-alone platform to carry out our evaluation in an isolated environment in order to avoid any potential system interference and overheads. In the future we are planning to repeat our evaluation on a production system.

Dataset We utilized the DEBS12 Grand Challenge Dataset [16] which contains events generated by sensors of large hi-tech manufacturing equipment. Each tuple in this dataset incorporates 3 energy readings and 51 values signifying various sensor states. The records were sampled at the rate of 100Hz, and the whole

dataset includes ~33 million unique events, which we made into a dataset of 134 million tuples.

Workload Clearly, the performance of the final aggregation techniques heavily depends on the window size, i.e., the larger the window size the longer it takes to process updates to it. Thus, we varied the window size from 1 tuple to 134 million tuples, which is the maximum window size with our dataset. Given that the goal of our evaluation is just to compare different final aggregation techniques, we eliminated any side effects (i.e., overheads or benefits) induced by partial aggregation by setting all query slides to one tuple.

Evaluation Metrics We chose to compare the algorithms using throughput, latency, and memory requirement. *Throughput* is measured as the number of query results returned per second in a single query environment, while in a multi-query environment it is measured as the number of slides of a shared execution plan processed per second. *Latency* is measured in terms of the total time it took to calculate and return the answer to each query. *Memory Requirement* is measured by the maximum resident set size of processes running the corresponding techniques.

5.2 Experimental Results

We ran our experiments on an Intel(R) i7-4770 CPU @ 3.40GHz with 16 GB of RAM. For robustness, all the results were averaged over three independent runs of each experiment aggregating three different energy readings from the DEBS12 dataset.

Exp 1: Single Query Throughput

Exp1(a) Invertible Aggregates (Fig. 10)

In this experiment we varied the window size from 1 to 134 million tuples where each window is a power of two, and ran a query calculating the invertible aggregation Sum over the entire window after each new tuple arrival. From the results in Fig. 10 we clearly see that there are two groups of algorithms based on their behavior with increasing window size: (1) with constant throughput (*SlickDeque*, *FlatFIT*, *TwoStacks*, and *DABA*), and (2) with steadily degrading throughput (*FlatFAT*, *B-Int*, and *Naive*). Notice that the throughput rates are similar to what we expected from the theoretical analysis of the algorithms in Section 4.

Fig. 10 shows that *SlickDeque*'s throughput is on average 15% higher than the throughput of the second best algorithm (*FlatFAT* on windows 1 through 16, and *FlatFIT* on the rest) with a maximum of 19%. We also observed that *SlickDeque* starts outperforming other algorithms on windows as small as 4 tuples and increases its gain rapidly. *FlatFAT* showed to be more beneficial than *SlickDeque* only on window sizes from 1 to 4 tuples, however this benefit is negligible (1% at max).

Exp1(b) Non-Invertible Aggregates (Fig. 11)

In this experiment we replaced the calculation of Sum with the non-invertible aggregation Max, that again runs over the entire window after each tuple arrival. Similarly to Exp1(a), we see that the throughput of some algorithms is practically unaffected by the increasing window size. The results are depicted in Fig. 11. Once again, the throughput rates correspond to what we expected from the theoretical analysis of the algorithms.

In this experiment *SlickDeque*'s throughput is on average 7% higher than the throughput of the second best algorithm with a maximum of 10%, and *SlickDeque* starts outperforming all other algorithms on windows as small as 16 tuples. *FlatFAT* showed to be more beneficial than *SlickDeque* only on window sizes from 1 to 8 tuples with an advantage of 7% at max.

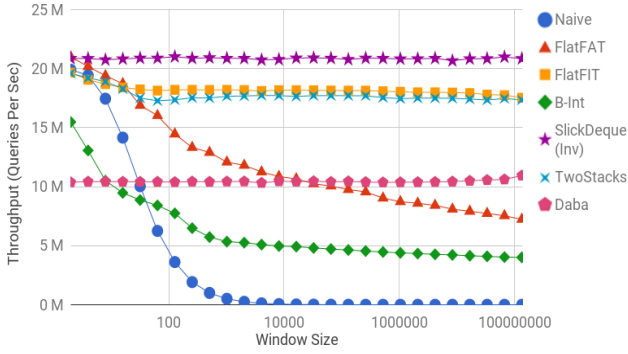

Figure 10: Exp 1 Throughput in processed queries per second in single query environment (Sum)

Figure 12: Exp 3 Throughput in processed slides per second in multi-query environment (Sum)

Figure 11: Exp 2 Throughput in processed queries per second in single query environment (Max)

Figure 13: Exp 4 Throughput in processed slides per second in multi-query environment (Max)

Exp 2: Max-Multi-Query Throughput

Exp2(a) Invertible Aggregates (Fig. 12)

In this experiment we ran a maximum number of queries calculating Sum value over the ranges from 1 to the window size after each new tuple arrives. In this context increasing the window also increases the number of queries that are processed after each slide, enabling higher reuse of unchanged partial results among them. Thus, in Fig. 12 we see that the throughput gradually increases until the moment when the overhead of dealing with the large window outweighs the benefit of sharing between queries.

In this setting, our approach demonstrated superior scalability yet again by yielding throughput that is on average 45% higher than the throughput of the second best technique with a maximum of 60%. Notice that *SlickDeque* performs the best on window sizes from 4 tuples to 134 million tuples and only underperforms compared to other algorithms on window sizes 1 and 2 by 3% and 2%, respectively.

Exp2(b) Non-Invertible Aggregates (Fig. 13)

In this experiment we ran the maximum number of queries calculating Max over all ranges from 1 to the entire window after each tuple arrival. The results are depicted in Fig. 12, and are close to our results in experiment Exp2(a).

In this setting *SlickDeque* yielded throughput on average 266% higher than the throughput of the second best technique with a maximum of 345%. *SlickDeque* showed to perform the best on windows from 4 tuples to 134 million tuples while falling behind *Naive* and *FlatFAT* on windows 1 and 2 by 7% on average.

Summary In all throughput experiments *SlickDeque* exhibits the best results, while being slightly outperformed on small window

sizes (between 1 and 8 tuples) when the overhead of maintaining its structure outweighed the benefit of using it.

Exp 3: Query Processing Latency (Fig. 14)

In this experiment we fixed our window size at 1024 tuples and ran all algorithms on the first million tuples of the DEBS data set while recording how long it took to return an answer to each query. We executed a single query processing Sum (invertible) in the first test, and Max (non-invertible) in the second test. We dropped the highest 0.005% latencies from all algorithms as outliers. The latency results of both tests were nearly identical for all algorithms except *SlickDeque*, thus we combined them in Fig. 14, where only *SlickDeque* has separate entries for invertible and non-invertible cases.

Fig. 14 shows that both invertible and non-invertible *SlickDeque* versions exhibited the lowest latency in all the following categories: Min, Max, Average, Median, 25th Percentile, and 75th Percentile. Across all of the abovementioned categories, *SlickDeque* outperformed the second best algorithm by 8% on average and 17% at most (for the non-invertible version), and by 75% average and 548% at most (for the invertible version). Also, *SlickDeque* outperformed the second best *DABA* algorithm by 283% on average in terms of the lowest max latency spike.

Exp 4: Memory Requirement (Fig. 15)

In this experiment we again varied the window size from 1 tuple to 134 million tuples (but also included window sizes that are not powers of two). We executed a query calculating the invertible Sum aggregation in the first experiment, and the non-invertible Max aggregation in the second. We measured the maximum

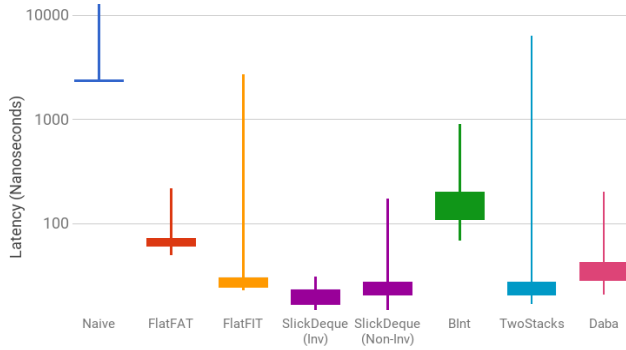

Figure 14: Exp 4 Latency in nanoseconds per query answer

Figure 15: Exp 5 Experimental Memory Usage in Gigabyte increments

resident set size (RSS) of the processes for all runs. The results of this test are depicted in Fig. 15. On this graph, we combined the results of both invertible and non-invertible runs of all algorithms since their space requirements were identical in both Sum and Max cases except for *SlickDeque*, which we plotted separately for each case. Notice that due to the great similarity of space requirement for several algorithms, we plotted: *FlatFAT* together with *B-Int*, *FlatFIT* together with *TwoStacks* and *DABA*, *Naive* together with *SlickDeque (Inv)*, and *SlickDeque (Non-Inv)* was plotted separately. The memory requirement rates correspond to what we predicted from the theoretical analysis in Section 4. *SlickDeque* demonstrated excellent scalability by matching the space usage of *Naive* for the invertible case, and for the non-invertible one outperforming the second best algorithm (*Naive*) by 2 times on average with a maximum of 5 times.

6 CONCLUSIONS

The key contribution of this paper is *SlickDeque*, a novel technique for incremental sliding-window final aggregation processing for single- and multi-query environments. Its power is the differentiated handling of aggregate operations based on their invertibility, which allows *SlickDeque* to use optimizations tailored towards each type and that are not available in the general case.

We theoretically showed that *SlickDeque* significantly decreases the number of operations required for a continuous query to return results while reducing its space requirement. As far as we know, there are no prior algorithms that can achieve the same time and space complexities without loss of query generality. We showed experimentally that *SlickDeque* achieves up to 3.5x higher throughput compared to the state-of-the-art algorithms,

while maintaining up to 5.5x lower latency and utilizing up to 5x less memory. Our next step is to evaluate *SlickDeque* in dynamic and multi-node environments on production systems.

ABSTRACT

Recommender systems are used to identify those items in a large collection that are more likely to be of interest to a user. A common principle of most recommenders is that whatever happened in the past is a good indicator of the future. We offer a different perspective. Considering the fact that in real life users do their selections with certain goals in mind, we recommend items (or actions) that help users fulfilling their intended goals using their past only as a way of identifying goals of interest. We introduce a model that connects goals and actions through action sets implementing the respective goals. Such a model captures latent associations among goals and actions and allows the ranking of actions considering different user strategies such as to complete at least one goal with the minimum effort (i.e., minimum number of actions), or to open up more paths for fulfillment of more goals in the future. For each strategy we recommend an algorithm that exploits the user action and goal spaces to rank the actions in a different way. We have performed extensive experimental studies to understand how these techniques are related and compare the results against traditional recommendation methods. The experiments illustrate that it is not possible to replicate the results of our approach using existing techniques.

1 INTRODUCTION

People are daily facing situations in which they have to make choices from large collections of items. Selecting the best answer to a search engine query among those satisfying the query conditions, selecting a movie to watch, an item to purchase, or friend activities to read about in social media, are only some of the most characteristic examples. Recommender systems [3, 7, 12, 16, 20] give advice to users on items that are likely of interest to them. There are two main categories of recommender systems. The first is the collaborative filtering, which is based on the idea that similar users have similar preferences, thus, the analysis of the choices of similar users can result in successful recommendations of items that have not been selected yet. The second category is the content-based which is based on the idea that users would like items that have similar features with items they have liked in the past. The principle behind both approaches is that whatever the past indicated as preference, it is likely to be preferred also in the future.

In this work, we approach the problem based on a different principle. There have been studies in psychology and social sciences [4] that have shown that human actions are not random and unrelated events. They may be of course affected by preferences but they are mainly results of rational selections performed with

the purpose of achieving some specific goal that a person has set and aims to fulfill [1].

Based on these studies, we advocate that by recognizing the goals for which actions of the past have been performed, it is possible to identify the driving forces of the users' future actions and make recommendations that better fit these needs. Since the fulfillment of a specific goal may require actions that are highly different in nature, this form of recommendation may recommend actions that are highly different from those of the past, or from those that similar users have done in the past. Note that we may use the term "actions" and not "items" as typically done in recommender systems; with this option we are being more generic since the selection of an item, the purchase of a product, or the watching of a movie are practically all actions.

Existing studies in recommender systems have already recognized that methods taking into account similarity with what has happened in the past are not always matching user expectations and have tried different techniques that focus on other aspects such as serendipity, novelty and diversity to improve the quality of recommendations [9]. However, these solutions are not principled and are not driven by some specific, user-selected, well-defined target while in many recommendation scenarios there exist targets that users are willing to reach. For instance, in online learning platforms, users may target at specializations or/and degrees. In employment-oriented social networking services such as LinkedIn users are encouraged to take actions that will lead them into their next position. In addition, they can see how some actions can lead to the same target following different career paths. Moreover, users may perform actions that will lead them to the fulfillment of commercial goals such as to get discount coupons, or everyday goals such as to become fit or to cook.

Consider, for instance, the case of a customer in a supermarket that has placed in the cart a kilo of potatoes and carrots. A content-based recommendation will try to propose products that are close to what is already in the cart, i.e., similar to potatoes and carrots which means it may propose other kinds of vegetables, or even suggest other types of potatoes. On the other hand, a collaborative filtering system may suggest light beer or red peppers, because these items have been bought in the past by customers with similar preferences. Both methods, through clearly different routes, recommend items based on the customer's past. Instead, by taking into account that the items in the customer's cart can be combined with other items to produce one or more food recipes, the system can open up new options to the customer. For instance, considering a recipe to make an olivier (russian) salad that includes: potatoes, carrots and pickles, an item to be recommended would be pickles. Another useful ingredient would be nutmeg that is a spice used for mashed potatoes and pan-fried carrots, two recipes that require products some of which are already in the customer's cart. Such a recipe-based recommendation of products may not be justified by similarity to products already in the cart, neither by other product combinations found frequently in the

carts of other customers. This means that neither association rules nor techniques that detect correlations among items can be employed to make such recommendations since they highly depend on the popularity of these item sets. So, unless we consider the product combinations found in the recipes, these products will not be recommended by other techniques. Furthermore, given the recipes, the recommendations can be optimized for an overall benefit. For example, recommended products may give the ability to the customers to maximize the number of recipes that they can materialize.

Considering goals in the recommendation problem is challenging. The challenge comes from the fact that, in real life, there are typically multiple goals that one needs to fulfill at any given time. Each of these goals may require fewer or more actions in order to be fulfilled, and there may exist alternative ways for the fulfillment of a specific goal. Users have to reason on the priorities between the goals they try to achieve and the benefit they will have by the execution of each action towards the fulfillment of these goals. For instance, some users may prefer actions that help them fulfill a goal as soon as possible, while others may prefer actions that help the advancement of as many goals as possible. A goal-oriented recommender will have to leverage the goals by first recognizing the intended user goals, decide the priorities among them, and quantify the benefit of each action in relationship to the intended goals and in conjunction with the other possible actions.

We introduce a new family of recommendation strategies, i.e., *goal-based recommendations*, that deal with the above challenges. The goal-based strategies identify the goals for which exists evidence that the user is aiming at achieving. The evidence originates from the previous user activity, i.e., the actions that the user has already performed. Given this goal space, the strategies explore the sets of actions that lead to the fulfillment of these goals and contain actions that the user has already performed to find actions which the user has not performed and may be willing to complete. The sets of actions together with the goals they fulfill constitute the user's *goal implementation space*. The likelihood that the users will like an action from the candidate set of actions in this space depends on their approach towards the goals they would like to fulfill. We have identified three different strategies for exploring and exploiting the user's spaces in order to select the actions to be recommended. The three strategies correspond to three different policies based on which users often make their selections.

The first strategy is the *Focus* that examines each of the action sets in the user's goal implementation set to find which of them lead to the fulfillment of the goal that is closest to completion, either because most of the required actions have been already performed (*Focus_{cmp}*), or because they require only a few more actions (*Focus_{cl}*). Then, it forms the recommendation lists from the actions in these action sets. It is the policy preferred by users that need to fulfill at least one goal through the actions in the current recommendation list. The second strategy, *Breadth*, is not examining each action set in the user's goal implementation space separately. It considers more than one set of actions at the same time. Specifically, it evaluates and ranks the actions in the user's action space based on all the sets this action participates and selects those actions that belong in as many sets as possible together with as many as possible actions from the user activity. This strategy is for users that would like to fulfill as many goals as possible, if possible, through this recommendation list, but in order to maximize the number of fulfilled goals, they are willing to complete some or all of them in the future, i.e., not only through the actions in the current recommendation list. This way it keeps some "paths"

open for the future (i.e., unfulfilled goals) but those paths contain the minimum number of additional actions. We also suggest a third strategy, the *Best Match*, that similarly to *Breadth* is not trying to fulfill at least one goal through the current recommendation list. It recommends actions that contribute to the goals of the user's goal space. However, in contrast to *Breadth*, *Best Match* evaluates an action considering the whole goal space, not only the goals to which this specific action contributes. It generates a profile for the user and estimates a similarity between this profile and the actions to be recommended. The action representation shows how much that action contributes to the fulfillment of the various goals and the user profile how many of the user actions contribute to the various goals. It is a policy that may end up in the fulfillment of many goals in the future. However, it is a strategy for users that are interested in actions that are more useful (contribute more) to the goals to which the user has put more effort in the past (and respectively less to goals to which the user has put less effort).

Our contributions can be summarized as follows:

- We introduce and formally define the notion of goal-oriented recommendation, which evaluates every action considering the goals which the current user may be willing to fulfill and how that action contributes to the fulfillment of one or more of these goals together with other actions of the user (Section 3).
- We explain how it differs from existing techniques and why the latter cannot be used to offer this type of recommendation (Section 2).
- We present different strategies for ranking the candidate actions, with each strategy implementing a different policy in prioritizing the goals and selecting the actions to be recommended (Section 5).
- We describe efficient ways of implementing the above strategies and materializing the goal oriented recommendation paradigm (Section 4).
- We study the effectiveness of our methods and compare them to the state-of-the-art recommendation approaches. We show that goal-based approaches can recommend actions that bring the user closer to the fulfillment of goals that are related to her/him, are highly different from each other and at the same time from actions performed by other users in the past (Section 6).

2 RELATED WORK

Goal modeling. Goal modeling has attracted a lot of research interest for decades. However, the focus of the different fields has been in goal and next action inference [13] such as prediction of the next action in a sequence, e.g., the next web page to click or the next location to be [11, 18]. The purpose of such systems is for instance to promote the inferred actions or act in anticipation of the user's actions [2]. To infer the next action(s) they employ models such as probabilistic (state transition) models, e.g., Bayesian Networks [15], or Markov models [18] or other variations [2].

Recommender Systems. Our method retrieves actions to be recommended but does not consider neither the user's neighborhood activity nor the activity of the current user as in state-of-the-art recommendation approaches but the actions in the implementations of the various goals. In contrast to *Collaborative Filtering* [7, 8] that exploits previous item selections or interactions that similar users have performed, it selects implementations that contain subsets of the user activity and can be adequately extended to lead to

the fulfillment of one or more goals. It also differs from *Content-based Filtering* [3] that recommends items similar to what the user has used in the past with a high degree of satisfaction.

Association rule mining. Association rule mining analyzes the user’s histories to identify groups of items appearing together and use this as the basis for making recommendation [19]. The approach is based on popularity, while our technique is not affected by popularity fluctuations. Furthermore, different actions may often appear together but for different goals, which means not only that recommendations different than ours will be made, but these recommendations will also be incomplete, i.e., they will manage to fulfill none of the goals, since the system is confused and unable to distinguish the different intended goals of the actions that appear together.

3 GOAL-BASED RECOMMENDATIONS

Actions, Goals and Goal Implementations. We assume the existence of a set \mathcal{U} of users. Users perform actions such as the purchase of an item, the visit of a web page, the watching of a movie, or any other recordable task. We consider the existence of a set \mathcal{A} of actions.

People set the goals that they need to achieve and then they decide to perform those actions that they believe will help them fulfill their goals. We denote \mathcal{G} the set of goals. A set of actions constitutes an *activity*, which means that there are $2^{|\mathcal{A}|}$ different possible activities. The activities that are intended for a goal $g \in \mathcal{G}$, alongside the respective goal, are referred to as *goal implementations*.

Definition 3.1. A *goal implementation*, or simply implementation, is a pair $\langle g, A \rangle$ with $A \subseteq 2^{|\mathcal{A}|}$ and $g \in \mathcal{G}$.

Goal Implementation Data sources. Goal implementations can be found in sources related to almost every aspect of human activity. Recipes, for instance, are implementations of specific goals (the food that the recipe is about). Online learning platforms have specializations and degree that are implemented through courses. Each specialization is associated with one or more set of courses indicating the actions required to achieve the goal, i.e., the specialization. Goals can also be found in online stores. Many online clothing stores, for instance, give users the ability to form *outfits* and annotate them with labels such as “for friend meetings”, “to be warm” and so forth. Those outfits constitute implementations of the goal, with the goal being the label. With this knowledge, when the system recommends some item to a user apart from considering the user preferences on characteristics such as color or material (content based filtering) or considering what clothes others have bought in the past (collaborative filtering), it can employ a goal-based recommendation technique and suggest items that can be combined with clothes the user has bought in the past to form complete outfits.

Another rich source of goal implementations are social networks or specialized web sites where users record and share success stories of things that they do in life. Examples include 43Things (<https://43things.com>) and wikihow (www.wikihow.com), where users describe actions to achieve real-life goals. There are many works on transforming such textual descriptions into a structured form, like an ontology [10, 14, 17], or a taxonomy [6, 21]. They typically employ structural information such as HTML tags or enumeration. A different way to create such datasets from web pages is by posing queries of the form “in order to + a goal description” on search engines [21].

Figure 1: Combinations and the goals they serve

One of the datasets that we are using in the experimental evaluation of this work contains 18k goal implementations that we have extracted by performing *action identification* on user-generated descriptions about everyday goals such as *learn english*, *travel to Italy* and so forth from the 43Things website. We did this action extraction with a module that we have developed for this purpose, that works on a simpler model and for plain text (ref. Section 4). We do not elaborate further on the extraction task since it is orthogonal to the focus of the current paper and a different line of work of ours.

Example 3.2. Figure 1 depicts a set of goal implementations from an online clothing store. We denote a goal implementation set as L . The columns indicate outfit purposes (the goals) while the rows are the items (the actions). If we depict by a_k the action of buying the item i_k , then the implementation set is:

Implementation	$\langle \text{Goal}, \text{Activity} \rangle$	
$p1$	$\langle g_1, A_1 \rangle$	where $A_1 = \{a_1, a_2, a_3\}$
$p2$	$\langle g_2, A_2 \rangle$	where $A_2 = \{a_1, a_2, a_4\}$
$p3$	$\langle g_3, A_3 \rangle$	where $A_3 = \{a_1, a_4, a_5\}$
$p4$	$\langle g_3, A_4 \rangle$	where $A_4 = \{a_3, a_5, a_6\}$
$p5$	$\langle g_3, A_5 \rangle$	where $A_5 = \{a_1, a_3, a_5, a_6\}$

Recommendation Setting We assume an implementation set L . The set may have been constructed through one of the many methods mentioned earlier that are already available in the literature, or through the text-based module we developed for the experimental evaluation.

The actions that the user has already performed is referred to as the *user activity* H . We do not know why these actions have been performed but given the goal implementation set, there is a number of possible goals that the user may have had in mind when performing each of these actions. These goals constitute the *goal space* of the activity H .

The goal space makes all the actions that contribute to one or more goals in the goal space to be likely of interest to the user. Our aim is to recommend to the user actions that are not in H , and which the user would be happy to perform. However, not all the actions offer the same benefit. What action the user would be more willing to perform depends on what priorities the user puts on the goals. Some actions may help towards the fulfillment of many goals, while others towards the fulfillment of goals almost completed. Thus, we need to create a ranked list of the actions to recommend according to some criterion. Depending on the criterion/policy we use, a different recommendation strategy is materialized. These policies comprise the topic of the next section.

Figure 2: Illustration of our model.

4 GOAL MODEL

Our aim is to recommend to the users a set of actions considering the goals that they can fulfill given their activity. Those goals are associated with at least one action from the user activity, i.e., at least one action contributes to one or more of their implementations. An action $a \in A$ is said to *contribute* to a goal g through a goal implementation p , when there exists a goal implementation $p = (g, A)$. and we denote it as $a \rightsquigarrow^P g$.

The set of goals that are associated with an action forms its *goal space*.

Definition 4.1. Given a goal implementation set L , the *goal space* of an action a is the set $\mathcal{GS}(a) = \{g \mid g \in \mathcal{G} \wedge p \in L \wedge a \rightsquigarrow^P g\}$.

The goal space extends naturally to the case where we have a set of actions A instead of one, to be the union of the goal spaces of the individual actions in A , i.e., $\mathcal{GS}(A) = \bigcup_{a \in A} \mathcal{GS}(a)$. Considering the individual goal spaces of each action $a \in H = \{a_1, \dots, a_n\}$ there are two extreme cases: (i) $\mathcal{GS}(a_1) \cap \dots \cap \mathcal{GS}(a_n) = \emptyset$ (i.e., there are no common goals) and (ii) $\mathcal{GS}(a_1) \cap \dots \cap \mathcal{GS}(a_n) = \mathcal{GS}(H)$ (i.e., the goal spaces of all actions are the same), where we have no evidence whether one or more goals constitute a priority for the user. In all the other cases the goal spaces are a valuable source of information and should be exploited for retrieving the actions.

Another important factor that should be considered is that actions are not independent from each other since subsets of actions co-contribute to one or more goals. Therefore, given an action, there exist other actions that should be also performed in order for a goal in the goal space to be fulfilled. The set of these actions forms the *action space* of an action.

Definition 4.2. Given a goal implementation set L , the *action space* of an action a is the set $\mathcal{AS}(a) = \{a' \mid g \in \mathcal{G} \wedge p \in L \wedge a \rightsquigarrow^P g \wedge a' \rightsquigarrow^P g \wedge a \neq a'\}$.

The action space, similarly to the goal space, extends naturally to the case where we have a set of actions A instead of one, to be the union of the action spaces of the individual actions in A , i.e., $\mathcal{AS}(A) = \bigcup_{a \in A} \mathcal{AS}(a)$.

Example 4.3. In the implementation set of Example 3.2, since action a_1 participates in the activities A_1, A_2, A_3 and A_5 , its implementation space is the $\mathcal{IS}(a_1) = \{p_1, p_2, p_3, p_5\}$, and its goal space the $\mathcal{GS}(a_1) = \{g_1, g_2, g_3, g_5\}$. Its action space is the set of all the other actions in A_1, A_2, A_3 and A_5 , i.e., $\mathcal{AS}(a_1) = \{a_2, a_3, a_4, a_5, a_6\}$.

Thus, above we have determined two very important association types that correspond to two basic “operations” given an activity, i.e., a set of actions A : to form the *goal space* $\mathcal{GS}(A)$, and

the *action space* $\mathcal{AS}(A)$. Moreover, we need a matching function connecting the goals with the action set(s) that implement them.

We suggest a model that sees each activity A in the L as a *hyper-edge* that connects the actions that participate in it. Moreover, it labels each activity A with the goal that fulfills given a goal implementation (g, A) . Figure 2 graphically illustrates our model that we call *association-based goal model*.

Given a small goal implementation set, we can, for instance, form the user goal space by visiting one by one all the implementations and check whether there exist any common actions in the user activity and their activity (i.e., the set intersection). However, when moving to hundreds or millions of implementations, the cost gets prohibitive. Therefore, we should implement our model in a way that apart from capturing all the associations, *allows us to form efficiently the goal and action spaces considering the interconnections among actions and goals through the goal implementations*.

In order to retrieve the information we need in real time, we employ a set of indexes. We first build an index A -*idx* for the action set and an index G -*idx* for the goal set. Keeping the information derived from the goal implementation set L needs a more complex structure. We refer to each goal implementation using a unique identifier *id*. We split the information of the goal implementation pairs in two indexes: *Goal Implementation ActiVity index (GI-AV-idx)* and *GI-G-idx (Goal Implementation Goal Index (GI-G-idx))*. The first one matches the activity of a goal implementation to the *id* of the goal implementation where it belongs. We store a set with the *ids* of the actions. The second index matches each goal *id* to all the implementation *ids* that exist for the specific goal. Now we need to connect the goal implementations with the actions they contain. For this, we use A -*GI-idx (Action to Goal Implementation Index)* that retrieves all the goal implementation *ids* where an action contributes, i.e., the implementation *ids* (*pIds*) s.t., $a \rightsquigarrow^P g$.

Equations 1 and 2 describe how we exploit the above index structures to implement the basic operations that we described earlier, i.e., to form the goal and action space given an activity.

$$\mathcal{GS}(A) = \{GI-G-idx[pId] \mid a \in A \wedge aId = A-idx[a] \wedge pid = A-GI-idx[aId]\} \quad (1)$$

$$\mathcal{AS}(A) = A - \{GI-AV-idx[pId] \mid a \in A \wedge aId = A-idx[a] \wedge pid = A-GI-idx[aId]\} \quad (2)$$

5 STRATEGIES

Having built the *association-based goal model* described above, we can retrieve the actions to be recommended exploiting their associations with the actions in the user activity and the goals in the user goal space. In practice, we perform set operations to evaluate how strong the associations are. We suggest different strategies considering options with which we believe users prioritize actions. The first strategy examines the associations of the user activity and each of the sets of actions that contribute to goals from the user goal space. Examining each set of actions separately and not in conjunction with other action sets as well helps users to stay *focused* on one goal at a time (*Focus* strategy). On the other hand, the second strategy examines more than one action sets at the same time. For this reason we call it *Breadth*. Breadth gives priority to actions that are strongly associated with each other and the user activity; such actions can be exploited in the fulfillment of a subset of the user goal space at the same time. There is

also a third strategy that considers at the same time all the action sets that are associated with the user activity. In this case, the associated goals are an evidence of the user preferences on goals (goal-oriented profile). The strategy is referred to as *Best Match*. The three strategies that are called respectively *Focus*, *Breadth* and *Best Match* are described in the Subsections 5.1 and 5.2, 5.3 respectively.

5.1 Focus

Strategy *Focus* gives the user the option to have access to actions that lead to the *completion* of one of the goals in the user goal space. For an action set A in a goal implementation $\langle g, A \rangle$ where $g \in \mathcal{GS}(H)$, the intersection $|A \cap H|$ gives the number of actions in the implementation that have been already performed. Focus does consider the association of the user activity and the actions sets in the implementation set. But that is not enough to retrieve the actions that together with a subset of the user activity H form the activity of a goal implementation in the library L , i.e., they comprise the actions that are required for the goal to be completed. For this purpose we introduce two measures, goal implementation *completeness* and *closeness*, that evaluate and rank the candidate action sets and by extension the respective goal implementations. Completeness considers the proportion of the actions that are common in the user activity (set intersection) and the actions in the examined action set while closeness considers the common actions in comparison with the remaining actions.

$$completeness(\langle g, A \rangle, H) = |A \cap H|/|A| \quad (3)$$

$$closeness(\langle g, A \rangle, H) = 1/|A - H| \quad (4)$$

Goal implementation completeness is inspired by plan inference in plan libraries for intelligent agents [5]. However, in intelligent agents the aim is to predict which sequence of actions the agent is following (i.e., the agent has already selected a plan) while in our problem the recommendation mechanism aims to guide the user to options that s/he may have not considered without the recommendation system.

Algorithm 1 Focus Ranking

Ranks actions based on completeness (step 3) or alternatively closeness (step 3) of the corresponding goal implementations*

Input Set H , Set CA , int k

Output List R

1 $CI \leftarrow [], R \leftarrow \{\}$

//get the goal implementations that connect the goals in $\mathcal{GS}(H)$ with the actions in H

2 *for all* $aId \in H$, *for each* $pid \in A-GI-idx[aId]$

3 $IS = \{ A-GI-idx[aId] \mid a \in A \wedge aId = A-idx[a] \}$

4 *end for all*

5 *for each* pid in IS

6 $\langle p, sc \rangle \leftarrow \langle pid, \frac{|A \cap H|}{|A|} \rangle$

6* $\langle p, sc \rangle \leftarrow \langle pid, \frac{1}{|A-H|} \rangle$

7 $CI.add(\langle g, A \rangle, sc)$

8 *end for all*

9 rank CI based on sc

10 return the top k actions from the action sets of the top implementations (set CI)

We rank the goal implementations in the set of the implementations that are associated with the user activity in descending

order of completeness. Given this ranking, the list of action recommendations is formed as follows. We pull from the first goal implementation all the actions that have not been performed yet, i.e., that are not in the user activity, and we add them to the recommendation list. If more actions are needed for the top- k list, we pull the next goal implementation and so forth, until the list gets full. Note that it may be the case that the remaining slots in the top- k list are fewer than the actions of the next goal implementation in the ranked list of implementations. In this case, we can decide to leave the list with fewer recommendations or expand k to include the required actions for this implementation.

The completeness ranking function promotes the actions in the activities of the goal implementations with the largest completeness (see Algorithm *Focus Ranking*, line 3). This way the recommendation mechanism guides the user to actions that will lead to the fulfillment of the goal for which the user has already done most of the work, i.e., she has performed most of the actions needed for its fulfillment.

5.2 Breadth

With the strategy *Focus*, a single goal drives the recommendation process. This can be very restrictive if the user is not that determined to fulfill the specific goal. Therefore, we give the user another option: *Breadth* that evaluates every candidate action a considering a subset of goals in the goal space. This subset consists of the goals that are connected to the candidate action a through one or more goal implementations, i.e., the goal space $\mathcal{GS}(a)$. The reasoning behind this is that since every action in the action set \mathcal{A} can participate at the same time in more than one goal implementations in the set L and possibly contribute to a number of goals, its benefit should be estimated based on all these goals.

First, in order to evaluate a candidate action a , we should take into consideration the number of goal implementations in its implementation space, i.e., the $IS(a)$. We will refer to this quantity as *utility*.

$$u(a) = |\{A - GI - idx[aId] \mid a \in A \wedge aId = A - idx[a]\}| \quad (5)$$

$\forall pid \in A-GI-idx[aId]$. The larger the utility of an action, the larger the benefit that the user can have by a single action. For instance, in the Example 3.2, the action of buying item i_5 (i.e., a_5) is part of three goal implementations: p_3, p_4, p_5 , i.e., it can be used in 3 different outfits. Hence, it can be considered as more beneficial to the user compared to the action of buying i_6 (i.e., a_6) that contributes only through 2 goal implementations: p_4 and p_5 . However, considering the user activity $H = \{a_2, a_3\}$, we remark that the user has not showed interest to goal implementation p_3 ($p_3 \notin IS(H)$). Consequently, goal implementation p_3 should not have been taken into consideration. Thus, we need a measure that captures the utility of an action considering the user activity as well. Moreover, recommending actions of high utility is not enough. We should also consider how related, or else strongly connected, is a candidate action to the user activity. To do so, we need to consider how many of the actions in the user activity are connected to action sets that fulfill goals in the examined goal subspace.

$$sc(a, H, Breadth) = \sum_{\forall \langle g, A \rangle \text{ where } A \cap H \neq \emptyset, \text{ and } a \in A} |A \cup H| \quad (6)$$

The above equation captures both the utility of a candidate action and its relatedness to the user activity. Now, we can rank

Algorithm 2 Breadth Ranking

Ranks Candidate actions based on all the Implementations of the user's Implementation space where they participate

Input: Set H (user activity), int k

Output: top k actions

```
1   $R \leftarrow \{ \}$ 
2  for all  $aId \in H$ , for each  $pid \in A\text{-GI-idx}[aId]$ 
3   $\mathcal{IS} = \{ A\text{-GI-idx}[aId] \mid a \in A \wedge aId = A\text{-idx}[a] \}$ 
4  for each  $pId$  in  $\mathcal{IS}$ :
5     $ActionsInP \leftarrow GI\text{-AV-idx}[pId]$ 
6     $comm \leftarrow |ActionsInP \cap H|$ 
7    for each  $aId \in ActionsInP$ 
8      if  $aId$  in  $R.keys$ :
9         $R.add( \langle aId, R[aId] + comm \rangle )$ 
10     else:
11        $R.add( \langle aId, comm \rangle )$ 
12  rank  $R$  on score value and return the top  $k$  actions
```

the candidate actions and get the recommendation list R . To form the recommendation list, we rank the candidate actions using the function described in Equation 6.

Algorithm *Breadth Ranking* presents in pseudocode the steps of the *Breadth*. The algorithm does not estimate the score (ref. Eq. 6) of each action in the $\mathcal{AS}(H)$ separately. It examines each associated implementation and updates the score of all the actions of the $\mathcal{AS}(H)$ that belong in the current implementation. This way, when all the implementations have been examined the action scores (ref. Eq. 6) are ready and the action ranking takes place.

5.3 Best Match

Best Match policy in contrast to *Breadth* that evaluates each action in the user action space considering only the goals in the goal space to which this specific action contributes, considers the whole goal space. In fact, it generates a user profile that reflects the effort that the user has made towards all the goals and retrieves actions that contribute similarly to those goals. *Best Match* considering the user goal space, represents every action as a vector and aggregates the representations of the individual actions in the user activity into a single vector. The final vector constitutes the user profile. Subsequently, the candidate actions can be ranked based on their similarity to the user profile. Such an approach promotes actions that contribute to most of the goals in the user's goal space.

Goal-based user representation. In recommendation systems, user profiles are described in terms of the features of the items that a user prefers. In our case, a profile captures the user dedication towards a set of goals. We consider that the more actions from the user activity H contribute to a specific goal in the goal space $\mathcal{GS}(H)$ of the user activity, the more the user cares for this goal.

Hence, we consider that an action a can be represented as a vector \vec{a} in the feature space $F^{\mathcal{GS}(H)}$ (as an item is represented by considering features in content-based recommendation methods). One option would be to form a boolean vector, $\forall i \in \{0, |\mathcal{GS}(H)|\}$, where $g \leftarrow F^{\mathcal{GS}(H)}[i]$:

$$\vec{a}[i] = \begin{cases} 1, & \text{if } \exists p \leftarrow \langle g, A \rangle \text{ s.t. } a \in A, g \in \mathcal{GS}(H) \\ 0, & \text{otherwise} \end{cases} \quad (7)$$

The problem with the above representation is that it disregards the fact that an action in the user activity may contribute to a goal through one or more implementations. Therefore, instead of the boolean representation, we adopt a vector representation where $\vec{a}[i]$ is defined to be the number of goal implementations p s.t.

Algorithm 3 Get-Goal-Based-Profile

Creates the user profile that reflects her connections with the Goal Space

Input: Set H (user activity)

Output: \vec{H} vector in $\mathcal{GS}(H)$ that aggregates the contribution of all actions in H

```
1   $\vec{H} \leftarrow \emptyset$ 
2   $GP_{map} \leftarrow \emptyset$ 
3  for all  $aId \in H$ , for each  $pid \in A\text{-GI-idx}[aId]$ 
4   $\mathcal{IS} = \{ A\text{-GI-idx}[aId] \mid a \in A \wedge aId = A\text{-idx}[a] \}$ 
5  for each  $pId$  in  $\mathcal{IS}$ :
6     $gIdTmp \leftarrow GI\text{-G-idx}[pId]$ 
7    if  $gIdTmp$  in  $GP_{map}.keys$ :
8       $GP_{map}[gIdTmp] \leftarrow GP_{map}[gIdTmp] + 1$ 
9    else:
10      $GP_{map}[gIdTmp] \leftarrow 1$ 
11  /*convert map  $GP_{map}$  to a vector in  $F^{\mathcal{GS}(H)}$  space*/
12  for each  $gId$  in  $\mathcal{GS}(H)$ 
13     $\vec{H}.add(GP_{map}[gId])$ 
```

$a \rightsquigarrow^p g$ and $g \in \mathcal{GS}(H)$. The value in each position of the vector \vec{a} becomes $\forall i \in \{0, |\mathcal{GS}(H)|\}$, where $g \leftarrow F^{\mathcal{GS}(H)}[i]$:

$$\vec{a}[i] = \sum_{\forall p \leftarrow \langle g, A \rangle \text{ s.t. } a \in A, g \in \mathcal{GS}(H)} 1, \quad (8)$$

To get the *user profile*, we aggregate all the representations of the actions of the user activity in the feature space $F^{\mathcal{GS}(H)}$ into a single vector. The user profile captures for each goal in $\mathcal{GS}(H)$ how many of the user actions contribute to this goal considering the different goal implementations for the same goal as well. Since the user profile is generated based on the current user activity H , we denote it as \vec{H} .

$$\vec{H} = \sum_{\forall a \in H} \vec{a} \quad (9)$$

For example, for the user activity: $H = \{a_2, a_3\}$, the number of goal implementations where at least one of the actions of the user activity participate is 4. The user profile is $\vec{H} = \{3, 0, 2\}$. In the user profile is reflected the fact that the user has performed a_1 and a_3 that contribute to g_1 : “meeting friends” 3 times and to g_3 : “going to the office” via one goal implementations each, and that the user has shown her/his preference to the goals g_1 and g_2 over the rest of the goals in the goal space $\mathcal{GS}(H)$.

Goal-based representation of candidate actions. To rank the candidate actions against the user profile, we represent each candidate action in the same goal space, i.e., as goal vectors in the space $F^{\mathcal{GS}(H)}$ in the exact same way the actions from the user activity have been represented (ref. Eq. 8).

Distance-based Ranking. To rank the candidate actions, we can use a standard metric between the user profile and each of the candidate actions, as follows:

$$sc(a, H, \text{Best Match}) = dist(\vec{H}, \vec{a}) \quad (10)$$

For instance, considering the Example 3.2, action a_1 from the user activity H would be closer (smaller distance) to the user profile than that of a_4 since the first contributes to g_1 : “meeting friends” via two goal implementations and via another goal implementation to g_3 : “going to the office” as well; while the latter contributes to g_1 via only one goal implementation and to g_2 : “be warm” to which the user has shown no interest.

Algorithm 4 Best Match Ranking

Ranks actions based on their distance to the goal-based user profile

Input user activity H , int k

Output top k actions

```
1  $R \leftarrow \{\}$ ,  $CA \leftarrow \mathcal{AS}(A)-H$ 
2  $\vec{H} \leftarrow \text{Get-GoalBased-Profile}(H)$ 
3 for each  $aId$  in  $CA$ :
4    $GP_{map} \leftarrow \emptyset$ 
5    $IS \leftarrow IS(aId)$ 
6   for each  $pId$  in  $IS$ :
7      $gIdTmp \leftarrow GI-G-idx[pId]$ 
8     if  $gIdTmp$  in  $GP_{map}.keys$ :
9        $GP_{map}[gIdTmp] \leftarrow GP_{map}[gIdTmp]+1$ 
10    else:
11       $GP_{map}[gIdTmp] \leftarrow 1$ 
12    /*convert map  $GP_{map}$  to a vector in  $F\mathcal{GS}(H)$  space*/
13    for each  $gId$  in  $\mathcal{GS}(H)$ 
14       $\vec{a}.add(GP_{map}[gId])$ 
15     $\langle aId, sc \rangle \leftarrow \langle aId, dist(\vec{a}, \vec{H}) \rangle$ 
16     $R.add(\langle aId, sc \rangle)$ 
17 rank  $R$  on  $sc$  and return top  $k$  actions
```

Algorithms *Get-GoalBased-Profile* and *Best Match Ranking* describe the procedure. *Get-GoalBased-Profile* forms the goal-based vector representation of the user (user profile) by considering for each action in the user’s activity all the implementations where the examined action belongs (i.e., its implementation space) in order to find to which of the goals of the user’s goal space it contributes and add one in the respective position of the vector \vec{H} . On the other hand, *Best Match Ranking* compares the user profile with the goal-based vector representation of each action in CA by considering again the goal implementation space of the actions and the goals to which they contribute. and ranks them according to their distance with the user profile to get the top k .

5.4 Complexity analysis of strategies

The complexity of the goal-based recommendation mechanisms is mainly determined by the action *connectivity* of the association-based goal model, i.e., the average number of implementations where an action belongs. *Focus* first retrieves all the implementations that are associated with the user activity and estimates the *closeness* or the *completeness* of each of the implementations. Therefore, the cost of the mechanism is estimated as the product of $|H|$, connectivity and of the cost of set intersection or asymmetric set difference that are the main operations of the two alternatives of the *Focus* algorithm. The estimation of completeness may be more time consuming in practice (ref. Figure 7). For instance, in our implementation, intersection takes more time than set difference for sets of equal size due to the larger number of element removals that are required in the latter. *Best Match* also starts with retrieving the implementations that are associated with the user activity and then transforms them to vectors in the feature space $F\mathcal{GS}(H)$ ($O(|H| * connectivity)$). Subsequently, this transformation is also performed in all the actions in the action space of the user activity $\mathcal{AS}(H)$. For an action a , the complexity of forming its space $\mathcal{AS}(a)$ depends again on the action connectivity and the average implementation length. Since connectivity is significantly higher than the size of the average goal implementation and the

user activity, the time cost is mainly determined by connectivity: $O(connectivity * |H| + connectivity * average\ implementation\ length)$. On the other hand, *Breadth* retrieves the associated implementations and gets the intersections of the actions in each of the implementations and the user history. The asymptotic time complexity for the first step is $O(|H| * connectivity)$ and for the second step $O(connectivity * set\ intersection\ cost)$.

In practice, if we consider two association-based goal models built on sets of the same connectivity with the second one containing more implementations, the recommendation time would be higher for the set with the larger number of implementations. The reason is that in larger implementation sets the spaces of associated actions, goals and implementations of the individual actions in the user activity are not overlapping and by consequence their union gets larger. Nevertheless, the algorithms scale very well even on sets of millions of implementations (ref. Figure 7).

6 EVALUATION

For our experimental evaluation, we examine two different scenarios: (a) a grocery store where clients (users) buy food products, and (b) a system where users record actions they perform in their lives such as *read a book* or *eat healthy*. We selected these scenarios to show that goal-based recommendation can be used both in practical scenarios where existing recommendation techniques have already been applied, and to offer innovative services that have not been available so far. In both scenarios, we want to recommend to the users *actions of interest* (i.e., buy + “a product” and everyday actions respectively). The actions are characterized to be of interest based on the goals that they serve: food products can serve *food recipes*, while everyday actions can serve *life goals* such as *lose weight* or *learn english*. Another reason for examining these scenarios is that they cover two different cases: the first one covers the case where the same action participates in a great range of goal implementations (on average 1.2K impl.), while in the second case, most actions are limited to specific “families” of goals (on average an action participates in 3.85 implementations).

Dataset Description. The first dataset is an open source grocery shopping dataset (<https://github.com/julianhyde/foodmart-data-mysql>) that contains 1560 *food products* (items) and records of customer purchases in different time slots, i.e., *carts*. The food products are organized in 128 (sub)classes such as “baking goods”, “seafood”, “fruit”, “spices” and so forth. Clients can utilize these products in various *recipes* to produce *different dishes* (goals). We used a dataset of 56.5k *recipes* from a food ontology (<http://data.lirmm.fr/ontologies/food#Recipe>). The number of implementations in which an action participates on average, i.e., the *connectivity*, is 1.2K. We run our recommendation techniques and the state-of-the-art algorithms using as input, i.e., current user activity, 20.5k client carts.

The second dataset consists of goal implementations from a *goal-setting online social platform* called 43Things where users could publish the goals they set in their lives, “cheer” other users’ goals and efforts, and provide descriptions about how they managed to fulfill their goals. We have extracted 18047 *goal implementations* that contain 3747 *goals* such *pay my debts*, *get a new job*, *lose weight*, and 5456 *actions* e.g., *stop eating at restaurants* and *drink more water*. Both goals and actions are identified by unique identifiers. In contrast to the foodmarket dataset, users are focused on a few real-life goals. In total, we have examined 8071 users. The majority of the users (5047 users) are pursuing one goal, 1806 of them pursue 2 goals, 623 pursue 3, and 595

Goal Id	Actions Performed for Goal Fulfillment
g_1	{3,4,5,6,7, 8,9,10,11}
g_2	{12,13,14,15,16,17,18,19,20}
g_3	{1,2}

Initial User Activity	{3,4,5,6,7, 8,9,10,11,12, 13,14,15,16,17,18,19,20,1,2}
User activity used as input (unhidden actions)	{11,20,8,12,1,13 }

Table 1: Forming of user activity.

pursue more than 3 goals. Moreover, the action *connectivity* is very low, 3.84. The fact that actions here in contrast to actions that involve food ingredients are useful in a narrow range of goals and by extension goal implementations makes the analysis of the two sets more intriguing. User activities consist of all the actions that a user has performed for the fulfillment of all the goals that s/he has set. Therefore, in order to evaluate the recommenders we should hide a portion of the actions from the real user activities before applying the recommendation techniques. For instance, Table 1 illustrates all the actions that a user has performed to fulfill three goals. To get the input for the recommenders, we first concatenate the actions of the three respective implementations into the vector {1, 2 . . . 20}. Subsequently, the vector elements are shuffled and the 30% of the actions is considered to be the known user activity. The rest 70% is kept for evaluation purposes. Specifically, the recommenders, having some evidence that the user is interested in fulfilling one or more goals, should retrieve actions that are associated with those goals. In the example, the activity that remains unhidden consists of 6 actions. Two of the actions regard the first goal, three of them the second goal, and one action regards the last goal. Actions are both about goals that are closer to fulfillment and about goals for which there is no strong evidence. Some goals may also remain hidden.

Comparison with the State-of-the-art. Beyond the goal-based mechanisms, we examine how state-of-the-art recommendation approaches behave under the same context. We consider a nearest-neighbor Collaborative Filtering method (CF KNN) [20] and a matrix factorization method that employs alternating least squares with weighted-lambda-regularization (ALS-WR) to factorize the user-item matrix before performing the recommendations (CF MF) [8]. For the CF KNN since the user feedback is implicit, i.e., user *selection*, *non-selection*, the neighborhoods have been formed by employing jaccard coefficient, or else Tanimoto coefficient. The used implementation of the CF MF is from Mahout framework (<https://mahout.apache.org/>). We also consider a Content-based method that represents actions and users using domain-specific features, i.e., that builds vector-based representations for profiling the actions and users. For the foodmarket dataset the used domain-specific features are the 128 (sub)categories of the food products (e.g., “baking goods”, “seafood”). Based on the description of each food product, we matched each product to an ingredient leaving out products that are not included in any recipe, such as napkins. Therefore, each cart can be seen as the *user activity*, the set of recipes as the *goal implementation set L*, while the *actions* refer to the purchase of certain products/ingredients. On the other hand, for the 43T dataset, there are no widely accepted domain-specific features; therefore, we do not apply the content approach. For the goal-based recommendations, we used the methods described in Subsections 5.1, 5.2, and 5.3), namely *Focus_{cmp}* and *Focus_{cl}*, *Breadth* and *Best Match*.

Subsection 6.1 compares all methods. Subsection 6.2 focuses on the time efficiency of the goal-based methods.

6.1 Evaluation and Comparisons

Since we are introducing a novel recommendation approach, in Subsection 6.1.1, we first verify that this approach, indeed offers a different perspective to the users. To do so, we perform several *comparisons* on the results (i.e., the recommendation lists) produced by all the goal-based and the standard recommendation mechanisms.

- We compare the lists formed by the goal based mechanisms with the two standard recommendation mechanisms (ref. C.1.1. *Result Overlapping*).
- Collaborative filtering is based on the past activities of similar users (to the current user), while our algorithm is intended for discovering useful actions, i.e., actions that will help the user fulfill one or more goals. Thus, we examine whether actions that appear frequently *in the activities of other users* (popular actions) appear frequently *in the recommendation lists* as well. In other words, we study which recommendation mechanisms perpetuate the collective user behavior (ref. C.1.2. *Correlation of appearances in the user activities and the respective recommendation lists*).
- Next, we examine how useful the actions in the top-10 lists of each algorithm are for the user. To measure *usefulness*, we estimate the completeness of the goals in the user’s goal space after s/he performs the recommended actions (ref. C.1.3. *Usefulness*).
- We also study how *similar* the recommended actions in each list are presenting their (max, min and avg) pairwise similarity based on their domain-specific characteristics. Retrieving items that are very similar to each other is often considered a drawback of the Content-based filtering. It is important to understand how the rest of the examined approaches work as well (ref. C.1.4. *Pairwise similarity of the recommended actions*).
- Moreover, we examine how many of the actions in the recommendation lists have been indeed performed by the users. These actions are not of course part of the considered user activity but the users “like” them since they have performed them at some point (ref. C.1.5. *Average Percentage Of Recommended Actions that the user has indeed Performed*.)

Subsequently, Subsection 6.1.2 further examines the actions retrieved by the goal-based mechanisms (ref. C.2.1 *Frequency of Retrieved Items*) and presents the percentage of common actions in their top-10 recommendation lists (ref. C.2.2 *Result Overlapping of Goal-based methods*).

6.1.1 Comparison of all Approaches. C.1.1. Result Overlapping. Table 2 illustrates a very low overlapping of the top-10 lists formed by the goal-based mechanisms with the lists formed by the two state-of-the-art approaches. This result is expected, since as we have explained in Section 2, these approaches adopt fundamentally different philosophies.

C.1.2. Correlation of the number of appearances in the user activities and the number of appearances in the respective recommendation lists of the top-20 most popular actions. Table 3 illustrates the Pearson’s correlation between these two numbers. Correlation

Methods	Food Market			43T

Breadth	0.16	0.8	0.076	0.76	0.8	0.72

Table 4: How complete become the goals of the user after s/he follows the recommended actions per list.

Figure 3: The average goal completeness per list after the user follows the recommended actions in each list.

takes negative values from -1 to 1, with 1 reflecting highly correlated values. Collaborative filtering, which looks into the past actions of similar users for actions that may be of interest to the current user, shows the highest correlation. On the other hand, goal-based methods show negative correlation. They do not promote actions that were popular (frequent) so far. The content-based approach shows a lower correlation than collaborative filtering, which is still high in comparison to the goal-based methods.

C.1.3. Usefulness: the completeness of the goals in the user's goal space after s/he follows the recommended actions. The actions recommended to the user can help her get closer to the fulfillment of (or fulfill) one or more goals. Table 4 shows the average average

(AvgAvg), min (MinAvg) and max (MaxAvg) completeness values for all the recommendation lists formed for the two datasets. Figure 3 shows graphically the average values. These values are estimated by finding first the average, minimum and maximum values of completeness of all the goals that are related to the user considering each list separately. Subsequently, the average for all the recommendation lists is estimated. The goals that we consider in the estimation of goal completeness in the case of the 43T are those that the user has added in the system, while in the case of the food market we consider the whole user's goal space since we do not have any information about which goals the user is pursuing in reality. In the foodmarket dataset, the goal implementation space can be large and not every goal can be fulfilled by performing only 10 actions (i.e., the actions in the recommendation list) in any case. As a consequence, the AvgAvg values in this dataset are not that informative in comparison to those of the 43T dataset.

We observe that *Breadth* and *Best Match* in the first dataset and *Focus_{cmp}* in the second dataset manage the largest completeness (considering both the user activity and the recommended actions), while the lowest contribution is met in the state-of-the-art algorithms. The results are explained by the fact that *Best Match* considers the whole user's goal implementation space, *Breadth* creates a well-connected subspace, while *Focus_{cmp}* selects a single goal (actually a single implementation), if possible, and extends to a few more to complete the recommendation list. *If the user wants to get closer to a wider range of goals, s/he should select Breadth; otherwise (i.e., if s/he is focused on a few goals), s/he should select Focus_{cmp}. Best Match and Focus_{cl} follow.*

C.1.4. Pairwise similarity of the recommended actions (i.e., the corresponding products) in each list. Table 5 shows the pairwise similarity among the retrieved actions in each recommendation list. Due to the lack of widely-accepted domain-specific characteristics for the actions in the 43T dataset, we study the food market

Methods	Pairwise Action Similarity		
	AvgAvg	AvgMax	AvgMin
<i>Content</i>	0.81	1	0.6
<i>Collaborative KNN</i>	0.16	0.5	0.05
<i>Collaborative MF</i>	0.15	0.77	0.04
<i>Best Match</i>	0.33	0.72	0.22
<i>Focus_{cmp}</i>	0.24	0.31	0.21
<i>Focus_{cl}</i>	0.24	0.34	0.19
<i>Breadth</i>	0.33	0.73	0.22

Table 5: Pairwise feature-based similarity among the actions within each recommendation list for the foodmarket dataset.

dataset. AvgAvg is estimated in two steps: first *the average pairwise similarity* considering all the action pairs within each list is estimated, and then the average of the derived values is estimated. The same applies for AvgMax and AvgMin. As expected *Content* shows the highest value with an AvgAvg pairwise value 0.8 and AvgMin value 0.6. Collaborative filtering shows the lowest similarity (AvgAvg 0.15), while all goal-based mechanisms are found in the middle (avg-avg: 0.24-0.33). However, looking at the average maximum pairwise values (AvgMax), we see that the goal-based methods *Best Match* and *Breadth* often share a pair of very similar actions in their lists (on average their max pairwise similarity values are 0.72 and 0.73 respectively). The two *Focus* methods are the goal-based methods that retrieve highly dissimilar actions in most of the cases.

C.1.5. Average percentage of recommended actions that the user has indeed performed (per recommendation list). In the food market dataset, we consider as the user’s current activity a single cart; we have more than one cart for the same user in different time slots though. On the other hand, in the 43T dataset we consider only the 30% of the actions that the users have performed to fulfill their goals. Therefore, we can check whether the different techniques by considering only the actions in the user activity, recommend actions that the user has performed. We should clarify that the average percentage of recommended actions that the user has indeed performed does not reflect the precision of the recommendation tasks since the user has not acted after checking the recommendation lists. In fact, it shows the percentage of the recommended actions for which the user has shown interest at some point. Unlike precision, being able to retrieve actions that the user would anyway perform can be an advantage or a disadvantage for a recommendation technique depending on the view point of the application. If the purpose of the recommendation system is to show to the user unknown actions as well, a very high percentage is not preferable. On the contrary, if the purpose of the system was to provide the user with a discount coupon in order to keep her/him satisfied, a high value would be preferable. Keeping that in mind, we can say that the average percentage represents the Average True Positive Rate. Figure 4 illustrates for each method the Avg TPR for top-5 and top-10 lists. In the top-5 lists, first the *Best Match*, then the *Focus_{cmp}* and *Breadth* show the largest percentage. In the top-10 lists of the foodmarket dataset though, it is the *Content* method that shows the highest percentage. Nevertheless, all the methods show low percentages in the foodmarket dataset. This is explained by the fact that we have no more than 3 carts for each user.

6.1.2 Further Comparison of Goal-based results. Considering the lists derived from the goal-based methods, we have already argued about the fact that the appearance of an action in

Figure 4: Percentage of recommended actions that the user has indeed performed (True Positive Rate for top-5 and top-10 lists).

the recommendation lists is not correlated to its appearance in the user activities (ref. Table 3). Next we also present whether there exist actions that monopolize the recommendation lists, and how different the recommendation lists formed by the alternative goal-based methods are (*Result Overlapping of Goal-based methods*).

C.2.1. Frequency of Retrieved Items. In recommenders, we do not want certain actions to monopolize the recommendation lists. In the 43T dataset, the frequency of an action in different recommendation lists is very low: *at maximum 0.001*. On the other hand, in the food market dataset, where there are a lot of actions that participate in a great number of implementations (average connectivity 1.2k), the frequency is higher. Figure 5 illustrates that the majority of actions appear with frequency less than 0.2. However, *Best Match* and then *Breadth*, in their effort to serve more than one goal at the same time, repeat the same actions in more recommendation lists (22% and 14% actions respectively with frequency above 0.2). *The actions with high frequency are those that appear frequently in subsets of implementations that share common actions.* Actions that appear in many goal implementations *but together with different actions in each goal implementation* are not selected more frequently. On the contrary, Figure 6 shows that very few actions that appear frequently in the goal implementation sets are in the end selected by any goal-based mechanism. The great majority (more than 92%) of the retrieved actions (by all the goal-based mechanisms) appear in the implementation set with a frequency less than 0.2.

C.2.2. Result Overlapping of Goal-based methods. In Paragraph *C.1.1*, we have presented how different are the results of the goal-based mechanisms from those of the standard recommendation methods, next we present the result overlapping of the goal-based mechanisms. Table 6 illustrates the percentage of common actions in their top-10 lists considering again as input the 21k real carts and the 8k user activities of the food market and the 43T datasets respectively. First of all, we observe a great overlapping in the results of *Best Match* and *Breadth*: 98% and 79% respectively.

Figure 5: How often the same action appears in the recommendation lists that have been formed for the user activities of the food market dataset. Distribution of actions in frequency ranges.

Figure 6: How often the same retrieved action appears in the goal implementation set (herein recipes). Distribution of actions in frequency ranges.

	Food Market	43T
<i>Methods</i>	<i>Overlapping</i>	<i>Overlapping</i>
Best Match- <i>Focus_{cmp}</i>	42%	68%
Best Match-Breadth	98%	79%
<i>Focus_{cmp}</i> -Breadth	44%	71%
<i>Focus_{cl}</i> - <i>Focus_{cmp}</i>	35.6%	78%
<i>Focus_{cl}</i> -Best Match	49%	72%
<i>Focus_{cl}</i> -Breadth	49%	72%

Table 6: Common actions in the top-10 recommendation lists.

The overlapping is higher in the first case because in the food market ingredients participate in a lot of recipes at the same time. Therefore, *Breadth* instead of examining subsets of the user’s goal space to evaluate a certain action, it ends up considering (almost) the whole goal space similarly to *Best match*. In general, the user profile that *Best Match* considers reflects more strongly her/his preference towards a subset of goal(s); thus it (almost) neglects the rest of the goals in the user’s goal space the same way *Breadth* does. Since the two algorithms show similar behavior, *Breadth* is preferred since, as we will see in Subsection 6.2, *Breadth* is significantly more efficient in terms of time.

Moreover, *Focus_{cmp}* and *Focus_{cl}* retrieve the same actions in 35.6% and 78% of the lists respectively. In these cases, there exist goal implementations for which the user has performed most of the actions (completeness) and at the same time these are the implementations with the less remaining actions. Furthermore, *Focus_{cl}* and *Focus_{cmp}* show an overlapping of over 40% and 70% (for the respective datasets) with *Breadth* and *Best Match*. This is justified by the fact that the Focus mechanisms after popping out all the actions of the goal implementation on which they have selected to focus, they move on to another goal implementation. Therefore, they select actions from different goal implementations as *Breadth* and *Best Match* do. Another way to see this is that the latter two algorithms select actions that serve more than one goals at the same time; but that means that the selected actions serve each single goal on its own as well.

Another observation is that the overlapping in the lists for the 43T dataset is larger than in the lists for the food market dataset in all the cases because the action space of the users are wider in

Set	Connectivity	Num Of Distinct Actions	Num Of Implementations
IS	1.2K	380	56K
IS ₂	7.6K	380	282K
IS ₃	15.6K	380	564K
IS ₄	50.3K	380	1.6M
IS ₅	8K	10K	120K
IS ₆	8K	100K	1.2M
IS ₇	8K	1M	12M

Best Match	0.713s	3.37s	5.38s
<i>Focus_{cl}</i>	0.0017 s	0.0026s	0.0034s
<i>Focus_{cmp}</i>	0.0024s	0.0035s	0.0055s
Breadth	0.0029s	0.0052 s	0.008s

Table 9: Average Execution Time in implementation sets with a large number of actions and implementations.

the latter dataset due to the high action connectivity. Considering a larger set of candidate actions, the algorithms are not forced to select the same actions due to lack of alternatives.

6.2 Scalability

We ran the 4 goal-based strategies (i.e., the 3 strategies plus the extra option for *Focus*) on goal-based association models that have been built based on 7 implementation sets of different characteristics: (a) implementation set size, (b) action set size, and (c) number of implementations in which an action participates on average (*connectivity*). Table 7 illustrates the implementation sets. In sets IS₂, IS₃ and IS₄ the connectivity is stretched up to 50.3K in a set of 1.2M implementations, while in IS₅, IS₆ and IS₇ the size of the action set and the number of implementations increases by 10 times (IS₇ consists of 1M actions and 12M implementations).

Results. Figure 7 illustrates the average time per information need (i.e., per user activity) in secs considering each of the different implementation sets. We observe that the *Best Match* shows the highest execution times in all the cases. The reason is that in goal-based profiles the feature space is not fixed, and thus the representation of the actions is formed on the fly. The rest of the mechanisms show low recommendation time even in the extreme cases of the sets IS₄ and IS₈ (connectivity: 50315, average participation: 19M, and connectivity: 12110, average participation: 137M respectively). On the other hand, *Focus_{cl}* shows the lowest

Figure 7: Average recommendation time considering implementation and action sets of different characteristics.

execution time. The difference between $Focus_{cl}$ and $Focus_{cmp}$ results from the two set operations that the mechanisms use, i.e., asymmetric difference and intersection respectively.

In conclusion, the goal-based mechanisms scale well even in sets of millions actions and implementations. Moreover, *the number of actions and implementations alone do not affect much the execution time, it is the higher connectivity that results in higher execution times.*

7 CONCLUSION

Based on the theory that goals rationalize and by consequence trigger user actions, we introduce a family of recommendation approaches that recommend actions seeing them in respect with a number of goals that the users may fulfill through different action sets. We have presented 3 strategies, each one incorporating goals into the scoring of actions in a different way. The action selections of the goal-based mechanisms are not affected by their domain-based similarity with the actions in the user’s activity, nor by the activities of other users. However, they are affected by the benefit of the actions to be recommended to the goals in the user’s goal space. The strategies *Breadth* and *Best Match* focus on more than one goal at a time. In fact, the latter considers all the goals in the goal space independently from the examined action. On the other hand, the *Focus* mechanisms focus on the fulfillment of one goal at a time. Nevertheless, they all increase the average goal completeness in the user’s goal space without retrieving actions that monopolize the goal implementations. Moreover, all the mechanisms create different recommendation lists for different inputs (i.e., user activities). As part of our future work, we have been examining methodologies that enhance the goal-based mechanisms by considering the user preferences on certain domain-specific characteristics, i.e., hybrid goal-based and content-based approaches.

ABSTRACT

For Big Data analytics, working in low dimensionalities is beneficial for high performance. Instead of projecting onto a single low dimensionality, we examine, both analytically and empirically, the effects on the ‘learning utility’ of the original dataset when combining several very low-dimensional random projections. The embedding proposed exhibits many favorable traits to existing low-dimensional methodologies, such as low runtime and equivalent or better embedding quality.

1 INTRODUCTION

Random linear projections are well studied owing to the Johnson-Lindenstrauss (JL) lemma [11]. The JL lemma states that any n point-set in high-dimensional Euclidean space can be projected into $O(\log n)$ dimensions while accurately preserving all pairwise distances. The lemma is *tight*, in the sense that $\Omega(\log n)$ dimensions are necessary –see [3] and [10] for lower bounds. Although these lower bounds suggest that reducing the dimensionality of the input data further is not feasible while preserving its metric structure, this could be possible by combining the information from *several very low-dimensional* random projections. So here we examine the following: Given any Euclidean set of n points \mathcal{P} in \mathbb{R}^d and a target dimensionality t which is smaller than $O(\log n)$, is it possible to preserve pairwise distances by combining multiple random projections? How many independent random projections would be required? We study this particular question both from a theoretical and a practical perspective. On a theoretical aspect, we derive bounds on the expected number of random projections needed to accurately answer proximity queries (Theorem 3.1). From a practical perspective, we propose an embedding, VLR-Map, that learns the k-Neighborhood structure of the data-points.

2 RELATED WORK

Several approaches exist in the literature that use several random projections for data analysis [2, 5, 8, 12, 13]. We enumerate a representative list of these efforts. The power of several one-dimensional random projections has been exploited by Kleinberg in an algorithm for nearest-neighbor search [12]. Several one-dimensional random projections of the input data are used as proximity tests for a given query point, which is the underlying idea for constructing efficient data-structures for nearest-neighbor search. The use of multiple random projections into an arbitrary small number of dimensions for nearest neighbor search has been also studied by [2], in which the author projects randomly the original data in several independent trials and then

builds a KD-tree data structure for each instance of the projected data. The set of these KD-trees are used for approximately answering nearest-neighbor queries. Designing a family of locality sensitive hashing (LSH) functions shares conceptual similarities to the framework proposed here [8, 13]. LSH principles also use random projections and aggregate the projections. Finally, data embedding techniques also follow a similar methodology. For example, Boostmap [5] learns a data embedding using triplets of inequalities; the learning process is driven by AdaBoost [7]. Boostmap works effectively in practice, but does not offer any formal analytical guarantees on the quality of its embedding, unlike the present work.

3 OUR APPROACH

The intuition behind the algorithm proposed is as follows: Although a *single* very-low-dimensional random projection might not be useful for approximately preserving all pairwise distances of a given set of points, it might be the case that *several* very-low-dimensional random projections are sufficient, when combined appropriately. There are several questions to be addressed: (1) How many dimensions should be chosen when projecting a given dataset? (2) How many different random projections are needed? (3) How should we combine these random projections? In the related literature there do not exist any satisfying answers to the first question, so far. However, we will see shortly, that as Theorem 3.1 suggests, one can set the number of dimensions t to be $\Omega(1/\varepsilon^2)$, where $\varepsilon > 0$ is the desired accuracy. Theorem 3.1 also provides a rigorous answer to the second question. Now, we turn our attention to the third question.

For the sake of presentation, assume that we want to preserve the distance between two input points $\mathbf{p}_1 \in \mathcal{P}$ and $\mathbf{p}_2 \in \mathcal{P}$ with respect to a query point $\mathbf{q} \in \mathbb{R}^d$. The proposed algorithm constructs several independent low-dimensional random projections using random matrices G_1, G_2, \dots, G_l . We view each random projection as a voter that advocates on the proximity of \mathbf{p}_1 (or \mathbf{p}_2) to \mathbf{q} : each random projection votes for (or against) the validity of the predicate $\{\|\mathbf{p}_1 - \mathbf{q}\|_2 < \|\mathbf{p}_2 - \mathbf{q}\|_2\}$ by checking whether the corresponding *projected* points satisfy the above predicate. If $\|\mathbf{p}_1 - \mathbf{q}\|_2 \ll \|\mathbf{p}_2 - \mathbf{q}\|_2$, then it is easy to show that \mathbf{p}_1 will be closer to \mathbf{q} than \mathbf{p}_2 in the projected space with at least constant probability [11]. An unbiased way to combine the votes of all random projections is to take their majority vote. More precisely, if at least half of the random projections vote that \mathbf{p}_1 is closer to \mathbf{q} than \mathbf{p}_2 is, then the algorithm reports that \mathbf{p}_1 is closer to \mathbf{q} , or vice versa.

To complete the description of the above algorithm, we have to specify the required number of independent random projections. Given \mathcal{P} , the following theorem bounds the number of random projections that are needed for the algorithm to be effective with probability $1 - \delta$. The proof of the theorem below (given in the appendix) is based on concentration of measure arguments appropriately combined with ε -net arguments. In more detail, we build a very dense net¹ \mathcal{N} , i.e., (ε/\sqrt{d}) -net, on the unit ball of

¹In a metric space $M = (X, d)$ and $\varepsilon > 0$, an ε -net is a subset \mathcal{N} of X so that for every $x \in X$ there exists $w \in \mathcal{N}$ so that $d(x, w) \leq \varepsilon$.

\mathbb{R}^d and bound the probability that for each pair of points in \mathcal{N} their norms are preserved for the majority of random projections. Although ε -net arguments of this type can be encountered previously in the relevant literature, the next theorem we state is novel, and appears, to the best of our knowledge, for the first time here.

Our main theorem states that if we draw $O(d \log(d) + \log(1/\delta))$ independent random projections then, with probability at least $1 - \delta$, proximity queries between any two points of \mathcal{P} can be answered correctly for well-separated points.

THEOREM 3.1. *Let $A \in \mathbb{R}^{d \times n} = [\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_n]$, $0 < \delta < 1$ and $0 < \varepsilon < 1/2$. Fix any integer $t = \Omega(1/\varepsilon^2)$ and let G_1, G_2, \dots, G_l be an i.i.d. sequence of $t \times d$ random-sign matrices rescaled by $1/\sqrt{t}$. If*

$$l \geq \Omega\left(\frac{d \ln(d/\varepsilon^2)}{\varepsilon^2 t} + \ln(1/\delta)\right) \quad (1)$$

then with probability at least $1 - \delta$ the following holds: Let $\mathbf{p}_i, \mathbf{p}_j \in A$ and given any query $\mathbf{q} \in \mathbb{R}^d$ with $(1 + \gamma) \|\mathbf{p}_i - \mathbf{q}\|_2 \leq \|\mathbf{p}_j - \mathbf{q}\|_2$ where $\gamma > 6\varepsilon$ then $\|G_k(\mathbf{p}_i - \mathbf{q})\|_2 < \|G_k(\mathbf{p}_j - \mathbf{q})\|_2$ holds for the majority of indices $k \in [l]$.

REMARK 1. *When we are only interested in answering nearest neighbour queries between points in \mathcal{P} , the parameter d in Equation (1) can be replaced with n . Indeed, repeat the proof of Theorem 3.1 by building an ε -net on the span of \mathcal{P} .*

Theorem 3.1 provides a guarantee on the preservation of nearest neighbor queries and as a direct consequence, it preserves the kNN metric structure of the input dataset. The kNN preservation property implies that the accuracy of the proposed kNN classification method converges to the accuracy of the kNN classifier in the original high dimensionality, as progressively more independent projections are used.

Discussion: Theorem 3.1 suggests that it is possible to bound the distortion even for very-low-dimensional projections. The result may appear pessimistic at first glance because it recommends a prohibitive number, for practical consideration, of $O(d \log(d))$ independent projections. It is important to consider that the analysis is necessarily pessimistic, because it is not based on the characteristics of a particular distribution or structure, but is generic. That is why the bounds may seem large. However, conditioned on the event that we possess a family of projections that satisfy the conclusion of Theorem 3.1, a Chernoff bound implies that only a constant number of projections are required.

LEMMA 3.2. *Sample S indices from $\{1, 2, \dots, l\}$ uniformly at random with replacement. If $S \geq \frac{2(1+2\eta)^2 \ln(1/\theta)}{4\eta^2}$, then with probability at least $1 - \theta$, $0 < \theta < 1$, the sample S will return the same answer as the majority over all $\{G_i\}_{i \in [l]}$.*

PROOF. Let I_i be the indicator random variable corresponding to the success of the i -th sample from S . By hypothesis, $\mathbb{E}[I_i] = 1/2 + \eta$. The multiplicative Chernoff bound implies that $\Pr\left(\sum_{i=1}^S I_i < (1 - \zeta)(1/2 + \eta)S\right) \leq \exp(-\zeta^2 S/2)$ for every $\zeta \geq 0$. Set $\zeta = 1 - \frac{1}{1+2\eta}$ which implies that $(1 - \zeta)(1/2 + \eta)S = S/2$, also $S \geq 2 \ln(1/\theta)/\zeta^2$ implies that $\exp(-\zeta^2 S/2) \leq \theta$. \square

Lemma 3.2 suggests that in practice there is no need to aggregate over all projections, but only over a small number of them. This is verified in the experimental section, in which we demonstrate that in practice substantially fewer number of projections are required for datasets with particular structure (i.e., real-world

datasets). For all our experiments, we set an upper bound of $l = 70$ independent projections which preserved accurately the neighborhood structure. In fact, in the experimental Section 5 one can see that using multiple but lower-dimensional projections is typically better than having a single higher-dimensional projection with the same storage space. The intuition, here, is that introducing randomness is a favorable component in classification, similar, for example, to the approach that random forests also follow.

4 VLR-MAP

Using the previous theoretical results, we now present VLR-Map, standing for Very-Low Random Projection Map. It capitalizes on very-low-dimensional projections which, when combined, yield an effective embedding. The power of the embedding proposed, lies on its simplicity of implementation and low runtime cost. At its core, VLR-Map learns a low-dimensional embedding by drawing independent random projections, until the distances of the kNN neighbors over all points are sufficiently preserved through a voting process in the low-dimensional space.

Training the embedding: Assume a set of $t \times d$ random-projection matrices G_1, G_2, \dots, G_l and an integer $1 \leq k < n$ representing the number of nearest neighbors. For each point $\mathbf{p} \in \mathcal{P}$, we define the i -th nearest neighbor of \mathbf{p} (w.r.t. \mathcal{P}) as $\gamma_i(\mathbf{p})$ for every $1 \leq i \leq k < n$. Define the following, $T(\mathbf{q}, \mathbf{p}_i, \mathbf{p}_j)$ equals 1 if $\|\mathbf{q} - \mathbf{p}_i\|_2 < \|\mathbf{q} - \mathbf{p}_j\|_2$ and -1 , otherwise. Similarly, for every random projection $s = 1, 2, \dots, l$, define

$$\tilde{T}^{(s)}(\mathbf{q}, \mathbf{p}_i, \mathbf{p}_j) := \begin{cases} 1 & \text{if } \|G_s(\mathbf{q} - \mathbf{p}_i)\|_2 < \|G_s(\mathbf{q} - \mathbf{p}_j)\|_2 \\ -1 & \text{otherwise} \end{cases}$$

In essence, $\tilde{T}^{(s)}(\mathbf{q}, \mathbf{p}_i, \mathbf{p}_j)$ gives us the *vote* of the projection matrix G_s regarding the proximity between the vectors \mathbf{q}, \mathbf{p}_i and \mathbf{p}_j . Now, given several different projections/voters, one can define the majority vote over them:

$$\text{Maj}(\mathbf{q}, \mathbf{p}_i, \mathbf{p}_j) := \begin{cases} \mathbf{p}_i & \text{if } \frac{1}{l} \sum_{s=1}^l \tilde{T}^{(s)}(\mathbf{q}, \mathbf{p}_i, \mathbf{p}_j) \geq 0 \\ \mathbf{p}_j & \text{otherwise} \end{cases}$$

Given a query \mathbf{q} , $\text{Maj}(\mathbf{q}, \mathbf{p}_i, \mathbf{p}_j)$ reports which point between \mathbf{p}_i and \mathbf{p}_j is nearest to \mathbf{q} . Following the above discussion, we define the misclassification rate for a given set of random projections given by Eqn. (2).

$$\text{Err}_k(A) = \frac{1}{n \binom{k}{2}} \sum_{\mathbf{p} \in \mathcal{P}} \sum_{i=1}^{k-1} \sum_{j=i+1}^k \mathbf{1}_{\gamma_i(\mathbf{p}) = \text{Maj}(\mathbf{p}, \gamma_i(\mathbf{p}), \gamma_j(\mathbf{p}))}, \quad (2)$$

where $\mathbf{1}_x$ is the indicator function, i.e., $\mathbf{1}_x$ equals to 1 if x is true, and zero otherwise.

The equation measures the average misclassification rate of each point $\mathbf{p} \in \mathcal{P}$ between all pairs of points in the kNN set and will be used as the measure of quality of any embedding.

Given the original high-dimensional points \mathcal{P} , VLR-Map learns the minimum number of random projections that are required to approximately preserve the nearest neighbors using very simple voting principles. We are only interested in preserving the nearest neighbor set of \mathcal{P} , so VLR-Map draws independent random projections until the misclassification rate in the kNN neighborhood is sufficiently small. We measure the error using the distance ordering over all pairs of points of the original kNN neighborhood, i.e., the ordering of the distances between any two nearest neighbor points of \mathbf{p} $\gamma_i(\mathbf{p})$ and $\gamma_j(\mathbf{p})$ for $1 \leq i, j \leq k$. VLR-Map is scalable because its complexity is essentially linear to the dataset size; the algorithm has an $O(nk^2)$ cost per iteration

and the bound of Theorem 3.1 points to the fact that the algorithm will terminate after a finite number of iterations. In the experimental section, we provide further empirical validation on the quality and runtime of our technique and compare it with other embedding methodologies.

Answering kNN queries: After execution of VLR-Map, the resulting set of projected instances of \mathcal{P} can be used for answering proximity queries. Given a query point $\mathbf{q} \in \mathbb{R}^d$ and any two points $\mathbf{p}_i, \mathbf{p}_j \in \mathcal{P}$ we can test whether \mathbf{q} is closer to \mathbf{p}_i or \mathbf{p}_j by using $\text{Maj}(\mathbf{q}, \mathbf{p}_i, \mathbf{p}_j)$. A crucial computational feature when evaluating $\text{Maj}(\cdot, \cdot, \cdot)$ is that it can be effectively approximated by random sampling as previously explained in Lemma 3.2. In practice, a constant number of projections are sufficient for approximately answering proximity queries. So, for any unlabeled query point \mathbf{q} , the algorithm will provide a label based on the consensus voting from all the very-low dimensional classifiers.

5 EXPERIMENTS

We examine the performance and quality of the algorithms presented on several publicly available datasets. [4, 15]. All the datasets are high-dimensional (with dimensionalities varying from 100+ to 10,000), and while they are not very big datasets, they serve well for showcasing the differences in performance and accuracy of the techniques compared. We compare the embedding quality of our approach with traditional random-projection approaches which project on a higher dimensionality that uses the same total space as our methodology. We show that our approach exhibits better classification accuracy and briefly analyze this result.

5.1 Validation of Main Theorem

First, we provide empirical validation for our main result of Theorem 3.1. Recall that the Theorem states essentially that as we increase the number of independent projections, preservation of nearest neighbor structure will be progressively better. Figure 1 plots the embedding error when preserving the 3-NN structure as we progressively increase the number of independent projections. For clarity, we plot the results on four datasets: Email, Gisettd, USPS and MUSK. The results for the other datasets exhibit similar pattern and are omitted.

Figure 1: Empirical validation of Theorem 3.1. When projecting to 10 dimensions (right) instead of 20 (left) an equivalent NN-error can be achieved by using additional independent projections.

We use two target dimensions, $t = 20$ and $t = 10$ and average the results over ten independent executions. Observe that Figure 1 validates the main result, because by using a lower target dimensionality of $t = 10$ an equivalent error of the higher target

dimensionality $t = 20$ can still be achieved through the use of additional projections.

Therefore, the power of the methodology proposed lies in its simplicity; by using and combining additional very-low-dimensional projections we can substantially influence the quality of the embedding and of the distance preservation. It is important to underscore that because the individual projections are independent of each other, the classifiers operating on each of the projections are totally segregated and could be run in parallel. Because each classification is independent of the others (aside from the small voting phase), given sufficient CPUs/cores, the overall runtime of our approach should remain approximately constant, even under increasing cardinality of projections/classifiers.

5.2 Random Projection Methodologies

We compare the classification error of various methodologies based on random projections: VLR-Map, a kNN classifier using a *single* projection onto t dimensions (sRP_t), a kNN classifier with a *single* projection onto $t \cdot l$ dimensions ($\text{sRP}_{t \cdot l}$) and locality-sensitive-hashing (LSH) [8]. $\text{sRP}_{t \cdot l}$ is included in the comparisons to compare the performance of VLR-Map with the traditional single random projection methodology which *uses the same space* ($\text{sRP}_{t \cdot l}$ has the same number of coordinates with our approach). The comparison with LSH is also done under fair settings; the number of hash functions equals the number of projections l of VLR-Map, and the number of bins for each hash function equals the projected dimensionality t . Finally, for reference, we also include the classification accuracy of the kNN classifier on the original high-dimensional points (kNN). We report the results for $k = 3$ nearest neighbors and target dimensionality of $t = 30$ in Table 1. The experiments indicate that our approach can, in fact, achieve comparable (or sometimes even better) performance than the kNN classifier which operates in the original data dimensionality. An advantage of our framework is that it is computationally lighter than a traditional kNN classifier, because in very low dimensional spaces (in which our framework operates) the nearest-neighbor search can be executed efficiently using data structures, such as KD-trees. However, in higher-dimensional spaces, the performance of these techniques degrades rapidly as validated both analytically and empirically in many studies [9].

More importantly, the results suggest that our approach outperforms the traditional projection methodology which uses the same space (i.e., a single random projection at dimensionality $t \cdot l$). One can think of this as quite analogous to the concept behind random forests [6]. Having multiple random classifiers (unweighted in our case) can boost classification and also introduce robustness. Finally, in Table 2 we report the runtime for one experiment on three datasets for the various techniques based on random projections. VLR-Map and $\text{sRP}_{t \cdot l}$ have equivalent runtime, while LSH is costlier.

6 CONCLUSION

Our main theorem highlights that it is feasible to combine many very-low-dimensional projections and guarantee a bounded distortion on the original distances. From a practical viewpoint, the embedding proposed, VLR-Map, exhibits many favorable traits, such as: i) simplicity of implementation, and, ii) scalability: significantly reduced run-time compared to state-of-art embedding techniques with comparable accuracy.

PROOF. of Theorem 3.1: Assume two points \mathbf{x}, \mathbf{y} of the pointset A and a query point $\mathbf{q} \in \mathbb{R}^d$. The goal is to decide whether \mathbf{q} is nearest to \mathbf{x} or to \mathbf{y} . Without loss of generality, we can assume that \mathbf{q} is the origin by linearity (otherwise apply the argument below to the vectors $\mathbf{x} - \mathbf{q}$ and $\mathbf{y} - \mathbf{q}$). So, it suffices to argue that one can check the distances of \mathbf{x} and \mathbf{y} .

Let G be a $t \times d$ random-sign matrix rescaled by $1/\sqrt{t}$, i.e., a matrix whose entries are i.i.d. uniformly distributed r.v. on $\{\pm 1\}$. For any $0 < \epsilon < 1/2$ and $\mathbf{z} \in \mathbb{R}^d$, the following bound is well-known [1]

$$\mathbb{P}\left(\left|\frac{\|G\mathbf{z}\|_2^2}{\|\mathbf{z}\|_2^2} - 1\right| > \epsilon\right) \leq \exp(-C_{\text{JL}}\epsilon^2 t) \quad (3)$$

where $C_{\text{JL}} > 0$ is an absolute constant. More precisely, C_{JL} is the constant of the Johnson-Lindenstrauss lemma with random sign matrices. For any $\mathbf{z}_1, \mathbf{z}_2 \in \mathcal{S}^{d-1}$, define the following event

$$\mathcal{E}_j(\mathbf{z}_1, \mathbf{z}_2) := \left\{ \left| \|G_j \mathbf{z}_1\|_2^2 - 1 \right| < \epsilon \text{ and } \left| \|G_j \mathbf{z}_2\|_2^2 - 1 \right| < \epsilon \right\}.$$

It follows by (3) that for every $j = 1, \dots, l$: $\mathbb{P}(\mathcal{E}_j^c(\mathbf{z}_1, \mathbf{z}_2)) \leq 2\exp(-C_{\text{JL}}\epsilon^2 t)$. Moreover, let us define the event $\text{Maj}(\mathbf{z}_1, \mathbf{z}_2) = \{\mathcal{E}_j(\mathbf{z}_1, \mathbf{z}_2) \text{ holds for } \geq \lceil l/2 \rceil \text{ indices } j.\}$. Let us first bound the probability

$$\begin{aligned} \mathbb{P}(\text{Maj}(\mathbf{z}_1, \mathbf{z}_2)^c) &= \sum_{s=\lceil l/2 \rceil}^l \mathbb{P}(\mathcal{E}_j(\mathbf{z}_1, \mathbf{z}_2)^c \text{ for exactly } s \text{ indices}) \\ &\leq \sum_{s=\lceil l/2 \rceil}^l \binom{l}{s} \mathbb{P}(\mathcal{E}_1(\mathbf{z}_1, \mathbf{z}_2)^c)^s \leq \sum_{s=\lceil l/2 \rceil}^l \binom{l}{s} 2^s \exp(-C_{\text{JL}}\epsilon^2 s t) \\ &\leq \sum_{s=\lceil l/2 \rceil}^l \binom{l}{s} 2^l \exp(-C_{\text{JL}}\epsilon^2 \lceil l/2 \rceil t) \\ &\leq 2^l \exp(-C_{\text{JL}}\epsilon^2 \lceil l/2 \rceil t) \sum_{s=0}^l \binom{l}{s} \leq 2^{2l} \exp(-C_{\text{JL}}\epsilon^2 t l/2). \end{aligned}$$

Now, we bound the probability that the majority of random projections $\{G_j\}$ preserves the norms of every pair of points in \mathcal{N} , where \mathcal{N} is an (ϵ/\sqrt{d}) -net of \mathcal{S}^{d-1} . Recall that $|\mathcal{N}| \leq (3\sqrt{d}/\epsilon)^d$ [14]. Namely, we bound the following $\mathbb{P}(\forall \mathbf{z}_1 \in \mathcal{N}, \forall \mathbf{z}_2 \in \mathcal{N} : \text{Maj}(\mathbf{z}_1, \mathbf{z}_2) = 1 - \mathbb{P}(\exists \mathbf{z}_1, \mathbf{z}_2 \in \mathcal{N}, \text{Maj}(\mathbf{z}_1, \mathbf{z}_2)^c))$. The last quantity can be bounded as follows:

$$\begin{aligned} \mathbb{P}(\exists \mathbf{z}_1, \mathbf{z}_2 \in \mathcal{N}, \text{Maj}(\mathbf{z}_1, \mathbf{z}_2)^c) &\leq \sum_{\mathbf{z}_1, \mathbf{z}_2 \in \mathcal{N}} \mathbb{P}(\text{Maj}(\mathbf{z}_1, \mathbf{z}_2)^c) \\ &\leq |\mathcal{N}|^2 2^{2l} \exp(-C_{\text{JL}}\epsilon^2 t l/2) \leq \left(\frac{\sqrt{d}}{3\epsilon}\right)^{2d} 2^{2l} \exp(-C_{\text{JL}}\epsilon^2 t l/2) \\ &= \exp(-l(C_{\text{JL}}\epsilon^2 t/2 - \ln(4)) + 3d \ln(d/\epsilon^2)), \end{aligned}$$

where in the first inequality we used the union bound and the final inequality by (3). Assume that $\epsilon^2 t > 2 \ln(4)/C_{\text{JL}}$ ($t = \Omega(1/\epsilon^2)$ by assumption), hence if $l \geq \frac{4d \ln(d/\epsilon^2)}{C_{\text{JL}}\epsilon^2 t - 2 \ln(4)} + \ln(1/\delta)$ then

$$\mathbb{P}(\forall \mathbf{z}_1 \in \mathcal{N}, \forall \mathbf{z}_2 \in \mathcal{N} : \text{Maj}(\mathbf{z}_1, \mathbf{z}_2) \geq 1 - \delta).$$

From now on, assume that the following event holds

$$\{\forall \mathbf{z}_1 \in \mathcal{N}, \forall \mathbf{z}_2 \in \mathcal{N} : \text{Maj}(\mathbf{z}_1, \mathbf{z}_2)^c\}. \quad (4)$$

Next we prove that (assuming (4)) if $(1 + \gamma) \|\mathbf{x}\|_2 \leq \|\mathbf{y}\|_2$, then the majority of the fixed projections $\{G_i\}_{i \in [l]}$ will satisfy $\|G_i \mathbf{x}\|_2 < \|G_i \mathbf{y}\|_2$.

Indeed, let \mathbf{x}_N and \mathbf{y}_N be the net points that are nearest to $\mathbf{x}/\|\mathbf{x}\|_2$ and $\mathbf{y}/\|\mathbf{y}\|_2$, respectively. Namely, it holds that $\|\mathbf{x}/\|\mathbf{x}\|_2 - \mathbf{x}_N\|_2 \leq \epsilon/\sqrt{d}$ and $\|\mathbf{y}/\|\mathbf{y}\|_2 - \mathbf{y}_N\|_2 \leq \epsilon/\sqrt{d}$. Conditioning on the event in Eq. (4) implies that for the majority of $\{G_j\}_{j \in [l]}$

$$\begin{aligned} \|G_j \mathbf{x}\|_2 &= \|\mathbf{x}\|_2 \|G_j \mathbf{x}/\|\mathbf{x}\|_2 - G_j \mathbf{x}_N + G_j \mathbf{x}_N\|_2 \\ &\leq \|\mathbf{x}\|_2 (\|G_j\|_2 \|\mathbf{x}/\|\mathbf{x}\|_2 - \mathbf{x}_N\|_2 + \|G_j \mathbf{x}_N\|_2) \\ &\leq \|\mathbf{x}\|_2 (\|G_j\|_2 \epsilon/\sqrt{d} + 1 + \epsilon) \leq (1 + 2\epsilon) \|\mathbf{x}\|_2, \end{aligned}$$

where the first inequality is triangle inequality combined with standard matrix norms, the second inequality follows by Eq. (4) and the definition of \mathbf{x}_N and the last inequality follows since $\|G_j\|_2 \leq \|G_j\|_F \leq \sqrt{d}$.

Similarly, for the majority of the indices j ,

$$\begin{aligned} \|G_j \mathbf{y}\|_2 &= \|\mathbf{y}\|_2 \|G_j \mathbf{y}/\|\mathbf{y}\|_2 - G_j \mathbf{y}_N + G_j \mathbf{y}_N\|_2 \\ &\geq \|\mathbf{y}\|_2 (\|G_j \mathbf{y}_N\|_2 - \|G_j\|_2 \|\mathbf{y}/\|\mathbf{y}\|_2 - \mathbf{y}_N\|_2) \\ &\geq \|\mathbf{y}\|_2 (1 - \epsilon - \|G_j\|_2 \epsilon/\sqrt{d}) \geq (1 - 2\epsilon) \|\mathbf{y}\|_2. \end{aligned}$$

Therefore, we conclude that the ratio $\|G_j \mathbf{y}\|_2 / \|G_j \mathbf{x}\|_2$ is at least $\frac{(1-2\epsilon)\|\mathbf{y}\|_2}{(1+2\epsilon)\|\mathbf{x}\|_2} \geq \frac{(1-2\epsilon)}{(1+2\epsilon)}(1 + \gamma) > 1$ for the majority of random projections $\{G_j\}_{j \in [l]}$ as $\gamma > 6\epsilon$. \square

Interval Count Semi-Joins

ABSTRACT

Interval joins find applications in several domains, including temporal and spatial databases, uncertain data management, streaming data processing. In this paper, we study the evaluation of an interval count semi-join (*ICSJ*) operation that can be used for selecting or ranking intervals based on the number of join pairs they appear in. We extend the state-of-the-art algorithm for interval joins to evaluate *ICSJ* at the cost of only scanning the sorted interval endpoints.

1 INTRODUCTION

The interval join (*IJ*) is an important and well-studied operation that finds several applications. In its most widely used definition, the interval join takes as input two collections of intervals R and S , and outputs the pairs $(r, s) \in R \times S$, such that intervals r and s overlap¹. In temporal databases [8], tuples are associated with validity intervals and interval joins can be used to find pairs of tuples with overlapping validity (e.g., find pairs of employees who worked in two enterprises during overlapping time periods). In spatial databases, multidimensional overlap joins reduce to interval joins if the spatial extent of the objects is represented by a set of intervals with the help of space-filling curves [11]. In probabilistic databases, values in continuous domains are often represented by intervals of values which have non-zero probability [4]. Finally, in applications that process streaming data, values read from different streams can be joined by (often parameterized) temporal windows [7]. Such sliding window joins can be modeled as overlap joins, if the values are extended by the window lengths and modeled as intervals. A number of single-processor [2, 5, 6, 13, 14] and parallel [1, 3, 9] algorithms for interval joins have been proposed. Among them, methods that are based on plane-sweep prevail due to their optimal worst-case complexity and their efficient implementations [1, 13].

In this paper, we study the efficient evaluation of an *Interval Count Semi-Join (ICSJ)* operation, where the objective is to find how many pairs in the interval join $IJ(R, S)$ result include each $r \in R$. For example, consider interval collections $R = \{r_1, r_2, r_3\}$ and $S = \{s_1, s_2, s_3, s_4\}$ depicted in Figure 1. $ICSJ(R, S) = \{(r_1, 2), (r_2, 1), (r_3, 3)\}$ because r_1, r_2 and r_3 overlap with 2, 1, and 3 intervals from S , respectively. *ICSJ*(R, S) can be seen as a case of temporal aggregation on S , using R as the set of fixed intervals [12]. The result of *ICSJ* can be used to select or rank objects that are associated with the intervals in R based on the number of intervals in S they intersect. For example, if R includes the employment periods of employees in company A and S includes the periods of employees in company B, we may wish to find the k employees in A whose employment time overlaps with that of

Figure 1: Collections $R = \{r_1, r_2, r_3\}$ and $S = \{s_1, s_2, s_3, s_4\}$.

the most employees in B (e.g., employee r_3 in Figure 1, if $k = 1$). This problem can be solved by ranking the *ICSJ* output, or by using a priority queue to keep track of the top- k *ICSJ* results while they are computed.

To our knowledge, *ICSJ* has not been adequately studied to date. Top- k count semi-joins have been studied in relational [15] and spatial databases [16], but the techniques in these studies are unsuited for *ICSJ*, as they apply on different data domains and they make use of indices. We present an efficient *smart counting* algorithm for evaluating *ICSJ*, which applies on two sorted input collections R and S and extends the state-of-the-art sweeping based *IJ* algorithm. The algorithm bears only the minimal cost of scanning the sorted inputs. Experiments on four real datasets show that it is orders of magnitude faster than simpler alternatives.

2 BACKGROUND

Related work on *IJ* includes techniques based on indexing or partitioning [2, 5, 6] and methods that sort inputs R, S to perform merge-join [14] or plane-sweep based join [1, 13]. Recent studies [1, 13] focused on in-memory processing and showed that plane-sweep based techniques are superior to other methods.

Algorithm 1 describes a plane-sweep based algorithm for interval joins. Initially, the domain points (or simply points) of all intervals in R, S are extracted and sorted into list L (Lines 2–3). Intuitively, L defines the stops of an imaginary line that sweeps the domain; so, the sweep line stops both at the start and the end point of an interval. An *active set* A^R and A^S is initialized for each of the two input collections. Sets A^R and A^S keep track of the intervals that are currently “open” (i.e., their start point has been encountered but not their end point). Each point in list L is accessed in order; if it is a start point of an interval, e.g., $r \in R$, r is guaranteed to overlap all intervals in A^S . Therefore, all pairs in $\{r\} \times A^S$ are reported. For example, consider Figure 1 and assume that the start point of r_3 is currently accessed (i.e., the sweep line is the leftmost vertical line). The active set of S is $A^S = \{s_2\}$, hence the algorithm outputs pair (r_3, s_2) as part of the join result. If an end point is encountered by the sweep line (Lines 11–12 and 18–19 of Algorithm 1), the corresponding interval is no longer open, so it is removed from its respective active set.

Assuming an efficient data structure, which performs insertions and deletions to the active sets in constant time (e.g., a hash table), Algorithm 1 computes the join in $O(|R| + |S| + K)$ time, where K is the number of result pairs, excluding the sorting cost of list L . Note that when a start point is encountered, an active set should be scanned to generate join results. Scanning a hash table

¹Two intervals overlap (or intersect) if they share at least one common value.

ALGORITHM 1: Plane-Sweep based Interval Join

Input : collections of intervals R and S
Output : set of all intersecting interval pairs $(r, s) \in R \times S$
Variables : interval points list L , active sets A^R, A^S

```
1  $A^R \leftarrow \emptyset, A^S \leftarrow \emptyset$ ;  $\triangleright$  sets of active intervals from  $R$  and  $S$ 
2  $L \leftarrow$  start and end points of all intervals in  $R \cup S$ ;
3 sort  $L$ ;
4 while  $L$  is not depleted do
5    $p \leftarrow$  next point in  $L$ ;
6   if  $p$  originates from collection  $R$  then
7      $r \leftarrow$  interval in  $R$  where  $p$  belongs;
8     if  $p$  is a start point then
9       add  $r$  to  $A^R$ ;  $\triangleright r$  is open
10      output  $\{(r, s) : \forall s \in A^S\}$ ;  $\triangleright r$  overlaps all
11      intervals in  $A^S$ 
12      else remove  $r$  from  $A^R$ ;  $\triangleright r$  no longer open
13    else
14       $s \leftarrow$  interval in  $S$  where  $p$  belongs;
15      if  $p$  is a start point then
16        add  $s$  to  $A^S$ ;  $\triangleright s$  is open
17        output  $\{(r, s) : \forall r \in A^R\}$ ;  $\triangleright s$  overlaps all
18        intervals in  $A^R$ 
19      else remove  $s$  from  $A^S$ ;  $\triangleright s$  no longer open
```

is expensive as it incurs random accesses in memory; to this end, Piatov et al. [13] designed the *gapless hash map* which efficiently supports all three insert, remove and getNext operations.² Finally, in [1], an implementation of the plane-sweep based interval join that replaces active sets (e.g., A^R) by forward scans to the other collection (i.e., S), was investigated and optimized.

3 EVALUATING ICSJ

We now investigate how the plane-sweep based Algorithm 1 can be extended to efficiently evaluate interval count semi-joins. Recall that the goal is to count for every interval $r \in R$, the number of overlapping intervals from S .

A naive approach for computing $ICSJ(R, S)$ is to evaluate $IJ(R, S)$ first. Then in an aggregation step, we need to sort or hash the (r, s) join pairs by their first element, and count and report the number of pairs for each $r \in R$. Naturally, this method is at least as expensive as the interval join problem. In fact, since the number of overlapping intervals can be much greater than the sizes $|R|$ and $|S|$ of the two inputs, the cost of sorting or hashing the $IJ(R, S)$ results may dominate the overall evaluation cost.³

To address these shortcomings, we next present two methods, which extend Algorithm 1 to directly compute $ICSJ(R, S)$.

3.1 The Simple Counting Approach

We first discuss an intuitive extension to Algorithm 1 based on the following observation. When the start point of an interval (e.g., $r \in R$) is encountered, the algorithm scans the active set of the other collection (i.e., A^S) to produce join pairs $\{r\} \times A^S$. As our objective is only to count the intervals from S that overlap interval r , we do not have to scan active set A^S ; instead, we only need to add its size $|A^S|$ to a dedicated counter for r . Note that

²In [13], Algorithm 1 is presented as the *Endpoint-Based Interval* (EBI) Join algorithm.

³Note also that this naive method is not suitable for in-memory evaluation of count semi-joins due to buffering all $IJ(R, S)$ result pairs.

ALGORITHM 2: Simple Counting

Input : collections of intervals R and S
Output : for each $r \in R$, $|s : s \in S, \text{ and } r \text{ intersects } s|$
Variables : interval points list L , active sets A^R, A^S , hash table C

```
1  $A^R \leftarrow \emptyset, A^S \leftarrow \emptyset$ ;  $\triangleright$  sets of active intervals from  $R$  and  $S$ 
2  $L \leftarrow$  start and end points of all intervals in  $R \cup S$ ;
3 sort  $L$ ;
4 while  $L$  is not depleted do
5    $p \leftarrow$  next point in  $L$ ;
6   if  $p$  originates from collection  $R$  then
7      $r \leftarrow$  interval in  $R$  where  $p$  belongs;
8     if  $p$  is a start point then
9       add  $r$  to  $A^R$ ;  $\triangleright r$  is open
10       $C[r] \leftarrow |A^S|$ ;  $\triangleright$  initialize counter for  $r$ 
11      else
12        remove  $r$  from  $A^R$ ;  $\triangleright r$  no longer open
13        output  $(r, C[r])$ ;
14        delete  $C[r]$ ;
15      else
16         $s \leftarrow$  interval in  $S$  where  $p$  belongs;
17        if  $p$  is a start point then
18          add  $s$  to  $A^S$ ;  $\triangleright s$  is open
19          foreach  $r \in A^R$  do
20             $C[r] \leftarrow C[r] + 1$ ;  $\triangleright s$  overlaps all
21            intervals in  $A^R$ 
22          else remove  $s$  from  $A^S$ ;  $\triangleright s$  no longer open
```

this is not the final value of this counter, because r may also overlap with intervals from S that start later. Nevertheless, we can eliminate the overhead of scanning the active set of collection S , which in practice also means that a typical hash table can be used for A^S instead of an optimized special structure (e.g., the gapless hash map of [13]) as we only need to support efficient insertions and deletions. In contrast, we still have to support efficient scans for active set A^R , because for each encountered start point from S , we have to scan A^R in order to increase the counters of all open intervals from r .

Algorithm 2 is a pseudocode of this *Simple Counting* approach. Compared to Algorithm 1, we define a hash table C to maintain the dedicated counter for each open interval from collection R . Further, as already discussed, Simple Counting initializes counter $C[r]$ in Line 10, when the start point of an interval $r \in R$ is seen. The counter for each $r \in A^R$ is then increased by 1, when the start of an interval from S is seen in Lines 19–20. Finally, as soon as the end point of r is accessed, counter $C[r]$ is finalized and hence removed from hash table C and reported as result (Lines 13–14). Consider for example r_3 in Figure 1; when accessing the start point of the interval, counter $C[r_3]$ is initialized to 1 as $A^S = \{s_2\}$. After the next two stops of the sweep line marked in the figure, i.e., when the start points of intervals s_2 and s_3 are encountered, $C[r_3]$ is increased to 3. Algorithm 2 is similar to the general approach for temporal aggregation, proposed in [12].

Simple Counting is expected to always outperform the naive solution; recall that the latter needs to completely evaluate IJ as its first step. On the other hand, Algorithm’s 2 cost is in same order to Algorithm 1 as half of the IJ results are still computed, i.e., the pairs generated in Lines 19–20 when encountering start points from S . Note that Simple Counting is also charged with the book-keeping cost for the counters of hash table C . In view

ALGORITHM 3: Smart Counting

Input : collections of intervals R and S
Output : for each $r \in R$, $|s : s \in S, \text{ and } r \text{ intersects } s|$
Variables : interval points list L , hash table C

```
1  $|A^S| \leftarrow 0$ ;  $\triangleright$  active set counter for intervals from  $S$ 
2  $g \leftarrow 0$ ;  $\triangleright$  global counter
3  $L \leftarrow$  start and end points of all intervals in  $R \cup S$ ;
4 sort  $L$ ;
5 while  $L$  is not depleted do
6    $p \leftarrow$  next point in  $L$ ;
7   if  $p$  originates from collection  $R$  then
8      $r \leftarrow$  interval in  $R$  where  $p$  belongs;
9     if  $p$  is a start point then
10       $C[r] \leftarrow |A^S| - g$ ;  $\triangleright$  initialize counter for  $r$ 
11     else
12       $C[r] \leftarrow C[r] + g$ ;
13      output  $(r, C[r])$ ;
14      delete  $C[r]$ ;
15     else
16       $s \leftarrow$  interval in  $S$  where  $p$  belongs;
17      if  $p$  is a start point then
18         $|A^S| \leftarrow |A^S| + 1$ ;  $\triangleright$  increase active set counter
19         $g \leftarrow g + 1$ ;  $\triangleright$  increase global counter
20      else
21         $|A^S| \leftarrow |A^S| - 1$ ;  $\triangleright$  decrease active set counter
```

of these shortcomings, we next present a significantly faster extension to Algorithm 1.

3.2 The Smart Counting Approach

The main idea behind the *Smart Counting* extension to Algorithm 1 is to maintain cheap statistics about the intervals from S instead of keeping track of A^S at every position of the sweep line. Algorithm 3 is the pseudocode of the Smart Counting approach. We now discuss its key features.

First, we observe that only the size of active set A^S is in fact needed for the *ICSJ* computation. Although the Simple Counting algorithm presented in Section 3.1 keeps track of the open intervals from S , the contents of A^S are never scanned and only $|A^S|$ is used on Line 10 of Algorithm 2. Hence, we can replace the hash table of active set A^S by a simple size counter $|A^S|$; when the start point of an interval $s \in S$ is encountered, this counter is increased by 1 (Line 18) while after an end point from S is accessed the same counter is reduced by 1 (Line 21). Next, we define a *global counter* g to keep track of the *number* of intervals from S that have opened (regardless whether their end point is already accessed or not). Similar to $|A^S|$, counter g is increased by 1 in Line 19 when a start point from collection S is seen but never decreased which means that $g \geq |A^S|$ always holds.

By combining counters $|A^S|$ and g , we are able to compute the number of intervals from S that opened or were open in-between the start and the end point of an interval $r \in R$. In specific, we initialize the dedicated counter $C[r] = |A^S|$ when the start point of r is encountered but then subtract the value of global counter g (Line 8). Compared to Algorithm 2, notice that we no longer maintain open intervals from R to active set A^R ; instead we employ hash table C to store the current value of r 's dedicated counter. After the end point of interval r is seen, we just need to add back the current value of g to $C[r]$ and report

Table 1: Characteristics of experimental datasets

	FLIGHTS	BOOKS	GREEND	WEBKIT
Cardinality	445,827	2,312,602	110,115,441	2,347,346
Domain duration (secs)	2,750,280	31,507,200	283,356,410	461,829,284
Shortest interval (secs)	1,261	1	1	1
Longest interval (secs)	42,301	31,406,400	59,468,008	461,815,512
Avg. interval duration (secs)	8,791	2,201,320	16	33,206,300
Distinct domain points	41,975	5,330	182,028,123	174,471

result $(r, C[r])$ (Lines 12–13). This procedure guarantees that we will end up with the correct value of $C[r]$, because the difference from global counter g corresponds to the number of intervals from S that opened after r 's start point. Note that these intervals overlap with r but were not considered when $C[r]$ was initialized.

We expect the Smart Counting approach to significantly outperform Simple Counting as the cost of maintaining and scanning active sets A^R, A^S is completely eliminated. Further, we manage to avoid the random accesses that incur during the for-loop on Lines 19–20 of Algorithm 2 when the counters for multiple intervals are concurrently updated. Overall, the cost of Smart Counting (excluding sorting) is $O(|R| + |S|)$ due to the constant-time cost of processing at each position of the sweep line.

4 EXPERIMENTAL ANALYSIS

4.1 Setup

For our experiments, we implemented all methods in C++ and compiled them using gcc (v5.2.1). Note that all data (input collections, active sets, interval points list etc.) resided in main memory.

Methods. Besides gapless hash map, the authors in [13] also discussed a lazy optimization for plane-sweep based Algorithm 1, which buffers consecutive start points in list L from the same input (e.g., R). When producing *IJ* results, a single scan over the active set of the other input (i.e., A^S) is performed for the entire buffer. By restricting buffers to fit inside L1 cache or even the cache registers, this technique reduces cache misses. To enhance *ICSJ* computation, we applied this lazy optimization on Naïve and Simple Counting. For the latter, we buffer consecutive start points from S allowing us to increase $C[r]$ for each $r \in A^R$ by the buffer size instead of 1 as in Lines 19–20 of Algorithm 2. On the other hand, lazy optimization has no effect on Smart Counting.

Datasets. Table 1 details our 4 real-world experimental datasets. FLIGHTS records domestic flights in USA during January 2016 (<https://www.bts.gov>); valid times indicate the duration of a flight. BOOKS records the transactions at Aarhus public libraries in 2013 (<https://www.odaa.dk>); valid times indicate the periods when a book is lent out. GREEND [10, 13] records power usage information in households across Austria and Italy from January 2010 to October 2014; valid times indicate the period of a measurement. WEBKIT records the file history in the git repository of the Webkit project from 2001 to 2016 (<https://webkit.org>); valid times indicate the periods when a file did not change.

Tests. We ran interval count semi-joins using a uniformly sampled subset of each dataset as outer input R and the entire dataset as inner S ; for this purpose, we varied ratio $|R|/|S|$ inside $\{0.25, 0.5, 0.75, 1\}$. To assess the performance of the methods, we measured their total execution time which breaks down to the time spent (i) to generate and sort the list of interval points L , denoted by Sorting, and (ii) to compute the *ICSJ* result, denoted by Joining.

4.2 Experiments

Figures 2 and 3 report the results of our experimental analysis. In specific, Figure 2 reports the total execution time of each method

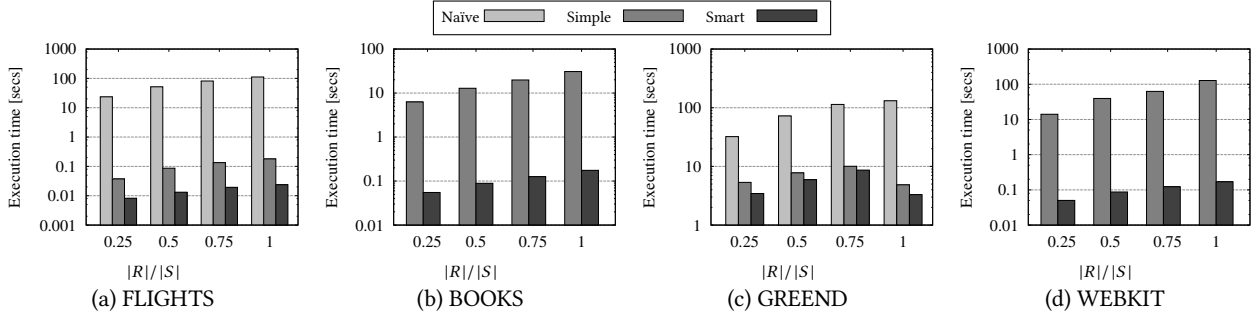

Figure 2: Total execution time while varying the $|R|/|S|$ ratio.

Figure 3: Execution time breakdown for $|R| = |S|$.

while varying the $|R|/|S|$ ratio and Figure 3 reports a breakdown of the execution time for the $|R| = |S|$ case. As expected, we were able to run the Naïve method only when $ICSJ$ was very selective, i.e., for datasets FLIGHTS and GREEND. Recall from Section 3 that Naïve first evaluates the IJ of the input collections; on BOOKS and WEBKIT, it was impossible to accommodate the enormous number of IJ result pairs in main memory.⁴

Figure 2 demonstrates the efficiency of the Smart Counting approach, which outperforms Simple Counting in all cases. In fact, Simple is competitive to Smart only for very selective join setups (see Figure 2(c)) while in all other cases, Smart is at least one order of magnitude faster. To explain the performance cost differences between Smart and Simple, we breakdown their execution times. In Figure 3(c), the execution cost of Simple is dominated by the generation and sorting of the points list L , because the number of overlapping interval pairs is small, rendering the inner loop at lines 19-20 of Algorithm 2 cheap. On other hand, when there is a large number of overlapping intervals, Figure 3 unveils that maintaining active sets and performing random accesses to update C counters severely impacts the joining time of Simple. In contrast, observe that the cost by Smart to compute the $ICSJ$ result is always much lower than that of generating/sorting L . This is expected because Smart is insensitive to the IJ result, as discussed in Section 3.2.

5 CONCLUSIONS

In this paper, we studied the evaluation of the interval count semi-join operation; we presented an efficient algorithm based on plane sweep. Our algorithm has lower complexity compared to state-of-the-art interval join algorithms if the number of join results is large. We experimentally showed that its overhead on top of sorting the data is minimal in all setups, which means that it is especially tailored in cases where the join inputs are already sorted (e.g., in streaming data applications). In the future, we plan to further study the semantics and the evaluation of top- k

⁴We also experimented with a version of Naïve that flushes the IJ result pairs on disk which was even slower.

interval joins. We also intend to investigate the applications of interval joins and other temporal operations in streaming data.

ABSTRACT

Query answering routinely employs knowledge graphs to assist the user in the search process. Given a knowledge graph that represents entities and relationships among them, one aims at complementing the search with intuitive but effective mechanisms. In particular, we focus on the comparison of two or more entities and the detection of unexpected, surprising properties, called *notable characteristics*. Such characteristics provide intuitive explanations of the peculiarities of the selected entities with respect to similar entities. We propose a solid probabilistic approach that first retrieves entity nodes similar to the query nodes provided by the user, and then exploits distributional properties to understand whether a certain attribute is interesting or not. Our preliminary experiments demonstrate the solidity of our approach and show that we are able to discover notable characteristics that are indeed interesting and relevant for the user.

1 INTRODUCTION

Search engines have greatly evolved from simple indexes of pages to complex systems that are able to predict user intentions and answer queries on a variety of data sources. One way to improve the search quality is by using a knowledge graph that represents entities (e.g., Angela Merkel, Germany) as nodes and relationships between them (e.g., leaderOf) as edges in a graph. The great expressiveness of knowledge graphs can complement the search with more flexible search paradigms. Assume for instance a scholar who requires to know some non-trivial facts about Angela Merkel and Emmanuel Macron with respect to other country leaders. It would be interesting to discover for instance that Angela Merkel studied Physics as opposed to most of the other leaders, and that she has no children. We call this fact a *notable characteristic*, to remark the unexpected and non-trivial aspect of the discovery. To this end, we propose a novel type of search called *notable characteristics search* that allows the retrieval of such facts from a set of input query entities. Discovering notable characteristics constitutes a ground for targeted analyses of products (e.g., comparing two cameras effectively) in electronic commerce or microorganisms in biological networks (e.g., two influence bacteria) with respect to a set of similars. As a consequence, in all the cases in which a knowledge graph is available, the discovery of notable characteristics becomes an expressive and powerful search type for any user, from experts and practitioners to novice users.

In our setting, we assume the user provides a set of *query* nodes to be compared and the algorithm finds a set of notable characteristics of these nodes. Given a node, a property is a relationship with other nodes (e.g., leaderOf). A characteristic or property is notable, if it deviates from what one would expect for the kind of nodes (e.g., presidents) into consideration. To the best of our knowledge, this is the first study of automatic discovery of notable characteristics (or properties).

Figure 1: An example knowledge graph, the query (Merkel and Macron), and the discovered context nodes (Putin, Xi Jinping, and Rajoy). The fact that Merkel and Macron do not have children is a notable characteristic.

The discovery of notable characteristics entails two challenges. First, given the set of query nodes we need to compare them to only those nodes that are similar to some extent. Second, we need to select only those properties that are significantly different from the one expressed in the query. Note that tackling the first challenge is very important, as the comparison of the query nodes has to be performed with a set of similar nodes, which we call the context of the query. Consider the naïve approach that returns notable characteristics simply by comparing the query nodes and assume that the user provides “Angela Merkel” and “Theresa May” as query. This is a counter example for the naïve direct comparison, as it will not return the gender as a notable characteristic. Both query nodes are female, however only in comparison with other presidents this becomes an interesting fact. On the other extreme, selecting all the nodes in the graph as context will mislead the analysis towards non-relevant nodes. Take our example of “Angela Merkel” and “Emmanuel Macron”. A naïve selection of all humans will not work as context, since the gender characteristic is not notable among all persons.

It is crucial to provide a thorough context selection to prevent the above cases. Therefore, we introduce the discovery of *context nodes*, i.e., nodes similar to the query nodes. An example of the proposed approach is depicted in Figure 1. To this end, we devise a method that exploits metapaths [12] and random walks for context discovery. We also propose a generic framework that efficiently discover notable characteristics through a novel probabilistic approach based on distribution comparison.

Our contributions are summarized as follows: (1) We formalize the problem of *notable characteristics search* given a set of query nodes as input. (2) We show how to effectively compute metapaths to find the context nodes in knowledge graphs. (3) We introduce a probabilistic approach to discover notable characteristics given a query node set. (4) We experimentally evaluate our context selection approach through a user study, and show evidence of our discovered notable characteristics and the real time performance of the proposed algorithms.

2 NOTABLE CHARACTERISTICS SEARCH

We are given a set \mathcal{A} of node labels and a set \mathcal{L} of edge labels. A *knowledge graph* is a directed graph $G : \langle \mathcal{V}, \mathcal{E}, \phi, \psi \rangle$, where \mathcal{V} is a set of nodes, $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is a set of edges, $\phi : \mathcal{V} \mapsto \mathcal{A}$, $\psi : \mathcal{E} \mapsto \mathcal{L}$ are node and edge labeling functions, respectively.

For simplicity, we assume that everything is modeled as relationships and nodes. This is the case for attributes such as birth date: we assume that the date itself is a node connected with a birthdate relationship. Additionally, we assume that for every edge $e \in \mathcal{E}$ with type $\psi(e) = l$ exists a reverse edge e^{-1} with $\psi(e^{-1}) = l^{-1}$ to model cases such as `presidentOf` and `hasPresident`. The above assumptions do not change the generality of the methods but simplify the notation and the analysis.

We aim at discovering *notable characteristics* expressed as a set of input query nodes (entities) in relation to their similars. This intuitive definition entails two questions: (1) what is the set of similars? (2) what are the notable characteristics?

Given a knowledge graph $G : \langle \mathcal{V}, \mathcal{E}, \phi, \psi \rangle$, the set of input nodes, referred to as *query set* or query in short, is any set $Q \subseteq \mathcal{V}$. The query is manually provided by the user and therefore considered reasonably small (i.e., ≤ 10 elements). The first question concerns the definition of a set of similars referred in this work as *context nodes*. We assume the existence of a *similarity function* $\sigma : \mathcal{V} \times 2^{\mathcal{V}} \mapsto \mathbb{R}$ that assigns a high score to nodes that are similar to those in the query set and low otherwise. Given such similarity, the context are the top- k most similar nodes.

Definition 2.1 (Context set). Given a knowledge graph $G : \langle \mathcal{V}, \mathcal{E}, \phi, \psi \rangle$, a query set $Q \subseteq \mathcal{V}$, a similarity function $\sigma : \mathcal{V} \times 2^{\mathcal{V}} \mapsto \mathbb{R}$, and a parameter k , the *context set* (or simply context) is a set $C \subseteq \mathcal{V}$ such that $Q \cap C = \emptyset$, $|C| = k$, and for each $n_c \in C \wedge n \in \mathcal{V} \setminus (Q \cup C)$, $\sigma(n, Q) \leq \sigma(n_c, Q)$.

The second question concerns the notable characteristics. The characteristics are attributes or relationships of a specific node since they implicitly represent a signature of the node itself. We assume the existence of a generic *discrimination function* $\delta : \mathcal{L} \times 2^{\mathcal{V}} \times 2^{\mathcal{V}} \mapsto \mathbb{R}_0^+$, which represents how a specific characteristic is discriminative or unexpected comparing two set of nodes. The discrimination function returns 0 if the value is not discriminative. We are now ready to define a notable characteristic.

Definition 2.2 (Notable characteristic). Given a knowledge graph $G : \langle \mathcal{V}, \mathcal{E}, \phi, \psi \rangle$, a query $Q \subseteq \mathcal{V}$, a context $C \subseteq \mathcal{V}$, and a discrimination function $\delta : \mathcal{L} \times 2^{\mathcal{V}} \times 2^{\mathcal{V}} \mapsto \mathbb{R}_0^+$ a *notable characteristic* is a relationship $l \in \mathcal{L}|_{Q \cup C}$ such that $\delta(l, Q, C) \neq 0$.

The notation $\mathcal{L}|_{Q \cup C} = \{l \mid \exists x \in Q \cup C, y \in \mathcal{V} \text{ s.t. } (x, y) \in \mathcal{E} \wedge \psi(x, y) = l\}$ denotes the set of edge labels restricted to those found in the edges directly connected to $Q \cup C$.

The general problem we aim to solve is efficiently returning the notable characteristics, given a query, a similarity function and a discrimination function.

PROBLEM 1 (NOTABLE CHARACTERISTICS SEARCH). *Given a knowledge graph $G : \langle \mathcal{V}, \mathcal{E}, \phi, \psi \rangle$, a query $Q \subseteq \mathcal{V}$, a similarity function $\sigma : \mathcal{V} \times 2^{\mathcal{V}} \mapsto \mathbb{R}$ and a discrimination function $\delta : \mathcal{L} \times 2^{\mathcal{V}} \times 2^{\mathcal{V}} \mapsto \mathbb{R}_0^+$, find the set of notable characteristics.*

3 A PROBABILISTIC SOLUTION

The problem entails the definition of appropriate σ (similarity) and δ (discrimination) functions. Section 3.1 introduces a graph-principled solution based on random walks for retrieving context nodes, while Section 3.2 describes a probabilistic approach to effectively discover notable characteristics.

3.1 Finding the context

Given the query Q , we define a similarity function σ to retrieve a set of context nodes. Although many notions of similarity functions have been developed, such as SimRank [4], none seems suitable to our case since they compare two nodes at the time. We devise an algorithm that takes into account edge labels and combines the advantages of random walk and metapath approaches.

In the random walk model, a walker chooses one of the outgoing edges from a node with uniform probability. Motivated by information theoretic notions applied to graphs [10], instead of uniform probability, we favor edge labels with lower frequency. We define $\mathcal{E}_l = \{(i, j) \in \mathcal{E} \mid i, j \in \mathcal{V}, \psi(i, j) = l\}$, the set of edges having label $l \in \mathcal{L}$. The frequency of a label l is the fraction of l -labeled edges with respect to the total number of edges. The weighted adjacency matrix is a $|\mathcal{V}| \times |\mathcal{V}|$ matrix, where for each node i and j , $A_{ij} = 1 - |\mathcal{E}_l|/|\mathcal{E}|$ if $(i, j) \in \mathcal{E}$ and $A_{ij} = 0$ otherwise.

The Personalized PageRank is the vector $\mathbf{p} = c\tilde{A}\mathbf{p} + (1 - c)\mathbf{v}$, where $\tilde{A}_{ij} = A_{ji}/\sum_k A_{jk}$, c is the damping factor, and \mathbf{v} is vector called personalization vector. In our experiments the damping factor is 0.8, in line with previous works. We compute \mathbf{p} starting from each node in the query to retrieve the k nodes with the highest score. This is done by setting $\mathbf{v}_n = 1/|Q|$ for each $n \in Q$. We refer to this baseline as RANDOMWALK.

The PageRank disregards which type of relationships are involved in the random walk, discarding the valuable information encoded in the surrounding of the query nodes. To this end, we adopt the notion of metapath [8, 12] which generalizes the concept of path. A metapath for a path $\langle n_1, \dots, n_t \rangle$, $n_i \in \mathcal{V}$, $1 \leq i \leq t$ is a sequence $\langle \phi(n_1), \psi(n_1, n_2), \dots, \psi(n_{t-1}, n_t), \phi(n_t) \rangle$ that alternates node and edge labels along the path.

We mine metapaths as follows. We sample a node in $\mathcal{V} \setminus Q$ uniformly and run a random walk until a query node is reached. The sequence of edge labels m encountered in the random walk is added to the set of metapaths M along with the number of times $c(m)$ the same metapath has been found so far. It has been proved that random walks are effective in mining metapaths [7].

Once the metapaths are retrieved, we compute a score for each node based on the probability that some metapath starting from a query node ends in such node. Given the set of metapaths M , $\{n \overset{m}{\rightsquigarrow} n'\}$ is the set of paths from node n to n' matching metapath $m \in M$. The score of a node $n' \in \mathcal{V} \setminus Q$ with respect to $n \in Q$ is

$$\sigma(n', Q) = \sum_{m \in M, n \in Q} \frac{|\{n \overset{m}{\rightsquigarrow} n'\}|}{|\{n \overset{m}{\rightsquigarrow} n'' \mid n'' \in \mathcal{V} \setminus Q\}|} \Pr(m) \quad (1)$$

$\Pr(m) = c(m)/\sum_{m \in M} c(m)$ is the probability of choosing metapath m . Intuitively, σ gives a higher score to nodes that are reachable through frequent metapaths connecting the query nodes or connected through many of these metapaths. Hence, nodes that are reached from infrequent metapaths will have a low score. We refer to this method as CONTEXTRW.

3.2 Comparing the distributions

We revise the definition of notable characteristics in probabilistic terms. Assume we have computed the distribution of values for each characteristic (i.e., edge label) for both query and context nodes found with the method in Section 3.1. Such distribution of the context represents the expected, or *normal* behavior, to be evaluated against the *notable* behaviour of the query set.

Formally, for each characteristic $l \in \mathcal{L}$, we consider two vectors in order to evaluate its notability. The first represents the count of the node labels (e.g., France) connected to a specific edge label (e.g., `bornIn`). This expresses information about the values in the nodes and can be used to identify cases where different attribute values are relevant. For instance, in the query in Figure 1 all people are European, while in the context half are Europeans and half Asian. We refer to these vectors as *instance vectors*

$$\mathcal{I}_q(l, C, Q) = (x_1, x_2, \dots, x_t), \mathcal{I}_c(l, C) = (y_1, y_2, \dots, y_t)$$

where x_i and y_i are the number of occurrences of node i at the end of an edge labeled l from a node in Q and C , respectively. In the example in Figure 1, $\mathcal{I}_q(\text{studied}, C, Q) = (1, 1, 0)$,

$\mathcal{I}_c(\textit{studied}, C) = (0, 0, 3)$, where the positions in the vector indicate (Physics, Philosophy, Law). Note that both vectors have the same size, so x_i is zero if i appears only in the context.

Similarly, the second vector represents aggregates over the number of occurrences of a specific edge label in the context, which are useful to represent the characteristic ‘‘Angela Merkel’’ has no child, instead of listing the children names. We refer to these vectors as *cardinality vectors*.

$$\mathcal{K}_q(l, C, Q) = (x_1, x_2, \dots, x_l), \mathcal{K}_c(l, C) = (y_1, y_2, \dots, y_l)$$

where x_i and y_i are the number of times a node in Q and C respectively has i edges labeled l .

Both vectors can be built by iterating through the nodes in each set and counting the respective occurrences. For a given $l \in \mathcal{L}$, this results in two scores $\delta_{\mathcal{I}}$ and $\delta_{\mathcal{K}}$. The final score δ is the maximum score between $\delta_{\mathcal{I}}$ and $\delta_{\mathcal{K}}$.

$$\delta(l, C, Q) = \max(\delta_{\mathcal{I}}(l, C, Q), \delta_{\mathcal{K}}(l, C, Q)) \quad (2)$$

Many measures have been proposed in statistics to compare two vectors in terms of distributions, such as the Kullback-Leibler (KL) divergence, the χ^2 test, and Earth Mover’s Distance (EMD). However, most of them draw specific assumptions, such as non-zero probabilities, or normality, that are not fulfilled in our case since \mathcal{I} and \mathcal{K} have no natural ordering and no distance-function between the values. Therefore, we resort to a more natural multinomial test that better expresses the relationship between our distributions. The multinomial test assumes that a set of observations (the query) is drawn from a multinomial distribution (the context). If the values observed in the query are drawn from the multinomial, than the hypothesis cannot be rejected and the characteristic is marked as non-notable; otherwise, the success of the test denotes that the characteristic is notable.

Assume we have a random variable $X_{N, \pi} \sim \text{Mult}(N, \pi)$, with parameters N and distribution π . We normalize \mathcal{I}_c and \mathcal{K}_c to express the probability distributions $\widehat{\mathcal{I}}_c = \mathcal{I}_c / \|\mathcal{I}_c\|_1$ and $\widehat{\mathcal{K}}_c = \mathcal{K}_c / \|\mathcal{K}_c\|_1$. The significance probability is

$$\Pr_s(X_{N, \pi} = x) = \sum_{y: \Pr(X_{N, \pi} = y) \leq \Pr(X_{N, \pi} = x)} \Pr(X_{N, \pi} = y)$$

where $\Pr_s(\pi, x)$ is the probability of x or any equally or less likely outcome being drawn from the probability distribution¹. A difference in distributions is considered significant if the hypothesis is rejected with probability $p > 0.95$.

$$\text{MT}(\pi, x) = \begin{cases} 1 - \Pr_s(X_{N, \pi} = x) & \text{if } \Pr_s(\dots) \leq 0.05 \\ 0 & \text{otherwise} \end{cases}$$

Finally, δ id defined as $\delta_{\mathcal{I}}(l, C, Q) = \text{MT}(\widehat{\mathcal{I}}_c(l, C), \mathcal{I}_q(l, C, Q))$ and $\delta_{\mathcal{K}}(l, C, Q) = \text{MT}(\widehat{\mathcal{K}}_c(l, C), \mathcal{K}_q(l, C, Q))$.

4 EXPERIMENTAL EVALUATION

We experimentally evaluate our approach on different datasets and show the impact of the parameters on the final results.

Datasets: We perform experiments on two real datasets.

- YAGO is a large knowledge graph based on Wikipedia, Wordnet and Geonames, with 3.3M nodes, 27M edges, 366K node types and 38 edge labels. We downloaded YAGO 2.5² and converted node attributes to edges and attribute values to node labels.
- Lmdb³: LinkedMDB is a knowledge graph for the movie domain, extracted from the Internet Movie Database (IMDB), with 739K nodes, 1.6M edges, and 18 edge types.

Experimental Setup: We implemented our solution in Java 1.8, and ran the experiments on a Intel i5-4210U 1.7 GHz machine

¹In case of large N , an approxiamte Montecarlo sampling is performed.

²<http://resources.mpi-inf.mpg.de/yago-naga/yago2.5>

³<https://datahub.io/dataset/linkedmdb>

with 12GB RAM. All datasets are loaded into Apache Jena triple store. Along our CONTEXTRW described in Section 3.1 for context selection and FINDNC for notable characteristics identification on top of CONTEXTRW, we implement RANDOMWALK, a baseline for context selection based on Personalized PageRank (see Section 3.1) computed through the power iteration method with 10 iterations and $c = 0.8$.

4.1 Evaluating Context selection

We compare the effectiveness of CONTEXTRW with the baseline RANDOMWALK within different topics. Since no ground truth for finding context nodes given a set of query nodes were available, we generated context nodes via CrowdFlower (<https://www.crowdfunder.com>) for 15 query sets in three domains, namely *politicians*, *actors*, and *movie contributors*. For each domain we manually determined 6 entities belonging to the domain and generated queries of increasing size (up to 6 entities). We asked 34 workers to provide a ranked list of related entities given the query, resulting in 7’650 entities. From such entities we removed those mentioned only once and obtained 36 to 76 entities per query that are mapped into YAGO.

Context size $|C|$. Context size affects the quality of the results, since more context nodes potentially lead to better recall but worse precision. Figure 2a compares RANDOMWALK and our CONTEXTRW in terms of F_1 score at different $|C|$. In all cases, CONTEXTRW performs up to four times better than the RANDOMWALK, vindicating the effectiveness of our metapath constrained random walk in finding context nodes, while RANDOMWALK mostly returns nodes that are close to the query nodes, but semantically irrelevant. Quality does not improve for $|C| > 100$ due to a loss in precision. We also experience a lower variance for CONTEXTRW that exploits metapaths for guiding the search.

Query size $|Q|$. We analyze the performance of the algorithms varying the query size $|Q|$. Figure 2 shows that CONTEXTRW improves in result quality when more query nodes are considered, which means that our method capture semantic relationships between the nodes. On the contrary, RANDOMWALK is not affected by the size of the query disregarding metapaths.

Figure 3a reports the time to compute the context, showing that RANDOMWALK is on average up to two orders of magnitude slower than CONTEXTRW, for $|Q| = 5$. Expectedly, CONTEXTRW is faster with larger queries (<20s comprising the database time), since the chance to end up in a query node is larger.

Figure 2c reports the maximum F_1 of CONTEXTRW at increasing $|Q|$, comparing YAGO and Lmdb datasets within the *actors* domain. Unsurprisingly, CONTEXTRW performs moderately better than YAGO in Lmdb due to the specificity of the dataset; however, YAGO result testifies the generalization ability of CONTEXTRW in larger, more complex datasets.

Number of paths $|M|$. The CONTEXTRW algorithm depends on the number of paths. Figure 2d shows the F_1 score in relation to the context size and the number of paths. The number of paths does not affect the score; however, as shown in Figure 3b the time increases as the length of the metapaths (and also the number, not reported) increases. Therefore, a reasonable choice for the number of metapaths $|M|$ and maximum length is 5.

4.2 Distribution Comparison

Test cases. We show preliminary evidence of the effectiveness of FINDNC with respect to the RANDOMWALK baseline for context retrieval with the multinomial test. The test case in Figure 4a shows the instance distribution of the query $Q = \{\textit{George Clooney},$

Figure 2: Average quality in terms of F_1 varying parameters $|C|$, $|q|$, and $|M|$ in YAGO dataset.

$ Q $		max F_1	$ C $
2	YAGO	0.23	23
	LMDB	0.30	101
3	YAGO	0.2	107
	LMDB	0.25	122
4	YAGO	0.19	130
	LMDB	0.24	124
5	YAGO	0.25	162
	LMDB	0.26	198
6	YAGO	0.22	285
	LMDB	0.25	139

$ C $	Number of paths ($ M $)

(a) Query size $|Q|$ (b) Maximum metapath length

Figure 3: Average time (s) in YAGO dataset.

(a) Created label in YAGO

(b) Method comparison

Figure 4: Test cases for the actors domain and 5 query nodes. A “C” in the labels denotes cardinality distributions

Brad Pitt, Leonardo DiCaprio, Scarlett Johansson, Johnny Depp over the top-100 context nodes for the *created* edge label. The *created* edge label is absent in 43% cases (represented as *None* instance), whereas all the other values are equally likely with 0.66% chances. The query presents a different distribution, with one actor without *created* labels and all the others with a different value. This clear deviation from the context is a notable characteristic by the multinomial test.

In the second test case, not reported due to space limits, we test the query $\{Douglas Adams, Terry Pratchett\}$ against the top-30 nodes as context. Our solution identified the edge *influences* as a notable characteristic. This is because the two authors in the query influenced an actor that was influenced by only 3 in total.

Algorithm comparison. Figure 4b compares FINDNC with RW-MULT, with query $\{George Clooney, Brad Pitt, Leonardo DiCaprio, Scarlett Johansson and Johnny Depp\}$. All items above the threshold, depicted as a dashed line, are considered not interesting ($\delta = 0$). The random walk selects mostly famous people in the movie business; hence, *actedIn* that connects actors with movies, is rare in the context but common in the query. However, this is clearly not correct and our FINDNC algorithm marks *actedIn* as uninteresting. Similarly, *hasWonPrize* shows a significant difference between the two algorithms, as winning a prize is common for actors (75%), but not so in the rather mixed random walk context (only 25%). The chart also shows that the significance level of the multinomial test can be used as a parameter to obtain the desired “interestingness” level. Choosing 0.1 would include the *owns* relationship as a notable characteristic, revealing that Brad Pitt is (according to the dataset) the only relevant actor to own a company (Plan B Entertainment).

5 RELATED WORK

Finding notable characteristics reminisces the problem of anomaly detection in attributed graphs [1]; yet, it is fundamentally

different, for it does not provide explanations on the nodes returned as anomalies, nor such approaches are query-driven.

Node comparison measures. Node similarities, typically defined in terms of neighbors, is a centerpiece for community detection, classification, and link prediction. Structural equivalence, such as SimRank [4] defines two nodes similar if the neighbors are similar. Random walk approaches, such as Personalized PageRank [2] and HITS [5] can also be used to find structurally similar nodes. However, node similarities cannot readily explain differences among query nodes and other similar nodes.

Seed set expansion. Seed set expansion, or example-based methods, refers to methods that ask the user to provide an initial set of entities or structures and retrieve similar nodes. Seed nodes are used to discover groups of nodes with similar characteristics [6] exploiting the specificity of each node in the seed set. Likewise, seed-based approaches are used to discover dense graph regions [3, 11]. Although these methods provide multiple groups of nodes they cannot properly explain the characteristics and the differences among them; in general, they do not directly compare the query nodes with the others.

Relevant path summarization. Our problem is connected to the discovery of metapaths between nodes [8, 12]. Methods have been proposed to automatically learn metapaths from a given seed set [9]. However, metapaths cannot express the lack of an edge (e.g., Angela Merkel has no children), nor they cannot detect notable characteristics: Being born in the same place is notable, only if similar people are born in different places.

ABSTRACT

While the growing corpus of knowledge is now being encoded in the form of *knowledge graphs* with rich semantics, the current graph embedding models do not incorporate ontology information into the modeling. We propose a scalable and ontology-aware graph embedding model, EmbedS, which is able to capture RDFS ontological assertions. EmbedS models entities, classes, and properties differently in an RDF graph, allowing for a geometrical interpretation of ontology assertions such as type inclusion, subclassing, and alike.

1 INTRODUCTION

A growing corpus of knowledge is being encoded in the form of *knowledge graphs*, i.e. in the form of (s, p, o) triples which represent simple subject-predicate-object sentences. These triple-based formats consist of binary relational data, where an (s, o) pair is effectively declared to be related by the p binary relation. Although more complex—or higher arity—information is difficult to express in this way, the simple syntax enjoyed by these triple-based data models has proved highly useful for a wide range of applications and has thus been widely adopted. Today, the linked open data cloud consists of hundreds of interlinked datasets, including a few very large knowledge graphs such as Freebase and DBpedia, which contain billions of triples and millions of entities.

Modern knowledge graphs are used in applications such as web search, where graph data provides structured data that complements hyperlink answers, artificial intelligence question answering systems such as Watson and voice-based assistants, and semantic web query engines that run powerful declarative query languages such as SPARQL. However, there are still important issues to be resolved. Even the largest knowledge graphs are extremely incomplete (i.e. many true facts have yet to be encoded as triples) and prone to errors (often triples encoding incorrect facts are included) [12]. The main tasks of link prediction (which consists of predicting new triples) and triplet classification (which seeks to assign a probability that a certain triple—be it new or existing—is true or not) look to address these shortcomings. In this context, there is renewed interest in machine learning over (binary) relational data. The techniques used vary [9] from rule-based learning [5] to tensor factorisation, neural network-based approaches, etc. In this work we focus on latent feature-based techniques, which are also known as graph embeddings.

Graph embeddings correspond to latent feature statistical relational learning models in that they assume the existence of a set of n latent features—or random variables—that account for the predictions we desire (triplet classification or otherwise). As such, these latent features provide machine learning-friendly representations of graph data, which can then be used as input to further

machine learning tools such as neural networks or logistic regression for classification. The input to a graph embedding model, as with other statistical relational learning techniques, is a knowledge graph, and the output is a mapping which associates to each entity in the graph the set of n real-valued latent features. The name *graph embedding* refers to the geometrical interpretation given to the obtained latent features: the entities are interpreted as points in an n -dimensional real coordinate space, and thus are said to have been embedded into said space. On the other hand, the relations of the knowledge graph are varyingly represented as translational vectors [3], matrix transformations [11], etc.

Graph embedding models are usually trained via the minimisation of a global cost function, which can be expressed as the sum of a cost assigned to each triple in the knowledge graph. The minimisation itself is achieved via stochastic gradient descent or similar methods. One of the greatest advantages of graph embedding models, and especially translational models (loosely defined as those models which represent relations as one or more translational vectors, as opposed to transformation matrices), is that they are able to perform efficiently for very large graphs and with high accuracy. Current graph embedding models achieve high performance on basic learning tasks such as link prediction—ranking the correct entity among the top ten candidates 95% of the time [10].

Despite the positive scenario described above, one of the greatest limitations of current graph embedding models is that they consider a very simple model of the data: they consider a knowledge graph to be a set of triples, where each triple mentions two entities and one relation, with no special semantics for any particular triple. In contrast, standard knowledge graphs are often accompanied by rich ontological information which encodes a wealth of metadata, including type hierarchies and other constraints. Current graph models are entirely agnostic to such metadata, and thus ontological triples are usually manually removed before training (or, if they are included, simply interpreted as plain data triples). One of the consequences of this is that current graph embedding models do not directly incorporate constraints that humans would consider obvious (e.g. knowing that a human cannot be friends with a building). A huge potential exists in the rich ontologies that inform modern knowledge graphs, and the objective of this work is to explore ways in which such ontologies can become first class citizens of graph embedding models.

Specifically, we explore the problem of graph embedding on ontology-rich knowledge graphs, where the ontology is specified in a standard language such as RDFS (more expressive languages such as OWL2 have been developed, but will not be considered in this study). Drawing on the geometrical interpretation that graph embeddings give to their latent features (namely, that entities are embedded as points in a real coordinate space), we explore the case where RDFS classes are correspondingly modelled as sets of points in the same coordinate space, and relations are embedded as sets of pairs of points. This generalisation of the basic geometrical interpretation allows for a natural expression of ontological constraints in the global cost function. The result

is a model we name EmbedS, which is able to model RDFS ontological constraints as first-class citizens. Along with providing the precise definitions for the EmbedS cost function, we provide experimental results that show EmbedS to be comparable to state-of-the-art graph embedding techniques when measured on traditional benchmark knowledge graphs, while performing well on a new ontology-rich dataset we have prepared for the purposes of studying the new enriched geometrical interpretation that EmbedS provides.

The preliminary results presented in this paper showcase the potential of extending current graph embedding research to include ontological information, and will hopefully encourage further development of the area. This paper is organised as follows. In Section 2 we introduce necessary mathematical notation and preliminary definitions. In Section 3 we introduce the EmbedS model, its global cost function, and the geometrical interpretation induced on embedded entities and relations. In Section 4 we explain the experimental setting and evaluation metrics, including a discussion of an ontology-rich benchmark dataset we have prepared for testing the EmbedS model. Finally, in Section 5 we present our conclusions and suggest future avenues of work.

2 PRELIMINARIES AND RELATED WORK

Graph embedding models are usually defined on a *knowledge graph*, which is essentially a set of triples, similar to the RDF data model, but lacking specialised features of the latter, such as the precise definition of IRIs, literals, and the semantics associated with certain keyword IRIs. In this section we will introduce necessary definitions, noting the similarities and discrepancies with the RDF data model. We will then introduce needed concepts such as graph embeddings, and finally we will discuss related work.

Let E and P be two mutually disjoint and countably infinite sets of *entities* and *relations*, respectively. A knowledge graph is then defined as a finite set of triples of the form $(s, p, o) \in E \times P \times E$. As such, a knowledge graph can be interpreted as a directed graph with labelled edges, or as a set of binary relations. As this work will seek to allow graph embeddings to operate on more expressive graph data, it is important to note the differences with the full RDF data model. RDF also considers an infinitely countable set of *literals* L , disjoint from E and P , and note that RDF triples are drawn from the more general set $(E \cup P) \times (E \cup P) \cup (E \cup P \cup L)$. For example, note that RDF allows relations to be mentioned in the subject position of a triple, thus blurring the distinction that exists between relations as edge labels and nodes of the graph. This is generally disallowed in the traditional definition of knowledge graph.

The base RDF data model described provides very little semantics other than the basic interpretation of the triple as a fact. To enrich an RDF dataset, several ontology languages have been developed, of which RDFS is one of the simplest. RDFS defines the following core keyword IRIs: `rdf:type`, `rdfs:subClassOf`, `rdfs:subPropertyOf`, `rdfs:domain`, and `rdfs:range` (abbreviated `type`, `sc`, `sp`, `dom`, `range`, `resp.`), which are assigned special semantics in order for richer knowledge—including basic type systems—to be encoded into RDF format¹.

In what follows, we will consider, in addition to the sets E and P , a set C of *classes*, also infinitely countable and disjoint from

the previous two. Furthermore, we define five special relations `type`, `sc`, `sp`, `dom`, `range` $\in P$. We will only consider triples $t = (s, p, o)$ for which one of the following hold:

- $(s, p, o) \in E \times P \times E$ (called data triples),
- $(s, p, o) \in E \times \{\text{type}\} \times C$ (called type triples),
- $(s, p, o) \in C \times \{\text{sc}\} \times C$ (called subclass triples),
- $(s, p, o) \in P \times \{\text{sp}\} \times P$ (called subproperty triples),
- $(s, p, o) \in P \times \{\text{dom}\} \times C$ (called domain triples),
- $(s, p, o) \in P \times \{\text{range}\} \times C$ (called range triples).

An RDF data graph (or, simply, a graph) D is a finite set of triples such that for every triple $t \in D$, t is a data triple or a type triple. An RDFS ontology (or, simply, an ontology) S is a finite set of triples such that for every triple $t \in S$, t is not a data triple or a type triple.

Example 2.1. Consider the graph $D = \{(anne, \text{type}, \text{Woman}), (john, \text{type}, \text{Man}), (john, \text{knows}, anne)\}$. This data about people and their relationships can be enriched with the ontology $S = \{(\text{Woman}, \text{sc}, \text{Person}), (\text{Man}, \text{sc}, \text{Person})\}$. The full dataset is then $I = D \cup S$. Notice that the semantics of RDFS allow us to conclude facts which are not explicitly included in the dataset, such as $(anne, \text{type}, \text{Person})$ and $(john, \text{type}, \text{Person})$. \square

Crucially, the semantics of RDFS allow for inferencing new triples using a series of inference rules. For example, the following is an inference rule for RDFS: $(x, \text{type}, c), (c, \text{sc}, b) \rightarrow (x, \text{type}, b)$, which is read as follows: given a dataset $I = D \cup S$ which contains two triples of the form (a, type, C) and (C, sc, B) , for any entity $a \in E$ and classes B, C , the triple (a, type, B) may be *inferred* to hold [1]. In this context, inferring a triple to hold would cause a query engine to return the inferred triple as an answer to a query.

Graph embedding—and statistical relational learning—models use varying techniques in order to obtain machine-usable representations of knowledge graphs. In general, however, the main problem—that of knowledge base completion—gives a common direction to these techniques: constructing statistical models of the data that allow for link prediction (e.g. given an incomplete fact $(\text{T arantino}, \text{inspiredBy}, ?)$ return the entity that would complete the triple) and triple classification (assign a probability that a triple is true).

The most expressive models involve tensor or matrix factorisation techniques, although these are also the models with the highest complexity, measured in the number of parameters that must be trained. A well-known example of this is RESCAL [11], which explains triples using pairwise interactions of the latent features of entities. Thus, the *cost* associated to a triple x_{ijk} has the form:

$$\text{cost}(x_{ijk}) = \mathbf{e}_i^T \mathbf{W}_k \mathbf{e}_j.$$

Other highly expressive models use techniques such as matrix factorisation, neural tensor networks, and multilayer perceptrons [6, 8]. The latter, also known as word2vec, was strictly a word embedding model, but had as an interesting and unintended consequence a translational property among the latent representation of words: simple binary relations between words could be captured when interpreting the latent representation—*embedding*—of the relation as a *translational vector*. For example, after training on a textual corpus, researchers found that incomplete sentences such as $(\text{Madrid}, \text{capitalof}, \text{Spain})$ had the property that the vector $\mathbf{e}_{\text{Madrid}} + \mathbf{e}_{\text{capitalof}}$ was nearest to $\mathbf{e}_{\text{Spain}}$.

¹The prefixes used are themselves abbreviations. Actually, `rdf:` expands to <http://www.w3.org/1999/02/22-rdf-syntax-ns#> and `rdfs:` expands to <http://www.w3.org/2000/01/rdf-schema#>.

Figure 1: Cost of a triple $(e_i, p_k, e_j) \in I$. The circle represents a $2n$ -sphere of radius σ_k centered at $(\mathbf{p}_k^\alpha, \mathbf{p}_k^\beta)$. The pair (e_i, e_j) is embedded as the $2n$ -dimensional point (e_i, e_j) . The (red) error line shows the cost.

The previous translational property spawned renewed interest in distance-based models that incorporated a *geometrical interpretation* for latent representations. The first of these was TransE [3], and was quickly followed by refinements such as TransH [13], and TransR [7]. While less expressive, translation-based models prove more scalable, as their model complexity is lower and a simpler cost structure allows for more efficient training.

The model proposed in this work draws from research in translation-based models. Our problem scenario focused on ontology-rich knowledge graphs, which contain specific semantics for keyword triples. This metadata has not been considered in previous work, to the best of our knowledge. The idea of considering ontological information in training statistical models, however, has been considered. In [4], type constraints are considered by removing type-constraint-violating triples, improving training speed and link prediction performance. They do not incorporate ontological information into the model as a first class citizen, however, and neither does the geometrical interpretation of the model adapt to reflect the presence of this metadata.

3 MODEL

Consider an RDF dataset $I = D \cup S$, and let $E_I \subseteq E$, $C_I \subseteq C$, and $P_I \subseteq P$ be the sets of entities, classes, and properties that appear in I , respectively. Define for each entity $e_i \in E_I$ an n -dimensional vector of parameters (i.e. variables) $\mathbf{e}_i = (e_{i1}, \dots, e_{in})$; for each class $c_i \in C_I$ define an n -dimensional vector of parameters $\mathbf{c}_i = (c_{i1}, \dots, c_{in})$ and a parameter ρ_i ; and for each property $p_i \in P_I$ define two n -dimensional vectors of parameters $\mathbf{p}_i^\alpha = (p_{i1}^\alpha, \dots, p_{in}^\alpha)$ and $\mathbf{p}_i^\beta = (p_{i1}^\beta, \dots, p_{in}^\beta)$ and a parameter σ_i . We have thus defined a total of $|E_I| \cdot n + |C_I| \cdot (n + 1) + |P_I| \cdot (2n + 1)$ parameters for our model.

For what follows, we first define a distance function **dist** which assigns to every pair of n -dimensional vectors $\mathbf{x} = (x_1, \dots, x_n)$, and $\mathbf{y} = (y_1, \dots, y_n)$ a non-negative real value **dist**(\mathbf{x}, \mathbf{y}), with the standard distance function properties². In this paper, we choose to set **dist**(\mathbf{x}, \mathbf{y}) = $\|\mathbf{x} - \mathbf{y}\|_2 = \sum_{i=1}^n (x_i - y_i)^2$, that is, the L_2 norm of $\mathbf{x} - \mathbf{y}$. We also define an activation function **act**, for which we choose the rectifier function, **act**(x) = $\max(0, x)$.

Assuming that $|E_I| = N_E$, $|C_I| = N_C$, and $|P_I| = N_P$, the cost \mathcal{L} will be a function of all the variables previously defined:

$$\mathcal{L} = \mathcal{L}(\mathbf{e}_1, \dots, \mathbf{e}_{N_E}; \mathbf{c}_1, \dots, \mathbf{c}_{N_C}, \rho_1, \dots, \rho_{N_C}; \mathbf{p}_1^\alpha, \dots, \mathbf{p}_{N_P}^\alpha, \mathbf{p}_1^\beta, \dots, \mathbf{p}_{N_P}^\beta, \sigma_1, \dots, \sigma_{N_P}).$$

We now define the precise form of the cost function \mathcal{L} . For the entire dataset, define $\mathcal{L}^I = \sum_{t \in I} \mathcal{L}_t$, where the cost of each

²(a) **dist**(\mathbf{x}, \mathbf{y}) ≥ 0 , (b) **dist**(\mathbf{x}, \mathbf{y}) = 0 $\Leftrightarrow \mathbf{x} = \mathbf{y}$, (c) **dist**(\mathbf{x}, \mathbf{y}) = **dist**(\mathbf{y}, \mathbf{x}), and (d) **dist**(\mathbf{x}, \mathbf{z}) \leq **dist**(\mathbf{x}, \mathbf{y}) + **dist**(\mathbf{y}, \mathbf{z}).

Figure 2: Cost (red error line) of $t = (e_i, \text{type}, c_j)$, where class c_j is embedded as an n -sphere at \mathbf{c}_j with radius ρ_j .

triple $t = (e_i, p_k, e_j) \in I$ (note that $e_i, e_j \in E_I \cup C_I \cup P_I$ and $p_k \in P_I$), is defined as follows:

$$\mathcal{L}_t = \mathbf{act}\left(\mathbf{dist}(\mathbf{e}_i, \mathbf{p}_k^\alpha) + \mathbf{dist}(\mathbf{e}_j, \mathbf{p}_k^\beta) - \sigma_k\right).$$

The geometrical interpretation of this cost is provided in Section 3.1, and is visualized in Figure 1. Next, we define a cost term for each possible RDFS assertion. For each $t \in S$:

- (1) If $t = (e_i, \text{type}, c_j) \in S$, where $e_i \in E_I$ and $c_j \in C_I$, define:

$$\mathcal{L}_t^S = \mathbf{act}\left(\mathbf{dist}(\mathbf{e}_i, \mathbf{c}_j) - \rho_j\right),$$

- (2) If $t = (c_i, \text{sc}, c_j) \in S$, where $c_i, c_j \in C_I$, define:

$$\mathcal{L}_t^S = \mathbf{act}\left(\mathbf{dist}(\mathbf{c}_i, \mathbf{c}_j) - (\rho_j - \rho_i)\right),$$

- (3) If $t = (p_i, \text{sp}, p_j) \in S$, where $p_i, p_j \in P_I$, define:

$$\mathcal{L}_t^S = \mathbf{act}\left(\mathbf{dist}(\mathbf{p}_i^\alpha, \mathbf{p}_j^\alpha) + \mathbf{dist}(\mathbf{p}_i^\beta, \mathbf{p}_j^\beta) - (\sigma_j - \sigma_i)\right),$$

- (4) If $t = (p_i, \text{dom}, c_j) \in S$, where $p_i \in P_I$ and $c_j \in C_I$, define:

$$\mathcal{L}_t^S = \mathbf{act}\left(\mathbf{dist}(\mathbf{p}_i^\alpha, \mathbf{c}_j) - \sigma_i\right),$$

- (5) If $t = (p_i, \text{range}, c_j) \in S$, where $p_i \in P_I$ and $c_j \in C_I$, define:

$$\mathcal{L}_t^S = \mathbf{act}\left(\mathbf{dist}(\mathbf{p}_i^\beta, \mathbf{c}_j) - \sigma_i\right).$$

Finally, we sum, for every triple $t \in S$, the cost of t depending on the RDFS relation it mentions. In that way, we define the cost term $\mathcal{L}^S = \sum_{t \in S} \mathcal{L}_t^S$, and thus define the final cost to be $\mathcal{L} = \mathcal{L}^I + \mathcal{L}^S$.

3.1 Geometrical interpretation

We now give a geometrical interpretation to the model definition. By embedding entities as single n -dimensional vectors we are modelling them as *points* in the n -dimensional euclidean space. Classes, on the other hand, are modelled as *regions* of the euclidean space, being embedded as a vector and a radius, representing n -spheres. This allows for the following geometrical interpretation: if an entity is embedded within the region defined by the embedding of a class, then it is interpreted to be of that type, and vice-versa (see Figure 2). Finally, properties, insofar as they represent binary relations, are modelled as *pairs of points*. Thus, each relation $p_k \in P_I$ has an embedding which consists of two n -dimensional vectors \mathbf{p}_k^α and \mathbf{p}_k^β and a radius ρ_k . The corresponding geometrical interpretation is analogous to the previous case: in $2n$ -space, a pair (e_i, e_j) is interpreted to be related by a relation p_k if the $2n$ -point $(\mathbf{e}_i, \mathbf{e}_j)$ is in the region defined by the $2n$ -sphere centered at $(\mathbf{p}_k^\alpha, \mathbf{p}_k^\beta)$ with radius σ_k (see Figure 1).

The main advantage conferred by this ontology-aware geometrical interpretation is that RDFS classes and ontological assertions are now first-class citizens of the model. By modelling classes as

regions of the euclidean space, for example, certain properties are obtained for free, such as type containment transitivity: if after training the entity `aturing` is (correctly) embedded within the class `Researcher`, and said class is (correctly) embedded fully contained within the region corresponding to class `Person`, then the transitive fact that `aturing` is a `Person` will be provided for free. In this way, the embedding space will presumably encode ontological information geometrically.

4 EXPERIMENTAL EVALUATION

In this section we provide preliminary experimental results showing that EmbedS can perform at state-of-the-art levels on a standard benchmark dataset, while providing a new complementary triple classification method based on the geometrical interpretation which shows encouraging results. An exhaustive experimental evaluation will be left for future work. We use the following datasets for experimental evaluations:

wn18 Dataset extracted from WordNet. This dataset consists of 151,442 triples, 40,943 entities, and 18 relations.

dbpedia32k RDF dataset extracted from DBpedia, consisting of 340,827 triples, 32,657 entities, and 296 relations.

The first dataset has become a standard benchmark in the graph embedding field [3], and allows for an apples to apples comparison between our model and existing work. However, EmbedS has been designed for a fundamentally different problem setting: that of embedding in *ontology-rich* RDF data. In order to test the performance of our model, we have prepared a dataset, named ‘dbpedia32k’ which includes an RDFS ontology.

We now describe the construction of the dbpedia32k dataset. It initially draws from three distinct downloads, which are freely available: the ‘DBpedia Ontology’ file, which contains ontology triples, the ‘Instance Types’ file, which contains data triples of the form (a, type, C) for some entity a and some class C , and the ‘Mappingbased Objects’ file, which contains general data triples, representing facts on entities present in Wikipedia articles. From the Mappingbased Objects file first define a relation to be useful if it appears in at least 1000 triples. We define an entity to be useful if it is mentioned at least 10 times in the file. A uniform sample of useful entities is built, keeping only triples which mention useful relations and these sampled entities only. Finally, we recalculate useful entities (in the filtered dataset) and remove triples which mention non-useful entities. We thus obtain the final set of Mappingbased Objects triples to be used. We complete the dataset by extracting, from Instance Types, triples (a, type, C) where a is mentioned in the previous dataset, and similarly we extract relevant ontology triples from DBpedia Ontology. The resulting complete dataset is split uniformly into three subsets for training, validation, and testing, with proportions 0.8, 0.1, and 0.1, respectively.

Selection of hyperparameters of the model is achieved via random search. Although more sophisticated methods have been proposed, random search is competitive with these systems [2] and thus serves our purposes. For each dataset-model choice (e.g. dbpedia32k with EmbedS), a suitable bounding box for the hyperparameters of the model is chosen, and training is performed over 500 epochs for 1,000 different random hyperparameter values.

To measure the performance of the model, we use the standard *filtered hits@10* and *filtered mean reciprocal rank* metrics. The final model selected after training is that which maximizes the estimated mean reciprocal rank for the validation dataset.

As EmbedS allows for a geometrical interpretation of triples, we also evaluate a triple classification performance. For each triple in the dataset, and an equal amount of randomly generated false triples (i.e. triples not in the dataset), if $t = (e_i, p_k, e_j)$, the binary classification consists in asking whether the $2n$ -dimensional point (e_i, e_j) is contained in the sphere centered at (p_k^α, p_k^β) with radius σ_k or not. Precision and recall values are obtained for this test.

EmbedS was trained on the wn18 dataset, optimizing for best validation (filtered) hits@10 value, obtaining 94.9%, which is comparable to state-of-the-art models such as HoLE [10]. HoLE is clearly superior in the mean reciprocal rank metric, however, with a value of 0.938, compared to 0.560 for EmbedS. It must be noted, though, that these values correspond to *harmonic* mean ranks of 1.07 for HoLE and 1.79 for EmbedS. If EmbedS is now instructed to optimise the geometrical interpretation, we achieve a precision of 84.2% and a recall of 83.9%, corresponding to an f-measure of 84.0%.

On the dbpedia_v2 dataset, we find that EmbedS achieves a performance on hits@10 of 22.7% and a mean reciprocal rank of 0.133 (corresponding to a harmonic mean rank of 7.52). TransE, on the other hand, performs at 11.6% hits@10 and 0.054 mean reciprocal rank (corresponding to a harmonic mean rank of 18.52).

5 CONCLUSIONS

In this paper we study the new problem of training graph embeddings on ontology-rich datasets. We propose a model which considers RDFS classes and other ontological information as first-class citizens, providing a geometrical interpretation for triples and for ontology assertions. Preliminary experimental results show that the model can perform at state-of-the-art levels on standard benchmark datasets, while on ontology-rich datasets it is also able to provide an alternative form of triple classification which takes advantage of the geometrical interpretation. An exhaustive experimental evaluation is required to be able to fully understand the limitations of this new model, although the encouraging results shown seem to indicate that incorporating ontological information into graph embedding models can potentially open a new avenue of research.

ABSTRACT

Complex Event Processing (CEP) deals with matching a stream of events with the query patterns to extract complex matches. These matches incrementally emerge over time while the partial matches accumulate in the memory. The number of partial matches for expressive CEP queries can be polynomial or exponential to the number of events within a time window. Hence, traditional strategies result in an extensive memory and CPU utilisation. In this paper, we revisit the CEP problem through the lens of complex queries with expressive operators (*skip-till-any-match* and *Kleene+*). Our main result is that traditional approaches, based on the partial matches' storage, are inefficient for these types of queries. We advise a simple yet efficient recomputation-based technique that experimentally outperforms traditional approaches on both CPU and memory usage.

1 INTRODUCTION

Complex Event Processing (CEP) matches a sequence of events within a stream against a complex query pattern that specifies constraints on the extent, order, values, and quantification of the matching events. Most of the CEP systems incrementally produce matched patterns, where partial matches are stored and then computed to avoid the recomputation cost [11, 14]. That is, with the arrival of an event, a CEP system (i) can generate a new partial match by matching incoming event with the prefix of the defined query pattern; (ii) checks with the existing partial matches if the incoming event can be part of them or complete them. The number of partial matches for such strategy can be polynomial or exponential to the number of events within a window [1, 9, 14]: some partial matches lead to the complete matches while others fail. This results in extensive memory and CPU utilisations. In the following, we present a real-world CEP query to showcase the issues of incrementally processing partial matches.

Example 1. A stock market application processes thousands of financial transactions per second to detect patterns that signify emerging profit opportunities. An example of such a pattern, called V-shaped pattern [12, 14], is described in Query 1 using the syntax from SASE [13]. Query 1 detects an increasing and then decreasing pattern per company. Hence, the price of the events must first increase from an initial value ($a.price < b.price$), then the events should show an uptrend ($b.price < NEXT(b.price)$) using the *Kleene+* operator, and then the price of the matched events should decrease such that it is less than the first reported increase ($c.price < FIRST(b.price)$). All the matched events should

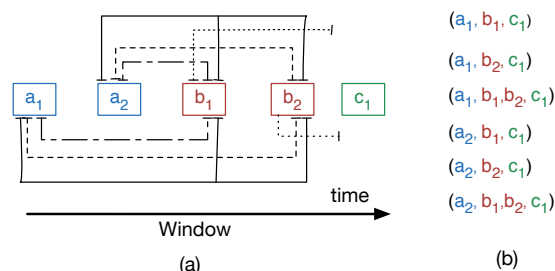

Figure 1: (a) Partial matches for Query 1 over the event stream, (b) complete matches for the Query 1

be within a window of size 30 minutes which slides every 2 minutes.

```

QUERY 1. PATTERN SEQ (a, b+, c) WHERE [companyID]
AND a.price < b.price AND
b.price < NEXT(b.price) AND c.price < FIRST(b.price)
WITHIN 30 minutes SLIDE 2 minutes

```

To reveal all the profit opportunities, Query 1 detects all the combinations of patterns using an operator called as *skip-till-any-match* event selection strategy in the literature [1, 12, 14]. This operator assists in ignoring the local price fluctuations to preserve opportunities for detecting longer and thus more reliable patterns. Fig. 1 shows the evaluation of Query 1 over an event stream. From Fig. 1 (a), before the arrival of an event c_1 , six partial matches (shown with the connected lines) for a_1 and a_2 are produced, and one for each b_1 and b_2 . Note that the prefix of the Query 1 is highly unselective ($a.price < b.price$) and any event can start a partial match. Consequently, there can be a large number of partial matches that would not produce full matches, which result in wasted computation. The complete set of matches, after the arrival of a *trigger* event c_1 are shown in Fig. 1 (b).

State of the art and limitations. The issues with a large number of partial matches and their effect on the memory and CPU resources have been acknowledged in the literature [1, 9, 12, 14]. The usual remedy proposed for such issues is to factorise the commonalities between the partial matches that originate from the same set of events [12, 14]. Hence, the query evaluation is broken into two phases. The first phase tracks the commonalities between the partial matches and compresses them using an additional data structure, e.g. an events graph. The second phase constructs the complete matches while decompressing the set of common partial matches, e.g. through *depth-first-search*. This strategy can reduce the memory requirements from exponential to polynomial, at the cost of the compression/decompression operations. Moreover, since a sub-partial match can be part of

multiple complete matches, this strategy recomputes common sub-partial matches for each match that contains one. This results in redundant computations, and the high cost of maintaining additional structure and reconstruction of the matches remains quite significant. For instance, in Fig.1 (a), all the partial matches are kept – and computed – even if a trigger event, i.e. c_1 , never arrives within a window. Finally, due to the high space complexity, these systems spend a considerable amount of time in repeated memory allocation and reclamation with the expiration of a window.

Contributions. This paper initiates the study of a recomputation-based CEP that addresses the following two main points.

- Since storing partial matches is expensive, only events should be stored in a window. This reduces the memory cost from polynomial or exponential to linear
- The matches should be recomputed only when the trigger events’ arrive and results should be directly stored on the disk. Hence, redundant computations are not performed and only the subsets of events are processed to produce the matches. Furthermore, since matches are directly stored on the disk, repeated in-memory allocation and reclamation operations are avoided.

In theory, both recomputation and incremental evaluation techniques have the same worst-case run-time cost. However, in practice, recomputation process provides the following properties: (1) it is performed for a fewer number of times (depending on the trigger events); (2) it alleviates the redundant computations that arrive due to the partial matches that would not produce a complete match; (3) it avoids the cost of creation and deletion of partial matches.

The detailed structure and contributions of this paper are as follow. We first provide the compilation of the query tree for a CEP query (§ 2.2). We then present the design of an algorithm for recomputing matches and analyse its complexity (§ 2.3). Based on this algorithm, we present the techniques to process joins between events and to execute the Kleene+ operator (§ 2.4). We implemented our solution and demonstrate that it outperforms existing solutions both in terms of memory and CPU cost (§ 3).

2 RECOMPUTATION BASED CEP

2.1 Preliminaries

In this section, we present the CEP specific definitions, query representation and query evaluation techniques.

Event. An event e is tuple (A, t) , where $A = \{A_1, A_2, \dots, A_m\}$ ($m \geq 1$) is a set of attributes and $t \in \mathbb{T}$ is an associated timestamps that belongs to a totally ordered set of time points (\mathbb{T}, \leq) .

Event Stream. An event stream \mathcal{S} is a possibly infinite set of events such that for any given timestamps t and t' , there is a finite amount of events occurring between them.

Event Sequence. A chronological ordered sequence of events, with a total ordering given by \mathbb{T} is represented as $\vec{E} = \langle e_1, e_2, \dots, e_n \rangle$ with e_1 refer to the *first* event and e_n to the *last*.

CEP Query. A CEP query Q has the following form:

PATTERN P [WHERE Θ] WITHIN w SLIDE s

where $P = \text{SEQ}(p_1, \dots, p_k)$ is a sequence of pairwise disjoint variables of the form p and p^+ , $\Theta = \theta_1, \dots, \theta_l$ is a set of predicates (constant and variable) over the variables in P (see Query 1 in Example 1), w is the time window and s is slide of the window to define the scope of event stream. A variable $p \in P$ binds a sequence of a single event $\langle e_i \rangle$, while the qualified variables

$p^+ \in P$ binds a sequence of one or more events $\langle e_1, \dots, e_n \rangle$, $n \geq 1$ for a query match.

CEP Query Match. To define the matching of a CEP query Q , we use a substitution $\gamma = \{p_1/\vec{E}_1, \dots, p_k/\vec{E}_k\}$ to bind the event sequences (\vec{E}) with the variables. Given Q and the event stream \mathcal{S} , a substitution γ is a match of Q in \mathcal{S} , iff (i) all the predicates Θ in Q evaluate to true, (ii) for events in the two event sequences $e \in \vec{E}_i$ and $e' \in \vec{E}_{i+1}$, we have $e.t < e'.t$ and (iii) all the events in each event sequence \vec{E}_i has timestamps less than the defined window w . Since no order is imposed on the selected events, it complies to the skip-till-any-match selection strategy.

2.2 Query Tree

Given the CEP query, we need to compile it from the high-level language into some form of automaton [1, 4, 6, 13] or a tree-like [5, 11] structure to package the semantics and execution framework. Since we are working with the recomputation-based model, a traditional tree structure customised for the streaming and recomputation settings would suit our needs. Given Q we construct a tree, where leaf nodes are the substitution pairs, i.e. (p_i/\vec{E}_i) , to store the primitive events and the internal nodes represent the joins on the defined predicates Θ and temporal ordering. We call it a query tree \mathcal{T}_q . Our model differs from other tree-structures [5, 11] since we do not store any partial matches. An example of such a tree for Query 1 is shown in Fig 2, where we have three leaf nodes for the variables bindings a/\vec{E}_1 , b/\vec{E}_2 and c/\vec{E}_3 . The internal nodes in Fig. 2 evaluate the defined Θ in terms of joins (denoted as \bowtie_{Θ}) for all the variables $p \in P$. Furthermore, since for a CEP query, the matched events should follow the sequential order, joins on the timestamps (denoted as \bowtie^t) are also provided in the \mathcal{T}_q .

Figure 2: (a) Left-deep and (b) Right-deep Query tree for Query 1 in Example 1

2.3 Query Evaluation

We now present the algorithm to evaluate the query tree over the event stream without storing the partial matches. Algorithm 1 shows the query evaluation and is divided into three main steps.

Step 1. For each incoming event e , we add e to the compatible event sequence \vec{E}_i , such that constant predicates (e.g. $a.price > 10$) filter the unwanted events for each \vec{E}_i in \mathcal{T}_q . For instance, for a constant predicate $a.price > 10$, all the events in a/\vec{E}_1 , should have the $price > 10$. This step (lines 4-6) constitutes to the accumulation of events within a defined window.

Step 2. For each incoming event e , check if it can trigger the query evaluation to produce matches. That is, if e can be part of \vec{E}_k ($k = |P|$), it can complete a set of matches; since it contains the highest timestamp within the window. For instance, Query 1

Algorithm 1: CEP Query Evaluation

Input: Query Tree \mathcal{T}_q and an event stream \mathcal{S}
Output: A set of query matches

```

1  $Q \leftarrow (P, \Theta, \omega, s);$  // CEP Query
2  $\vec{E} \leftarrow \{\vec{E}_1, \vec{E}_2, \dots, \vec{E}_k\}, k = |P|;$  // Event sequences for  $\mathcal{T}_q$ 
3 for each  $e \in \mathcal{S}$  do
4   for each  $\vec{E}_i \in \vec{E}$  do
5     if  $\text{isCompatible}(\vec{E}_i, e)$  then
6        $\vec{E}_i = \vec{E}_i \cup e;$  // Step 1
7   if  $\text{isCompatible}(\vec{E}, e)$  then
8      $\text{ExecuteJoins}(\vec{E}, \Theta);$  // Step 2
9      $\text{ExecuteKleenePlus}(\vec{E}, \Theta);$  // Step 3
```

produces the matches only when an event of type c arrives. Hence, we execute the query tree for a trigger event. By execution, we mean executing the joins between events within each \vec{E}_i using the predicates Θ and timestamps t . This step (lines 7-8) assembles all the events, in a batch manner, for each \vec{E}_i that can produce the set of matches.

Step 3. For a $p_i^+ \in P$, we need to compute all the combinations for the events in p_i^+ / \vec{E}_i , i.e. a power set of events in \vec{E}_i . For instance, in Fig. 1 and using Query 1, each a event has $2^2 - 1$ matches for two b events. This step (line 9) groups all the combinations by following the one or more semantics of the Kleene+ operator.

2.4 Detailed Analysis

We now present the details of the two main processes of Algorithm 1, i.e. joining the set of events and computing the power set of events for the Kleene+ operator.

Execution of Joins. Let \vec{E}_i and \vec{E}_j are two event sequences with theta-join $\vec{E}_i \bowtie_{\Theta}^t \vec{E}_j$ over the timestamp t and predicates Θ . Hence, we have joins on multiple relations for the **Step 2**. The generic cost of such joins, i.e. pairwise join, is $O(|\vec{E}_i||\vec{E}_j|)$ and the problem of its efficient evaluation resembles the traditional theta-joins with inequality predicates [8]. The wide range of methods for this problem includes: the textbook merge-sort, hash-based, band-join and various indices such as Bitmap [7]. These techniques are mostly focused on equality joins using a single join relation, however. The inequality joins on multiple join relations are notoriously slow and multi-pass *projection-based* strategies [3, 8] are usually employed. These strategies, however, require multiple sorting operations, each for a distinct relation, and are only optimised for the static datasets, where indexing time is not of much importance. Considering this, we employ the general nested-loop join for our preliminary algorithm. Our experimental analysis showcase that even such a naive algorithm provides competitive performance.

Execution of Kleene+ Operator. For **Step 3**, we need to create all the possible combinations of matches over the joined events. That is, enumerating the powerset of event sequences' with p^+ bindings. A traditional solution in this context would be to generate Gray code sequence of events with p^+ bindings, where a new match can be constructed from its immediate predecessor by adding or removing an event. However, this would require storing the predecessor matches to produce the next one and would result in an extra load on the memory resources. To implement Kleene+ operator efficiently, we use the joined results (from **Step 2**) while generating the binary representation of the

Figure 3: Execution of the Kleene+ operator using the Banker's sequence and generated binary numbers

possible matches using the Banker's sequence [10]. That is, we check the number of events in event sequences' with p^+ bindings after the join process. For $|m|$ number of such events, we need to create 1 to $2^m - 1$ matches. This means if we generate all binary numbers from 1 to $2^{|m|} - 1$, and translate the binary representation of numbers according to the location of the events in the p^+ / \vec{E}_i , we can produce all the matches for the Kleene+ operator in a batch manner. For instance, consider Fig. 3 (using Query 1), where there are three b events for the Kleene+ operator. Hence, we generate binary numbers from 1 to $2^3 - 1$. Now equates 1 as take element at the specified location of the \vec{E}_2 and 0 as do not take the element. Then using the generated binary numbers, we generate all the combinations of matched events.

Complexity Analysis. Herein, we briefly present the complexity analysis for the three steps described in Algorithm 1. **Step 1** results in a constant time operation since an incoming event can be directly added to an event sequence. **Step 2** has a polynomial time-cost (pair-wise joins) and depends on the number of patterns P defined in a CEP query. For n events in a window and $k = |P|$, we have $O(n^k)$. **Step 3** requires producing an exponential number of matches for a Kleene+ operator. For n events in a window, we have $O(2^n)$. The memory cost for the Algorithm 1 is linear to the number of events within a window.

3 EXPERIMENTAL EVALUATION

In this section, we report the results of our experimental study on both incremental and recomputation-based methods for CEP. Our proposed techniques have been implemented in Java and our system is called RCEP. All the experiments were performed on a machine equipped with Intel Xeon E3 1246v3 processor and 32 GB of memory. For robustness, each experiment was performed 3 times and we report median values.

Datasets. We employ both real and synthetic datasets to compare the performance of our proposed techniques.

Synthetic Stock Dataset (S-SD): We use the SASE++ generator, as used in [14], to produce the synthetic dataset. Each event carries a timestamp, company-id, volume and the price of a stock. This dataset enables us to tweak the selectivity measures of matches $\frac{\#ofMatches}{\#ofEvents}$ to evaluate the performance of the systems at different workloads. In total, the generated dataset contains 1 million events.

Real Credit Card Dataset (R-CCD): We use a real dataset of credit card transactions [2]. Each event is a transaction accompanied by several arguments, such as the time of the transaction,

Figure 4: Memory cost and throughput analysis of the CEP systems over the two datasets S-SD and R-CCD

the card ID, the amount of money spent, etc. This dataset contains around 1.5 million events.

Queries. We consider 8 different variations of Query 1 (Section 1) against the stock dataset. These queries variations differ by the constant predicates and time window to control the selectivity of produced matches. For the credit card dataset, we use a CEP query describing “Big after Small” pattern [2] using the SEQ($a, b+$) template. That is, an outstandingly large amount of transactions after one or a series of small amounts.

Methodology. We compare RCEP with the SASE++ [14] and the open source streaming system Apache Flink [6]. All of these systems support skip-till-any-match and Kleene+ operator: both SASE++ and Flink employ incremental evaluation of partial matches. Flink guarantees that events are processed in parallel but in-order by their timestamps. Unless otherwise specified, all experiments use a slide granularity $s = 1$. We measure two standard metrics common for the CEP systems: throughput and memory requirements [1, 12, 14]. The memory requirements were measured by considering the resident set size (RSS) in MBs. RSS was measured using a separate process that polls the /proc Linux file system, once a second. We use the selectivity measures $\frac{\#of\ Matches}{\#of\ Events}$ and window size to test different workloads.

Memory Cost. Figs. 4 (a) and (b) show the memory consumption of all the systems for both datasets. As expected, increase in the selectivity measures (subsequently window sizes) results in a large number of partial matches and an extensive memory cost for both SASE++ and Flink. In particular, Apache Flink consumption is exponential in terms of the number of events in the window. SASE++ managed to sustain memory requirement due to the superior compression of Kleene+ matches. However, with the increase in the number of events that prefixed a new partial match, its memory utilisation increases to about two orders of magnitude compared to our recomputation-based approach. This phenomenon is largely observed in Fig. 4 (b), where the credit card dataset contains a large number of events that can initiate a new partial match. In contrast, RCEP scales linearly to the number of events within a window and not the partial matches.

CPU Cost. Figs. 4 (c) and (d) show the relative performance of the CEP systems over both datasets. We can see that, in general, RCEP have much higher throughput (more than an order of magnitude) than Flink and SASE++. As a matter of fact, SASE++ and Flink do not produce results for several hours for the moderate selectivities and window sizes. This is because the cost of SASE++ and Flink is highly dependent on the number of partial matches within a window. As the window size (subsequently selectivity) increases, both systems produce a large number of partial matches and spend most of their time in compressing and decompressing of the common events within the partial matches. That is, traversing through the stack of pointers using depth-first-search to extract

all the matches. In contrast, (i) RCEP initiates the recomputation of matches only if the triggered events’ arrive; (ii) the execute joins over the stored events; and (iii) the Kleene+ operator is executed only for the events that can be part of the final matches. Hence, RCEP performs much better and consume less memory than SASE++ and Flink, often by 1-2 orders of magnitude.

4 LOOKING AHEAD

In this preliminary study, we have highlighted the utility of recomputation-based CEP for expensive CEP queries. We have proposed our first algorithm for recomputing the matches with the arrival of new events. To our knowledge, ours is the first algorithm of this kind in the context of CEP. Our experimental results show that recomputation-based approach outperforms the incremental approach used by the existing systems.

Our study opens up several directions for the future work. A major direction is to establish techniques to efficiently store and index events within a defined window. Without this, we cannot discard events within an event sequence unless it is accessed and compared with all the other events. Hence, the indexing of events would enable us to prune irrelevant events before the joining process. Further, we plan to consider new algorithms for the multi-relational and inequality joins in the streaming settings since existing algorithms are only effective for the static workloads and require extensive indexing time. Finally, we would like to incorporate our solution in the open-source Apache Flink framework.

ABSTRACT

Do you dream to create good visualizations for your dataset simply like a Google search? If yes, our visionary system DEEPEYE is committed to fulfill this task. Given a dataset and a keyword query, DEEPEYE understands the query intent, generates and ranks good visualizations. The user can pick the one he likes and do a further faceted search to easily navigate the visualizations. We detail the architecture of DEEPEYE, key components, as well as research challenges and opportunities.

1 INTRODUCTION

Nowadays, the ability to create good visualizations has shifted from a nice-to-have skill to a must-have skill for all data analysts. However, the overwhelming choices of interactive data visualization tools (e.g., Tableau, Microsoft Excel and D3 [5]) only allow experts to create good visualizations, assuming that the experts know many details: the meaning and the distribution of the data, the right combination of attributes, and the right type of charts – these requirements are apparently not easy, even for experts.

Unfortunately, creating good data visualization is hard. From the user perspective, there are many possible ways of visualizations for a given dataset (for example, different attribute combinations and visualization types), and many ways of transforming data (for example, grouping, binning, sorting, and a combination thereof) – these make it infeasible for the user to enumerate all possible visualizations and select the ones he needs. From the system perspective, among numerous problems, no consensus has emerged to quantify the “goodness” of a visualization. What makes it harder is when the system does not even know what the user wants. Recently, there have been proposals for visualization recommendation systems [15, 18], which focus on automatically recommending “interesting” visualizations from a diversified criteria, such as relevance, surprise, non-obviousness, diversity and coverage. However, as pointed out by [3], these systems may mislead the user, by generating visualizations that might be *worse than nothing*, since it is basically impossible to guess a user’s query intent from nothing.

The natural problem arises: *What is the most feasible way to (automatically) create good visualizations even for dummies?*

We have three key intuitions for handling the above problem.

(1) *What is the ideal language for the user to specify his intent?* Of course, the mother tongue – Google-like natural language search interface is friendly to everyone. Note that (i) most visualizations

are generated using declarative languages like Vega-Lite [12]; and (ii) using machine learning to convert text to SQL queries for relational databases has been proved effective [11]. Hence, we can allow users to pose keyword queries and our system automatically converts them to declarative visualization queries.

Keyword-to-Visualizations is hard: keywords are typically ambiguous and underspecified; and good visualizations concern statistical properties such as trends, comparisons, which are rather hard to grasp even for human.

(2) *How can we solve the fundamental cognitive science problem for quantifying good visualizations?* Evidently, good visualizations exist, which can be collected from many sources that take experts hours or even days to produce such valuable visualizations. Naturally, the research problem is how to transfer the knowledge from these known good visualizations to judge a new visualization.

Transferring good visualizations. The basic intuition is: a new visualization is good, if it *matches* some known good visualization (see Section 2.2 for a further discussion).

(3) *How can we rank visualizations?* Ranking is the secret sauce to any search engine. Note, however, that it is almost impossible to rank visualizations, if they are independent of each other.

Visualization link graph. We propose a novel graphical model to link good visualizations. Informally speaking, two visualizations are linked if they are *relevant*, which are further classified into different types (or facets), e.g., similar or diverse that are captured by different facet functions (or criteria [15]).

The main benefit of having the above graph is twofold. (i) We can devise *PageRank* [6] like algorithms to rank visualizations. (ii) We can leverage the edge types to provide faceted search (*a.k.a.* faceted browsing) such that the user can easily set the compass to navigate the ocean of visualizations by simple clicks.

DEEPEYE is our visionary system to create good visualizations by *keyword search and simple clicks*.

DEEPEYE Workflow. A user can pose a keyword query K . DEEPEYE translates this keyword query to multiple candidate visualizations V , discovers good visualizations V' in V , ranks V' , and returns the top ones V'' . When the user selects a visualization V in V'' and further explores by clicking a facet of V , DEEPEYE discovers more visualizations and helps the user to easily explore his desired visualizations. The user may iterate over the above processes until he finds all visualizations that he wants.

Remarks. (1) Different from *visualization recommendation systems* [15, 18], (i) DEEPEYE is a visualization search engine that the user needs to provide his intent – we do not believe in the magic that one can guess something from nothing; and (ii) DEEPEYE decides and ranks good visualizations by comparing with

*Guoliang Li is the Corresponding Author.

Figure 1: The Architecture of DEEP EYE

known good visualizations. (2) After finding good visualizations, DEEP EYE will support to export them to a designated interactive data visualization tool (e.g., Tableau) for more customized manipulations. (3) Although intuitively, DEEP EYE, as a search engine, shares a similar architecture with well known search engines such as Google and Bing, there are many new challenges for designing visualization search algorithms (see Section 3).

2 THE DEEP EYE ARCHITECTURE

The architecture of DEEP EYE is given in Figure 1. DEEP EYE crawls, stores and indexes good visualizations from multiple sources.

The user starts by posing a *keyword search* and provides a dataset. The *visualization search engine* (VSE) will first generate a set of visualizations V by the *Keyword-to-Visualizations* module. These candidate visualizations V will be matched with known good visualizations by the *Visualization Transformation* module that produces $V' \subseteq V$, which will then be ranked by the *Visualization Ranking* module and the top ones $V'' \subseteq V'$ are returned to the user. The user may pick the one he likes and discovers more visualizations by the *Faceted Navigation* module. This module aims to reduce the number of user interactions and helps users to find the target visualizations as soon as possible.

2.1 Preliminary

Datasets. We crawl visualizations with data and visualizations charts (e.g., pie/line/bar charts) from multiple sources. Then we use them to visualize a user-given dataset D . For simplicity, we consider D as only one table, which can be easily extended to support multiple tables by relational joins (see SeeDB [16]).

Data Features. Typically, what will decide whether a visualization of a dataset is good or not depends more on its features (or representations [2]), not its data values. More specifically, we consider the following features of a dataset D : the data type of a column (e.g., categorical, numerical, and temporal), the number of distinct values of a column, the number of tuples in a column, the ratio of unique values in a column, the $\max()$ and $\min()$ values of a column, and statistical correlation between two columns (e.g., linear, polynomial, power, and log).

Visualization Queries. For *declarative visualization language*, we use Vega-Lite [12], a high-level grammar that enables rapid specification of interactive data visualizations. (Note that our system can support any declarative visualization query language.) Each *query* Q , specified in the Vega-Lite JSON format over the dataset D , denoted by $Q(D)$, will produce a visualization. A sample Vega-Lite query is as follows:

Edge labels: s (similar), d (diverse), c (coverage)

Figure 2: A Sample Visualization Link Graph

```

{
  "data": {"url": "flights.json"},
  "mark": "bar",
  "encoding": {
    "x": {
      "bin": true,
      "field": "carriers",
      "type": "qualitative"
    },
    "y": {
      "aggregate": "count",
      "type": "quantitative"
    }
  }
}

```

Visualization Crawler. The DEEP EYE *crawler* will extract tables and their associated visualizations from multiple sources, where *both* the table *and* the visualization specifications (or equivalent queries) need to be explicitly given. For example, there are hundreds of visualization examples in <https://www.highcharts.com>, with both data values and visualization specifications. Note that we do not require these sources to use Vega-lite – most visualization specifications can be easily converted to Vega-lite queries, for which we need to implement corresponding tools for query rewriting. When only the data and visualizations are given but the visualization queries are absent, an interesting open problem is to automatically infer the declarative visualization queries.

Visualization Link Graph. A *visualization link graph* is a directed graph $G(N, E)$ with nodes N and directed edges E . Each node $v \in N$ is a visualization (i.e., $Q(D)$). Each directed edge $e : (u, v) \in E$ can have multiple labels, denoted by $L(e)$, where each label $L(e) \in L(e)$ is a facet, such as similar, diverse, coverage.

In order to decide the edges and their labels, we have defined a set of *facet functions*. For example, there is a “similar”-edge from node u to node v , if the corresponding *similar-function* $f_s(u, v)$ returns *true*, denoting that u is similar to v . There can have another “similar”-edge from v to u if $f_s(v, u)$ also returns *true*. Note that any *facet function* does not have to be symmetric – $f(u, v)$ is *true* does not imply that $f(v, u)$ is *true* as well. The other edges and labels are generated similarly using different *facet functions*. Please find more details in the *Faceted Navigation* module in Section 2.2.

A sample visualization link graph is given in Figure 2. The number associated with each node denotes the importance of the node, which will be further discussed in Section 3.

2.2 Visualization Search Engine Modules

In this section, we will discuss the functionalities and our basic designs for the modules of DEEP EYE visualization search engine.

Keyword-to-Visualizations. Given a keyword query K and a dataset D , this module generates all candidate visualizations.

As mentioned earlier, this problem is hard because keyword queries are always ambiguous and underspecified – there might have a large number of candidate visualizations due to different attribute combinations and multiple data transformation operations (e.g., grouping, binning, sorting). Fortunately, there are simple observations about good/bad visualizations, e.g., pie charts are best to use when comparing parts of a whole, and they do not show changes over time; and bar graphs are used to compare things between different groups or to track changes over time, and too many bars (e.g., > 50) are hard for human to interpret. The traditional wisdom from visualization experts can be encoded into rules to prune many apparently bad charts (see e.g., <https://www.pinterest.com/pin/20125529565819990/> for a chart type cheat sheet that can be easily leveraged).

Visualization Transformation. The broad intuition is that, if a visualization V can “match” a known (crawled) good visualization, then V is probably good. As mentioned earlier in the data features, visualization matching focuses more on feature matching (e.g., similar domains and similar trends), in contrast to traditional value matching of strings.

Given a visualization V and another visualization N , it is to compute the similarity between their features, which typically falls in the range $[0, 1]$; and we say that V matches N if their similarity is above a threshold σ .

Given a set of visualizations V , the module of *Visualization Transformation* will find a set of existing good visualizations N that match these candidate visualizations. Note that one candidate query can match multiple good visualizations, and vice versa. Also, a candidate visualization that cannot match any existing good one will be removed, which will result in a subset V' of V .

Visualization Ranking. Given a set of visualizations V' and their matched good visualizations N , the *Visualization Ranking* module will rank V' based on N (i.e., a subgraph of the visualization linkage graph) and return to the user. We can either use the learning-to-rank [7] techniques to learn the features from known good visualizations or design new ranking functions. We can also use the user click-through data to rank the visualizations.

Faceted Navigation. When a user picks a visualization V he likes, he can further explore other visualizations by facets. The *Faceted Navigation* module will discover another set of visualizations based on V , which will also be ranked and returned to the user, in order to help users navigate the visualizations.

We plan to implement this module by providing each facet a programming interface (i.e., an API) that implements a *facet function*, e.g., similar, diverse, coverage. Also, we make it extensible by allowing domain experts to plug in other APIs for different facets. The main reason to allow this flexibility is that till now, there is no consensus about criteria of finding interesting visualizations, which remains an open problem. Note that these facet-functions do not need to be mutually exclusive.

3 RESEARCH OPPORTUNITIES

3.1 Visualization Data

An effective visualization system relies on high-quality and high-coverage visualization data. Although there are some open websites that we can crawl some data, the coverage is limited and we need to construct a visualization benchmark.

Opportunity. First, our system requires visualizations with data, visualization queries and visualization charts. Many websites, however, do not contain such data, and we need to infer one dimension based on the others, e.g., inferring a query based on the data and a visualization. Second, we also need some well-ranked visualizations to help us rank the visualizations for a new dataset. However many websites do not contain rankings, and it is challenging to infer rankings. Third, we can use crowdsourcing to collect more visualization data and rank the visualizations, and the challenge is to reduce the crowdsourcing cost, improve the quality, and avoid the redundancy with existing data.

3.2 Visualization Search Engine

3.2.1 Keyword-to-Visualizations. The essential problem is to understand natural language and generate visualization queries. Fortunately, the recent machine learning and deep learning techniques have made it easy to understand natural language (see e.g., the OpenNLP toolkit: <https://opennlp.apache.org>). Furthermore, several approaches have studied the problem of translating natural language to SQL queries, such as NLDBs [1] and NaLIR [11].

Opportunity. Although the above approaches shed some light on our problem, translating natural languages to visualization queries remains a hard problem. The main reason is that when searching visualizations, the user cares more about the statistical properties such as *trends*, *comparisons*, *fast increase*, which are more ambiguous than querying a DBMS such as “return the average number of publications by Bob in each year”. In other words, even if an expert knows precisely what is the meaning of the natural language query of the user, it is still hard for the expert to formulate using the declarative visualization language, since good visualizations are also data dependent.

The research problem is: Given a keyword query K and a dataset D , discovers candidate visualizations $Q(D')$ that the user wants, where D' could be transformed from D (e.g., by operations like binning, grouping, sorting, and a combination thereof).

3.2.2 Visualization Transformation. The fundamental problem of visualization transformation is to transform the knowledge (or features) from known good visualizations to deciding the goodness of unknown visualizations. A possible way is to compute the similarity between two visualizations $Q_1(D_1)$ and $Q_2(D_2)$ (i.e., the known good one). If $Q_1(D_1)$ is very similar to $Q_2(D_2)$ and $Q_2(D_2)$ is good, then by inference, $Q_1(D_1)$ is also good: showing an interesting trend, using the same chart as employed in Q_2 , etc.

Opportunity. The open problem is how to define the similarity function $\text{sim}(Q_1(D_1), Q_2(D_2))$, which relates to many factors.

- (1) The statistical correlation between the two visualizations $Q_1(D_1)$ and $Q_2(D_2)$, such as the same trend.
- (2) The domain similarity, i.e., whether the attributes used for $Q_1(D_1)$ and $Q_2(D_2)$ come from the same domain.
- (3) The type similarity, e.g., whether the data types used in $Q_1(D_1)$ and $Q_2(D_2)$ are both temporal data.

3.2.3 Visualization Ranking. As mentioned earlier, there is still no consensus to quantify the “goodness” of a visualization. Intuitively, it is harder to quantify “better” visualizations.

Opportunity. The great success of search engines has shown us multiple ways of doing link analysis, with the purpose of “measuring” the relative importance within a set of linked webpages. Maybe the most successful story is *PageRank* [6]. We have defined

our visualization link graph (see Figure 2) in a way that we can use a similar idea of PageRank, which is referred to as *VisualRank*. However, implementing *VisualRank* faces four challenges:

- (1) The edges in the visualization link graph and the edges in the Webgraph have different meanings. In the Webgraph, an edge from a page X to a page Y if there exists a hyper-link on page X referring to page Y . In the visualization link graph, the edges have diversified semantics (or facets).
- (2) The search behaviors between a normal search engine and a visualization search engine are quite different.
- (3) We also want to use the graph in faceted navigation to reduce the number of interactions with the user. It is challenging to design multi-goal optimization algorithms.
- (4) Our end goal is not to rank nodes in the visualization link graph, but the unlinked visualizations for an input dataset, for which we need to infer from the “importance values” of their matched good visualizations to rank.

Hence, a good research opportunity is how to design a *VisualRank* algorithm, which shares the basic intuition of PageRank, but serves the purpose of ranking visualizations.

3.2.4 Faceted Navigation. The recent proposal towards visualization recommendation systems [15] made an attempt to define the criteria of recommending good visualizations: relevance, surprise, non-obviousness, diversity and coverage. Another recent work proposes a general-purpose query language for visualization recommendation [18].

Opportunity. We can certainly use these criteria to create our facets. Unfortunately, these are just research hypothesis – whether they can lead to good visualizations is still not well justified. Besides, there is no well accepted implementation for each of them. Hence, it remains open that which facets should be considered and how to implement them.

3.3 Optimization

Response time is critical to real-time applications – response times under one second are usually considered to be good for search engines. Naturally, this requires us to carefully design DEEPEYE, from storage, indexes, to algorithms.

Opportunity. The first opportunity is about storage: What is the best physical representation of the data and the existing visualizations, assuming that they are stored in tables and JSON files? The work RodenStore [8] proposed an adaptive and declarative storage system providing a high-level interface for describing the physical representation of data. The similar idea can be adopted in the problem of storing datasets and visualizations. The second opportunity is how to store the visualization link graph – this will be tightly coupled with all (ranking) algorithms that use this graph. We can also group the visualizations effectively, e.g., in a hierarchy or using partial orders, to help users to quickly find target visualizations. The third challenge is how to design effective index, especially for large datasets. We can borrow the idea from the search engine, e.g., inverted index and forward index. However, it is rather challenging to design indexes for visualization search and ranking, because they involve more data features and more visualization operations.

4 RELATED WORK

Visualization Recommendation Systems. One important line of work is visualization recommendation systems [14–16]. Roughly speaking, given a dataset, they want to automatically

recommend visualizations to the user under different criteria. DEEPEYE differs from them in the following two key aspects: (1) instead of guessing the user’s intent, DEEPEYE accepts keyword search; and (2) DEEPEYE uses existing good visualizations to reason about the input dataset.

Interactive Data Visualization. There are some interactive data visualization systems, such as D3 [5], protovis [4], matplotlib [10], Tableau [17]. We do not plan to reinvent the wheel – DEEPEYE will export the user selected visualizations to the above toolkits for more complicated manipulations.

Visualization Languages. There are many visualization languages, e.g., Vega [13], Vega-Lite [12], VizQL [9], Ermac [19], and DeVIL [20]. We use Vega-Lite as it is simple yet general enough.

5 CONCLUDING REMARKS

With increasing interest and importance of data visualization for data science applications, there is an emerging need for a tool to easily create good visualizations. We believe that DEEPEYE, the first visualization search engine, will lead to interesting and impactful problems for many communities, including: database, information retrieval, machine learning, and visualization.

ABSTRACT

Blockchain technology has emerged as a primary enabler for verification-driven transactions between parties that do not have complete trust among themselves. Bitcoin uses this technology to provide a provenance-driven verifiable ledger that is based on consensus. Nevertheless, the use of blockchain as a transaction service in non-cryptocurrency applications, for example, business networks, is at a very nascent stage. While the blockchain supports transactional provenance, the data management community and other scientific and industrial communities are assessing how blockchain can be used to enable certain key capabilities for business applications.

We have reviewed a number of proof of concepts and early adoptions of blockchain solutions that we have been involved spanning diverse use cases to draw common data life cycle, persistence as well as analytics patterns used in real-world applications with the ultimate aim to identify new frontier of exciting research in blockchain data management and analytics. In this paper, we discuss several open topics that researchers could increase focus on: (1) leverage existing capabilities of mature data and information systems, (2) enhance data security and privacy assurances, (3) enable analytics services on blockchain as well as across off-chain data, and (4) make blockchain-based systems active-oriented and intelligent.

1 INTRODUCTION

Blockchain (a.k.a. distributed ledger [31]) is an emerging platform that is designed to support transactions services within a multi-party business network, with the goal of enabling significant cost and risk reductions for all parties through the creation of innovative new business models. Data maintained within the distributed ledger can only be accessed through the execution of a smart contract [29] (i.e., a stored procedure call on the distributed ledger) that describes rules that govern a transaction. In addition, the design of blockchain technology ensures that no one business entity can modify, delete, or even append any record to the ledger without the consensus from other business entities in the network, making the system useful for ensuring the immutability of data and legal documents.

Given the aforementioned important features, blockchain technology has taken the world by storm in the recent years for its promise to transform every industry. For instance, it has started to be used in a wider range of applications, e.g., Internet of Things (IoT) [11]. A blockchain enables IoT devices to send data for inclusion in a shared transaction repository with tamper-resistant records, and enables business parties to access and supply IoT data without the need for central control and management. Blockchain for IoT can optimize supply chains by

tracking objects as they traverse the export/import supply chain while enforcing shipping and expediting incremental payments.

Similarly, blockchain technology also has the potential to disrupt insurance industry. It has been used in a car micro-insurance application to enable the concept of pay-as-you-go insurance [20]. This application allows drivers who rarely use cars to only pay insurance premium for particular trips rather than the hefty yearly premium. By transparently storing on blockchain all the data pertaining to the actual trip and premium payment, every party in the insurance contract including the driver, the insurance company, and the financial institution is confident that the data are tamper-proof and traceable. This guarantees that any insurance claim request regarding to a trip can be processed quickly and indisputably, hence offering a better customer experience. Further, as the micro-insurance application also requires accessing multiple risk analytic databases such as past driving behaviour statistics and past vehicle runtime statistics for computing premiums, a system architecture that allows for maintaining and analyzing both on-chain and off-chain data was also proposed.

In fact, Gartner's 2016 research report¹ identified blockchain as one of the key platform-enabling technologies to track. Nonetheless, while there is currently no standard in the blockchain space, there is a growing consensus that blockchain is entering its peak of inflated expectations. The report anticipated that it would take 5 to 10 years for blockchain technology to get mainstream adoption. Further, most of nowadays blockchain efforts, especially when applied to business environments, are still in a nascent state. Research perspectives and challenges related to blockchain have been presented in [12], but they are mainly for cryptocurrencies and public blockchain environments. The time is ripe for database community to get more deeply involved in solving open problems pertaining to data management and analytics in a permissioned blockchain network for business applications [28].

As the building blocks of blockchain include some combination of database, transaction, encryption, consensus and other distributed system technologies, it is natural to investigate if it is possible to utilize existing capabilities of mature data and information systems through robust integration into blockchain systems. There exist open research issues such as multi-storage and index support, novel transaction concurrency model, scalable transaction throughput, master and reference data management, smart contract management, data security and privacy assurances, as well as information leakage prevention.

Furthermore, even though the blockchain database is useful for transparent persistence of streaming business data, there is no one-size-fits-all database solution for an application [30]. While blockchain is originally designed to maintain transaction data, there is a growing interest in providing analytics capabilities in blockchain-based data systems. Particularly, in this paper we shall elaborate on specific research problems such as built-in analytics for blockchain, and data integration and analytics across on-chain and off-chain data.

¹<http://www.gartner.com/newsroom/id/3412017>

Last but not least, with recent advances in areas such as information retrieval, machine learning, and AI, there is a tremendous opportunity to bring cognitive capabilities, e.g., understanding, learning, and contextual awareness into blockchain-based data systems so as to make them active-oriented and intelligent. We shall discuss open research issues encountered while developing intelligent blockchain-based data systems. Our list is by no means comprehensive and other research opportunities exist as well.

2 BACKGROUND

Blockchain. Blockchain technology [31] provides a framework for building a distributed ledger that can provide consensus, provenance, immutability and finality of transaction data. The use of blockchain was first popularised by Bitcoin [1], which is a cryptocurrency. In a blockchain, a group of ledger entries, i.e., a list of transactions, are periodically accumulated into a block which contains a cryptographic hash of the prior block linking the blocks together. This way of chaining the blocks allows the global order of the ledger entries to be established and to verify that the content of a particular block have not been modified. Every node in this distributed system maintains its own copy of the blockchain and participates in an appropriate consensus mechanism to keep the replicated data in sync across nodes. For example, Bitcoin uses a consensus protocol called “Proof-of-Work” [31], whereas Hyperledger Fabric [8] develops a variant of Byzantine fault-tolerant (BFT) state machines [32].

Permissioned/private blockchain. In Bitcoin, a public implementation of blockchain, entities that participate in the transfer of assets are anonymous and any entity can participate. In contrast, many business networks may have a need for a distributed ledger that is only accessible to a closed community of known entities. Permissioned blockchain technologies such as Hyperledger Fabric[8] and R3 Corda[5] have been developed to support these requirements, i.e., entities participating the network are identified so that their permissions can be determined and the activities of an entity are only visible to those participants of the business network that have a need to know.

Smart contract. Some distributed ledger technologies support an additional capability called a smart contract [29], which is similar to the concept of stored procedure in classical relational databases to some extent. Smart contracts allow the shared business processes within a business network to be standardised, automated and enforced via computer programs to increase the integrity of the ledger.

3 BLOCKCHAIN DATA MANAGEMENT

3.1 Leverage capabilities of mature data and information systems

Multi-storage and index support. Most blockchain platforms such as Ethereum [7] adopt key-value data model, while a few of them like R3 Corda [5] use relational data model. This makes any single blockchain platform not suited for different types of data used in a wide range of business applications. For example, geo-location data recorded from vehicles in a car micro-insurance application [20] as discussed in Section 1 may not be efficiently queried using a key-value store. Furthermore, even though blockchain platforms such as Hyperledger Fabric [8] opt for pluggable storage model, developer users have to decide at development time which storage to use, e.g., either LevelDB [9] (key-value store) or CouchDB [6] (document store). Therefore, novel techniques are needed for supporting multiple types of

data stores such as key-value, document, SQL and spatial data stores simultaneously in the same blockchain system.

Additionally, blockchain is originally not designed to store digital documents, which, however, are a popular type of data shared in a business network as observed in a majority of blockchain solutions that we have been involved. These digital records are usually large, and their aggregate size grows significantly over time. It is infeasible to store these data directly on the blockchain due to several constraints such as storage size, bandwidth and transaction throughput. One possible solution is to store these records in a third-party offline storage, and maintain their locations and a digital hash of the data on the blockchain for verification. Nevertheless, this approach requires integration of blockchain and offline storages. Thus, it is critical to develop blockchain systems with built-in offline storage strategies for handling big data.

We also observe from the implementation of those blockchain solutions that rich queries (e.g., conditionals, operators etc.) of data on blockchain are typically read-only and based on non-primary keys. To deal with these situations, explicit smart contracts for maintaining secondary indices have to be developed. This motivates exciting research problems related to index management in blockchain-based data systems.

Master data management. Unlike blockchains used in public cryptocurrency environments, a business blockchain network is not a single universal collaborative environment for every organization to join in this same network. Instead, each network usually includes a specific set of organizations sharing some common business interests, and more importantly, an organization may join a number of different blockchain networks due to the large scope of their business. It is likely that each network will have a different data schema and may record a different version of some common data referring to the same entity across the networks. Therefore, organizations need master data management rules, processes and techniques in order to consolidate data across multiple blockchain networks that they participate in. In addition, we also envision an interesting opportunity for future research to explore a new concept of cross-chain smart contracts that run across multiple blockchains.

Reference data management. Since the data in blockchain cross over the boundary of organizations, semantically right interpretation of data is must. Hence, one important problem is interpreting the data w.r.t. reference data and business glossary. Particular technical problems include identification of reference data entities, automatic interpretation/conversion, and managing the reference data as they are provided by external sources. Another technical question is whether this logic of references should be handled in the smart contract or at application level. Further, query processing on blockchain must take such context, i.e., references, into account to carry out meaningful processing.

Scalable transaction throughput. There continues to be the quest for scalable transaction throughput in blockchain. The blockchain in Bitcoin [1] uses “Proof of Work” (PoW) consensus method that is computationally expensive (by design) for having to solve a cryptographic puzzle in the process [12, 31]. Instead, the permissioned blockchains where participants are identified use consensus methods based on variants of Byzantine fault-tolerant (BFT) state machines [32], which have been chosen to provide higher transaction throughput and lower consensus latency as shown in the recent benchmark [16]. Nevertheless, even with that performance improvement, the benchmark paper concludes that current blockchain technologies are not suited for large-scale data processing workloads. Consequently, there still exists the

need of novel methods, e.g., implicit consensus [22] and sharding data [19] that provide high levels of transaction throughput for blockchain. A different direction to achieve scalable throughput, e.g., BigchainDB [4], is developing blockchain-like trusted transactions on top of existing modern distributed database systems.

ACID properties. Presently, no blockchain platform fully guarantees ACID properties [24] because blockchain is not designed to support databases, nor it is always tractable to support these properties on distributed ledgers. Nevertheless, as we apply transactional semantics to blockchain and use it for data management, we need to assure the important ACID properties. It is interesting to see that even though blockchain platforms are designed to maintain transaction data, they adopt a simple concurrency control, or not at all, to deal with concurrent transactions accessing the same data item. Transactions in blockchains are validated based on a first-come first-served basis. That is, the first transaction to get endorsed and committed by all nodes in the blockchain network wins and invalidates other conflicting transactions that are concurrently modifying some common data items. In this case, all other client applications executing those conflicting transactions have wasted time waiting for the notification from the blockchain about the rejected status of their submitted transactions. Hence, an important research issue here is to develop novel concurrency control models for blockchains so that they are applicable to a wider range of applications.

3.2 Enhance information protection

Blockchain-enabled applications involving security- and privacy-sensitive data, e.g., financial [17] and healthcare [33], requires confidentiality, security and privacy assurances at different levels to be supported by the system, which are mandated by regulatory compliance requirements such as HIPAA [2] and GDPR [3].

Confidentiality. Access control mechanism is mainly used to protect access data on permissioned blockchains [18]. However, access control is insufficient to provide protection from data exposure. Data that is stored on distributed ledger of the blockchain networks need to be encrypted. Thus, it is essential to determine the “computational hop” in which data shall remain encrypted, primarily because if we assume that data shall remain encrypted across its life cycle, processing of such data using smart contracts shall be difficult (unless we use fully homomorphic encryption or some form of malleable encryption schemes). Querying data on blockchain has to be enabled even when the data is encrypted. Models such as “search on encrypted databases” if implemented shall have severe impact on the performance of the blockchain system. Therefore, in the presence of encrypted data available for querying, the query execution system on blockchain has to be properly designed and implemented.

Privacy. Bitcoin [1] and Ethereum [7] claim to support some form of privacy for transactional information, which, however, has been shown not to be entirely privacy-preserving [23]. Data on blockchain may need to be shared across others for analytics. There are use cases where research needs to be carried out on implementing “right-to-forget” on blockchain. GDPR and EU regulation on data privacy have recently asked Google and other internet companies to support “right-to-forget” – a user may ask the service providers to remove their data from the search results or from the system altogether. When a blockchain stores healthcare, finance and such other sensitive data, a user may request the blockchain provider to delete some or all the records pertaining to the user, which is hard to support today due to

the immutability of blockchain. This necessitates cryptographic techniques to rewrite history in blockchains [10].

Information leakage prevention. For blockchains that maintain unstructured data such as business documents, a more comprehensive data redaction mechanism [15] would be needed to protect business-critical information contained in these documents from unintentional disclosure. Typically, these documents can be accessed fully or they are protected completely. However, there is real need that documents can be released partially by redacting certain data entities that should be prohibited from the users. Thus, it is important to support fine-grained access control on these documents (i.e., access control at data entity level rather than at document level). This fine-grained access control can be achieved by detecting and removing the business-critical information from the document shared on the blockchain based on the role of the user who requests to access the document.

3.3 Manage smart contracts

Smart contract governance. As smart contracts capture the shared business processes between parties in a blockchain network, the governance of these smart contracts at every step of their life cycle including business analysis, design, development, testing, deployment, and monitoring would in general require the coordination and approval of these multiple parties. Nevertheless, this governance process is not standardised and automated as per current practice. Instead, it is common that only one or a subset of parties are delegated and trusted to manage the entire life cycle of a smart contract. This points to the need of tools that allow automated and collaborative governance of smart contracts.

Smart contract template. As current practice, smart contracts are manually programmed by developers after studying requirements described in legal documents agreed by multiple parties. However, this process is time consuming and error-prone as there is currently no standard regarding the legal enforceability of code-based contracts. It is, therefore, important to make the development of smart contracts as much automated as possible. An open research issue in this direction is to define a standardised semantic framework for smart contracts that considers both operational and non-operational aspects based on existing legal documents [13]. Another related research challenge is to propose standardised templates for automated generation of legally-enforceable smart contracts from legal documents. This requires understanding natural language used in legal documents and identifying operational parameters that can be used as the connection between legal agreements and smart contracts.

Trusted smart contracts. Smart contracts vulnerable to attacks can expose blockchain data or contain backdoors that may be used to exfiltrate data from the blockchain. Hence, it is essential to develop security analysis technology for smart contracts and reasoning about their semantic trustworthiness, i.e., trust between parties defined based on the semantics of smart contracts rather than the digital signatures of the code for smart contracts. Several open questions need to be addressed, e.g., how to detect bugs in smart contract codes [26], how to deal with smart contract codes behaving erratically and how to update with correct codes without impacting the network [27].

4 BLOCKCHAIN DATA ANALYTICS

4.1 Built-in analytics for blockchain

As the original blockchain is purely a transaction repository, an execution engine will be required for analytics running directly

on blockchain data. A possible solution to this problem is to make blockchain data readily accessible by data parallel processing systems such as MapReduce [14] or Spark [34]. In particular, an input reader could be implemented so that MapReduce and Spark programs are able to scan through blockchain data efficiently. Further, MapReduce or Spark execution nodes can be physically co-located with blockchain data nodes to reduce the need of data transfer, and hence improving analytics performance. Apart from the above batch analytics, there are also use cases such as IoT applications in the supply chain domain as discussed in Section 1 in which lightweight or edge analytics capability (i.e., analyzing data as ingested into blockchain) would be critical to the system.

4.2 Integration and analytics across on-chain and off-chain data

It is worth noting that the need of data integration across multiple blockchains that an organization participates in, as discussed in Section 3.1, is just one dimension of the problem. Another dimension of data integration problem comes from common data entities referred by both the blockchains and the organization's legacy systems of record. In particular, whereas blockchains function independently of legacy systems in most cases, at some point in the application development process organizations will need to integrate blockchain data with their existing systems of record for deriving complete business insights. Since multiple parties are joining a blockchain network, cases of overlapping or inconsistent data between the blockchain and their legacy systems will likely arise. As a consequence, there is much scope for development of new techniques in entity resolution for big data spanning across blockchain and off-chain data.

In addition, as the analytics now spans across on-chain and off-chain data systems, query processing over federated data and optimisation techniques would be the key to the performance of query federation. For example, would the strategy that exports all data on blockchain into an off-chain database where all the analytics are executed be optimal? In contrast, are there better approaches that only materialize part of relevant blockchain data in the off-chain database and how it could be done dynamically given the changing workload? More importantly, it is also challenging to ensure the immutability of the data that has been exported from blockchain into external data stores. These are very interesting research issues and they require more exploration on query federation, translation, and optimization, as well as data security in the context of analytics over both on-chain and off-chain data.

5 INTELLIGENT BLOCKCHAIN SYSTEMS

As discussed in Section 1, blockchain technology has started to be used in a wider range of applications, e.g., Internet of Things (IoT) [11]. Nevertheless, the volume of data generated in this era of the Internet of Things is growing significantly, which puts blockchain systems to their limits of transaction throughput and storage capacity. Consequently, when a new piece of data arrives, it is important for the blockchain system to be able to understand the input data, reason about its relevance to the business so as to determine whether dropping the data or accepting and storing it in the blockchain. Recently, a technique to reduce data acquisition cost by only accepting data that is useful for answering queries has been proposed [25]. However, none of prior systems is able to self learn the relevance of incoming data to the business. This necessitates an active-oriented and intelligent

blockchain system for making sense and intelligently classifying incoming data, which greatly helps reduce redundant data storage and computation at later stages. In fact, intelligence can be embedded at every step in the pipeline of data processing inside a blockchain-based systems, similar to the concept of intellectual data warehousing [21].

6 CONCLUSIONS

We have highlighted research topics that characterize the common issues of on-going data management and analytics problems encountered in the development of real-world blockchain applications. We hope that this study could provide a basis for further research to identify likely solutions to these open problems.

ABSTRACT

We introduce a novel interactive framework to handle both instance-level and temporal smoothness constraints for clustering large temporal data. It consists of a constrained clustering algorithm which optimizes the clustering quality, constraint violation and the historical cost between consecutive data snapshots. At the center of our framework is a simple yet effective active learning technique for iteratively selecting the most informative pairs of objects to query users about, and updating the clustering with new constraints. Those constraints are then propagated inside each snapshot and between snapshots via constraint inheritance and propagation to further enhance the results. Experiments show better or comparable clustering results than existing techniques as well as high scalability for large datasets.

1 INTRODUCTION

In semi-supervised clustering, domain knowledge is typically encoded in the form of instance-level *must-link* and *cannot-link* constraints [8]. Such constraints specify that two objects must be placed in the same clusters or not. Constraints have been successfully applied to improve clustering quality in real-world applications, e.g., identifying people from surveillance cameras [8] and aiding robot navigation [7]. However, current research on constrained clustering still suffers from several issues.

Most existing approaches assume that we have a set of constraints beforehand, and an algorithm will use this set to produce clusters [2, 7]. Davidson et al. show that the clustering quality varies significantly using different equi-size sets of constraints [5]. Moreover, annotating constraints requires human intervention, an expensive and time consuming task that should be minimized as much as possible given the same expected clustering quality. Therefore, how to choose a *good* and *compact* set of constraints rather than randomly selecting them from the data has been the focus of many research efforts, e.g., [1, 11, 14].

Many approaches employ different *active learning* schemes to select the most meaningful pairs of objects and then query experts for constraint annotation [1, 11]. By allowing the algorithms to choose constraints themselves, we can avoid insignificant ones, and expect to have high quality and compact constraint sets compared to randomized constraint selection. These constraints are then used as input for constrained clustering algorithms to operate. However, if users are not satisfied with the results, they are asked to provide another constraint set and start the clustering again, which is obviously time consuming and expensive.

Other algorithms follow a *feedback* schema which does not require a full set of constraints in the beginning [4]. They iteratively produce clusters with their available constraints, show results to users, and get feedback in the form of new constraints. By iteratively refining clusters according to user feedback, the acquired results fit users' expectations better [4]. Constraints

are also easier to select with an underlying cluster structure as a guideline, thus reducing the overall number of constraints and human annotation effort for the same quality level. However, exploring the whole data space for finding meaningful constraints is also a non-trivial task for users.

To reduce human effort, several methods incorporate *active learning* into the feedback process, e.g., [10, 11, 14]. At each iteration, the algorithm automatically chooses pairs of objects and queries users for their feedback in terms of *must-link* and *cannot-link* constraints instead of leaving the whole clustering results for users to examine. Though these active feedback techniques are proven to be very useful in real-world tasks such as document clustering [10], they suffer from very high runtime since they have to repeatedly perform clustering as well as exploring all $O(n^2)$ pairs of objects to generate queries to users.

In this paper, we develop an efficient framework to cope with the above problems following the iterative active learning approach as in [10, 14]. However, instead of examining all pairs of objects, our technique, called *Border*, selects a small set of objects around cluster borders and queries users about the most uncertain pairs of objects. We also introduce a constraint inheritance approach based on the notion of μ -nearest neighbors for inferring additional constraints, thus further boosting performance. Finally, we revisit our approach in the context of evolutionary clustering. Evolutionary clustering aims to produce high quality clusters while ensuring that the clustering does not change dramatically between consecutive timestamps. We propose to formulate a temporal smoothness constraint and add a time-fading factor to our constraint propagation.

This paper's contributions are: (i) a new algorithm CVQE+ that extends CVQE [7] with weighted *must-link* and *cannot-link* constraints, (ii) a new algorithm, *Border*, that relies on active clustering and constraint inheritance to choose a small number of objects to solicit user feedback for, (iii) an evolutionary clustering framework which incorporates instance-level and temporal smoothness constraints, and (iv) experiments with 6 datasets that show the superiority of our algorithms over state-of-the-art ones.

2 PROBLEM FORMULATION

Let $D = \{(d, t)\}$ be a set of $|D|$ vectors $d \in \mathbb{R}^p$ observed at time t . Let $S = \{(S_s, D_s, ts_s, te_s)\}$ be a set of preselected $|S|$ data snapshots. Each S_s starts at time ts_s , ends at time te_s and contains a set of objects $D_s = \{(d, t) \in D \mid ts_s \leq t < te_s\}$. Two snapshots S_s and S_{s+1} may overlap but must satisfy the time order, i.e., $ts_s \leq ts_{s+1}$ and $te_s \leq te_{s+1}$. For each snapshot S_s , let $ML_s = \{(x, y, w_{xy})\}$ be a set of *must-link* constraints related to $x, y \in D_s$ with a degree of belief of $w_{xy} \in [0, 1]$. Similarly, let $CL_s = \{(x, y, w_{xy})\}$ be a set of *cannot-link* constraints of S_s . Initially, ML_s and CL_s can be empty.

In this paper, we focus on the problem of grouping objects in all snapshots into clusters. Our goals are (1) reduce the number of constraints thus reducing the constraint annotation costs (2) make the algorithm scale well with large datasets and (3) smooth the gap between clustering results of two consecutive snapshots, i.e., ensure temporal smoothness.

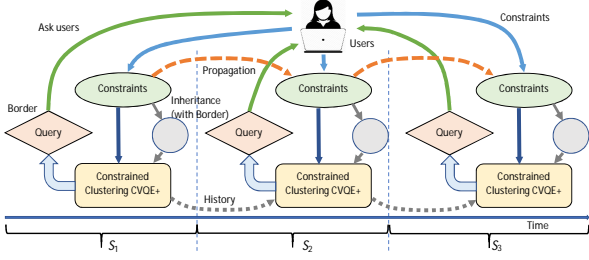

Figure 1: Our active temporal clustering framework

3 OUR PROPOSED FRAMEWORK

Figure 1 illustrates our framework which relies on two algorithms, Border and CVQE+. Our framework starts with a small (or empty) set of constraints in each snapshot. Then, it iteratively produces clustering results and receives refined constraints from users in the next iterations. This process is akin to feedback-driven algorithms for enhancing clustering quality and reducing human annotation effort [4]. However, instead of passively waiting for user feedback as in [4], our algorithm, Border, *actively* examines the current cluster structure, selects β pairs of objects whose labels are the least certain, and asks users for their feedback in terms of instance-level constraints. Examining all possible pairs of objects to select queries is time consuming due the quadratic number of candidates. To ensure scalability, Border limits its selection to a small set of most promising objects. When there are new constraints, instead of reclustering from scratch as in [10, 14], our algorithm, CVQE+, incrementally updates the cluster structures. We also aim to ensure a smooth transition between consecutive clusterings [3]. We additionally introduce two novel concepts: (1) the *constraint inheritance* scheme for automatically inferring more constraints inside each snapshot and (2) the *constraint propagation* scheme for propagating constraints between different snapshots. These schemes help significantly reduce the number of constraints for acquiring a desired level of clustering quality. To the best of our knowledge, Border is the first framework that combines active learning, instance-level and temporal smoothness constraints.

The new algorithm CVQE+. For each snapshot S_s , we use constrained kMeans for grouping objects. Any existing techniques such as MPCK-Means [2], CVQE [7] or LCVQE [13] can be used. Here we introduce CVQE+, an extension of CVQE [7] to cope with weighted constraints, to do the task. Let $C = \{C_i\}$ be a set of clusters. The cost of C_i is defined as its vector quantization cost VQE_i and the constraint violation costs ML_i and CL_i as follows. Note that, our ML_i cost is symmetric compared to [7].

$$\begin{aligned} Cost_{C_i} &= Cost_{VQE_i} + Cost_{ML_i} + Cost_{CL_i} \quad (1) \\ Cost_{VQE_i} &= \sum_{x \in C_i} (c_i - x)^2, \\ Cost_{ML_i} &= \sum_{(a,b) \in ML_i \wedge vl(a,b)} w_{ij} (c_i - c_{\pi(a,b,i)})^2 \\ Cost_{CL_i} &= \sum_{(a,b) \in CL_i \wedge vl(a,b)} w_{ij} (c_i - c_{\varphi(i)})^2 \end{aligned}$$

where, $vl(a,b)$ is true for (a,b) that violates *must-link* or *cannot link* constraints, c_i is the center of cluster C_i , $\pi(a,b,i)$ returns the center of clusters of a or b (not including cluster C_i), and $\varphi(i)$ returns the nearest cluster center of C_i . Note that, $Cost_{ML_i}$ is symmetric compared to [7]. Taking the derivative of $Cost_{C_i}$, the

new center of C_i is updated as:

$$c_i = \frac{\sum_{x \in C_i} x + \sum_{(a,b) \in ML_i \wedge vl(a,b)} w_{ij} C_{\pi(a,b,i)} + \sum_{(a,b) \in CL_i \wedge vl(a,b)} w_{ij} C_{\varphi(i)}}{|C_i| + \sum_{(a,b) \in ML_i \wedge vl(a,b)} w_{ij} + \sum_{(a,b) \in CL_i \wedge vl(a,b)} w_{ij}} \quad (2)$$

For each constraint (a,b) , CVQE+ assigns objects to clusters by examining all k^2 cluster combinations for a and b like CVQE. The major difference is that when we calculate the violation cost, we consider all constraints starting and ending at a and b instead of only the constraint (a,b) as in CVQE [6] or LCVQE [6], which is very sensitive to the cost change when some constraints share the same objects (changing these objects affects all their constraints). Thus, this scheme is expected to improve the clustering quality of CVQE+ compared to CVQE and LCVQE.

Active learning with Border. To avoid examining all pairs of objects, Border chooses a subset of $m = \min(O(\sqrt{n}), M)$ objects located at the boundary of the clusters as the main targets since they are the most uncertain ones, where M is a predefined constant. For each object a in cluster C_i , the border score of a is defined as $bor(a) = \frac{(a-c_i)^2}{(a-c_{\varphi(i)})^2(1+ml(a))(1+cl(a))}$, where $ml(a)$ and $cl(a)$ are the sums of weights of must and cannot-link constraints of a . Here, we favor objects that have fewer constraints for increasing constraint diversity. This also fits well with our constraint inheritance scheme. For each cluster C_i , we select $m|C_i|/n$ top objects based on their border score distribution in C_i . This can be done by building a histogram with $O(\sqrt{|C_i|})$ bins (a well-known rule of thumb for the optimal histogram bin). Then, objects are taken sequentially from the outermost bins.

For each selected object a , we estimate the uncertainty of a as $sco(a) = ent(\mu nn(a)) + \frac{vl(ml(a))+vl(cl(a))}{ml(a)+cl(a)+1}$, where $ent(\mu nn(a))$ is the entropy of class labels of μ nearest neighbors of a and $vl(ml(a))$ and $vl(cl(a))$ are the sums of violated must-link and cannot-link constraints of a . A high $sco(a)$ means that a is in high uncertain areas with different mixed class labels and a high number of constraint violations.

We divide $m^2 = O(n)$ pairs of selected objects into two sets: the set of inside cluster pairs X and between cluster pairs Y , i.e., for all $(x,y) \in X : label(x) = label(y)$ and for all $(x,y) \in Y : label(x) \neq label(y)$. For a pair $(x,y) \in X$, it is sorted by $val(x,y) = \frac{(x-y)^2(1+sco(x))(1+sco(y))}{(1+ml(x)+cl(x))(1+ml(y)+cl(y))}$. For $(x,y) \in Y$, $val(x,y) = \frac{(x-y)^2(1+ml(x)+cl(x))(1+ml(y)+cl(y))}{(1+sco(x))(1+sco(y))}$. The larger val is, the more likely x and y belong to different clusters and vice versa. We choose top $\beta/2$ non-overlapped largest val pairs of X and top $\beta/2$ non-overlapped smallest pairs of Y in order to maximize the changes in clustering results (inside and between clusters).

We show β pairs to users to ask for the constraint type and add their feedback to the constraints set and update clusters until the total number of queries exceeds a predefined budget δ .

Constraint inheritance in Border. For further reducing the number of queries to users, the general idea is to infer new constraints automatically based on annotated ones. Our inheritance scheme is based on the concept of μ nearest neighbors below.

Let h be the distance between an object p and its μ nearest neighbors. The influence of p on its neighbor x is formulated by a triangular kernel function $\phi_h(p,x)$ centered at p as in Figure 2. Given a constraint (p,q,w_{pq}) , for all $a \in \mu nn(p)$ and $b \in \mu nn(q)$, we add (a,b,w_{ab}) to the constraints set, where w_{ab} is defined as:

$$w_{ab} = w_{pq} \phi_h(p,a) \phi_h(q,b) \quad (3)$$

Figure 2: (A) Constraint inheritance from (p, q) to (a, b) . (B) The effect of the object b on its neighbors

The general intuition is that the label of an object a tends to be consistent with its closest neighbors (which is commonly used in classification). This scheme is expected to increase the clustering quality, especially when combined with the active learning approach described above.

Updating clusters. For incrementally updating clusters, we only need to take the old cluster centers and update them following Equation 1 with the updated constraints set.

Temporal smoothness. The general idea of temporal smoothness [3] is that clusters not only have high quality in each snapshot but also do not change much between sequential time frames. We re-define the cost of cluster C_i of snapshot S_s in Equation 1 as follows:

$$TCost_{VQE_i} = (1 - \alpha)Cost_{VQE_i} + \alpha Hist(C_i, S_{s-1}) \quad (4)$$

where $Hist(C_i, S_{s-1})$ is the historical cost of cluster C_i between two snapshots S_s and S_{s-1} and α is a regulation factor to balance the current clustering quality and the historical cost. We define the historical cost as follows:

$$Hist(C_i, S_{s-1}) = (c_i - \psi(C_i, S_{s-1}))^2 \quad (5)$$

where $\psi(C_i, S_{s-1})$ returns the closest cluster center to C_i in snapshot S_{s-1} . Taking the derivation of (4) as in (1), we have $C_i = \frac{(1-\alpha)A + \alpha\psi(C_i, S_{s-1})}{(1-\alpha)B + \alpha}$, where A and B are respectively the numerator and the denominator given in Equation 1.

Constraint propagation. Whenever we have a new constraint (x, y, w_{xy}) in snapshot S_s , we propagate it to snapshots $S_{s'}$ where $s' > s$ if $x, y \in S_{s'}$. The intuition is that if x and y are linked (either by must or cannot-link) in S_s , they are more likely to be linked in $S_{s'}$. Thus we add the constraint (x, y, w'_{xy}) to $S_{s'}$ where:

$$w'_{xy} = w_{xy} \frac{te_s - ts_{s'}}{te_{s'} - ts_s} \quad (6)$$

where $(te_s - ts_{s'}) / (te_{s'} - ts_s)$ is a time fading factor. This scheme helps to increase the clustering quality by putting more constraints into the clustering algorithm like the inheritance scheme.

Complexity analysis. Let n be the number of objects. Both CVQE+ and Border have linear time complexity to $O(n)$.

4 EXPERIMENTS

Experiments are conducted on a workstation with 4.0Ghz CPU and 32GB RAM using Java. We use 6 datasets Iris, Ecoli, Seeds, Libras, Optdigits and Wdbc acquired from the UCI archives¹. The numbers of clusters k are acquired from the ground truths. We use Normalized Mutual Information (NMI) [12] for assessing the clustering quality. All results are averaged over 10 runs.

Performance of CVQE+. Figure 3 shows comparisons among CVQE+ and existing techniques including kMeans, MPCK-Means [2], CVQE [7] and LCVQE [13]. CVQE+ consistently outperforms or acquires comparable results to CVQE and others, especially when the number of constraints is large. This can be explained

¹<http://archive.ics.uci.edu/ml/>

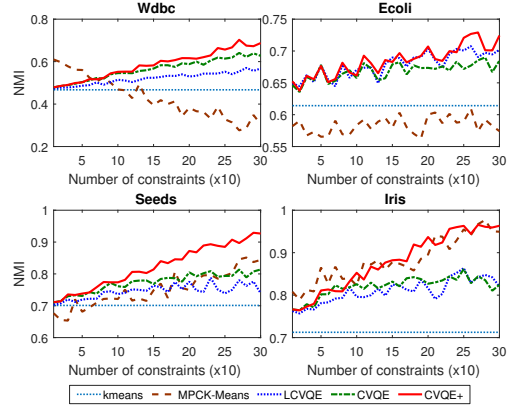

Figure 3: Performance of CVQE+ compared to others

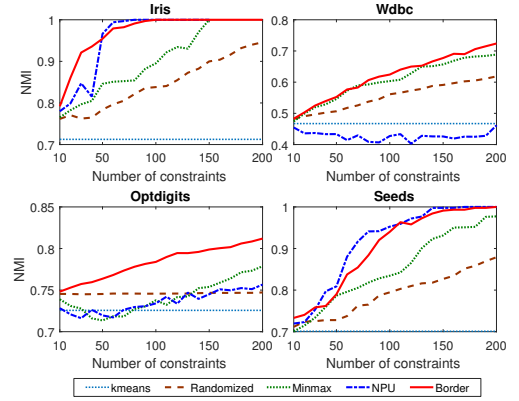

Figure 4: Comparison among different active learning techniques

by the way CVQE+ assigns objects to clusters. Compared to its predecessor algorithm CVQE or LCVQE, it deals well with constraint overlap (constraints that share the same objects), which increases with the number of constraints.

Active constraint selection. Unless otherwise stated, the budget limitation δ is set to 200, the query size $\beta = 10$ and the neighborhood size $\mu = 4$. Figure 4 shows comparisons between Border, NPU [14], Huang [14] (a modified version of [10] for working with non-document data), Min-max [11], Explorer-Consolidate [1], and a randomized method (Huang and Consolidate are removed from Figure 4 for readability). Border acquires better results than others on Libras, Wdbc and Optdigits, comparable results on Iris and Ecoli. For the Seeds dataset, it is outperformed by NPU. The difference is because Border tends to strengthen existing clusters by fortifying both the cluster borders and inter connectivity for groups of objects rather than connecting a single object to existing components like others. However, Border has some parameters to set such as the query size β . Tuning these parameters is a difficult problem that requires deeper investigation.

For runtimes, we create five synthetic datasets of sizes 2000 to 10000 consisting of 5 Gaussian clusters and measure the time for acquiring 100 constraints. Border is orders of magnitude faster than others in selecting pairs to query. For 1000 objects, it takes Border 0.1 seconds while NPU and Min-max need 439.4 and 3.0 seconds. For 10000 objects, Border, NPU and Min-max consumes 0.18, 5216.3 and 18.2 seconds, respectively. Additionally, the higher the number of objects and constraints, the higher the runtime differences. We omit the plots due to space limitations.

Cluster update. Figure 5 shows the NMI and the number of iterations of our algorithm for the Ecoli dataset. The NMI scores

Figure 5: Update vs. fully reclustering for the Ecoli dataset

Figure 6: Temporal clustering on the dataset Optdigits

are comparable, while it takes fewer iterations for our algorithm to converge in its update mode.

Temporal clustering. Figure 6 shows the active temporal clustering results for three snapshots of the Optdigits dataset (we set $\alpha = 0.5$). As we see, our active learning scheme can help boost clustering quality inside each snapshot compared to the original kMeans or a randomized constraint selection method. With the constraint propagation scheme (Border-Propagation), the clustering results are further boosted compared to Border. Since we only consider forward propagation, the clustering result in Snapshot 3 will be more affected than Snapshot 2 and Snapshot 1. We can easily extend the algorithm for the backward propagation case.

5 RELATED WORK

Constraint clustering. There are many proposed constrained clustering algorithms such as MPC-kMeans [2], CVQE [7] and LCVQE [13]. These techniques optimize an objective function consisting of the clustering quality and the constraint violation cost like our algorithm CVQE+. CVQE+ is an extension of CVQE [7], where we extend the cost model to deal with weighted constraints, make the must-link violation cost symmetric and change the way each constraint is assigned to clusters by considering all of its related constraints. This makes cluster assignment more stable, thus enhancing the clustering quality. Interested readers are referred to [6] for a comprehensive survey on constrained clustering methods.

Active learning. Most existing techniques employ *active learning* for acquiring a desired constraints set before or during clustering. In [1], the authors introduce the Explorer-Consolidating algorithm to select constraints by exploiting the connected-components of must-link ones. Min-max [11] extends the Consolidation phase of [1] by querying most uncertain objects rather than randomly selecting them. These techniques produce constraints sets before clustering. Thus, they cannot exploit the cluster labels for further enhancing performance. Huang et al. [10] introduce a framework that iteratively generates constraints and updates clustering results until a query budget is reached. However, it is limited to a probabilistic document clustering algorithm. NPU [14] also uses connected-components of must-link constraints as a guideline for finding most uncertain objects. Constraints are then collected by querying these objects again existing connected components like the Consolidate phase of [1]. Though more effective than pre-selection ones, these techniques typically have a quadratic runtime which makes them infeasible to cope

with large datasets like Border. Moreover, Border relies on border objects around clusters to build constraints rather than must-link graphs [1, 14]. The inheritance approach is closely related to the constraint propagation in the multi-view clustering algorithm [9] for transferring constraints among different views. The major difference is that we use the μ -nearest neighbors rather than the ϵ -neighborhoods which is limited to Gaussian clusters and can lead to an excessive number of constraints.

Temporal clustering. Temporal smoothness has been introduced in the evolution framework [3] for making clustering results stable w.r.t. the time. We significantly extend this framework by incorporating instance-level constraints, active query selections and constraint propagation for further improving clustering quality while minimizing constraint annotation effort.

6 CONCLUSION

We introduce a scalable novel framework which incorporates an iterative active learning scheme, instance-level and temporal smoothness constraints for coping with large temporal data. Experiments show that our constrained clustering algorithm, CVQE+, performs better than existing techniques such as CVQE [7], LCVQE [13] and MPC-kMeans [1]. By exploring border objects and propagating constraints via nearest neighbors, our active learning algorithm, Border, results in good clustering results with much smaller constraint sets compared to other methods such as NPU [14] and Min-max [11]. Moreover, it is orders of magnitude faster making it possible to cope with large datasets. Finally, we revisit our approach in the context of evolutionary clustering adding a temporal smoothness constraint and a time-fading factor to our constraint propagation among different data snapshots. Our future work aims at providing more expressive support for user feedback. We are currently using our framework to track group evolution of our patient data with sleeping disorder symptoms.

ABSTRACT

Skipping mechanisms have been extensively studied to improve query performance over large data volumes. A powerful skipping technique for in-memory columnar databases is partition elimination. The goal is to eliminate, as much as possible, *loading* physically partitioned data into memory and *probing* column partitions against queries. This is achieved by consulting column partition summaries. The summary is often very compact compared to the column partition itself, and is kept in memory, e.g. the MINMAX zone map. These summaries have been extensively integrated into modern in-memory database systems including SAP HANA [6]. In this paper, we argue that probing by MINMAX range is not efficient when there are gaps in the values that appear in a column partition. Any predicate that needs to probe values in a gap inside a MINMAX range naturally ends up requiring a candidate check; this reduces the benefits of column partition pruning. To address this problem, we propose a mechanism to encode each partition (likewise, query) using global ranges, carefully designed to reduce false positive rates. Our approach not only provides a compact in-memory representation, but also supports efficient partition pruning using bitwise operations. Compared to MINMAX, our experiments support that our approach significantly reduces the false positive rate. It can allocate memory budget among ranges in partition groups, based on column density, estimated false positive rates from recent workload, and gaps.

1 INTRODUCTION

Partition elimination is a powerful technique to improve query performance over large volume of data [1, 4, 6, 8, 9]. To increase parallelism and achieve operational scalability, physical partitioning is often employed to divide data into independent partitions. This is done to eliminate loading partitions, and probing them against the query, when partitions to access can be inferred explicitly from the query itself. For an in-memory database, this can prevent unnecessary loads of cold partitions (better memory utilization) and can bring significant performance improvement [6]. Small materialized aggregates for partitions, e.g. the MINMAX synopsis, are small memory footprint objects that are good candidate for partition examination [5, 6]. If the predicate range of a query does not intersect with the partitions's MINMAX synopsis, then it is safe to skip the column partition without incurring false negative. Pruning by partition synopsis is effective if:

- it causes no false negative (i.e. synopsis freshness [6]), and
- it minimizes the need for redundant partition examination.

This paper considers the second synopsis requirement.

2 MOTIVATION: THE LIMITATIONS OF MINMAX SYNOPSIS FOR SPARSE DATA

MINMAX synopsis has high false positive rate for sparse partitions [7]. If the synopsis of a column partition includes data points within its min-max range that do not actually exist in the column partition, pruning by MINMAX can yield false positive. This can happen when the column partition has gaps or values from a sparse distribution. For example, for a table storing the prices of an item over the years, there are usually some gaps in the price column. Although the price is expected to increase monotonically over time, it often does not increase by smallest price unit, and naturally some gaps are present. A natural improvement of the MINMAX synopsis is to store several ranges for each column partition. This way, some gaps can be excluded from the column partition representation. However, this approach has two limitations. First, it requires storing a number of value pairs for each partition. This is space-consuming as we usually have thousands of partitions. Second, processing predicates against this extended synopsis becomes very expensive; for each partition it requires comparison against ranges that represent the partition.

3 OVERVIEW OF OUR CONTRIBUTIONS

To address the two limitations stated in Sec. 2, we propose a new list-based structure called the Global Range Table (GRT). This structure helps to construct compact synopses for single column partitions, which supports efficient partition pruning using bitwise operations. Fundamentally, the pruning approach is very similar to the MINMAX synopsis [6] and to the Adaptive Range Filters [1] in that we use value ranges to determine whether to access each partition. The key properties of our ranges are:

- (1) We construct the list of value ranges that is common across all the partitions. This facilitates probing queries against synopsis using bitwise operations, and
- (2) We incorporate recent workload knowledge into our range extraction algorithm. This is motivated by the observation that frequently-accessed values can suffer more from false positives than rarely-accessed values, if the workload characteristics does not change significantly.

We use the extracted GRT to encode column partitions; each bit of the compact encoding indicates whether the corresponding column partition contains some values within the respective GRT range. The GRT ranges can be improved to have small false positive rates, based on the knowledge learned from recent workload and the importance of value ranges. We use the same encoding approach to represent each query as a bit string. This facilitates efficient query probing on partitions. Furthermore, storing only one GRT global to all partitions in memory is much cheaper, compared to storing multiple value ranges per partition. Finally, the amortized space overhead of our approach is one compressible bit string per partition. We propose algorithms to further reduce this overhead, when the memory budget to store partition synopsis is limited (Sec. 4.2.2).

Figure 1: Encoding column partitions using Global Range Table

Table 1: List of Notations

Notation	Description
V	The universe set of column values
$C[v]$	The popularity of column value v (Sec. 4.1)
N_p	The total number of partitions
N_V^p	The total number of distinct values on the column in partition p
k	The maximum number of sub-partitions for each partition
N_R	The number of ranges in rGRT (Sec. 4.2)
m	The desired number of final GRT (i.e. the length of each encoded bit string)

4 DEEP DIVE: GLOBAL RANGE ENCODING

We demonstrate pruning by Global Range Table (GRT) using an example. Table 1 summarizes the notations used in this section.

EXAMPLE 4.1. *The table shown in Fig. 1a has two columns, Age and Income. This table is divided into three partitions based on the Age attribute (Fig. 1b). The list of ranges in Fig. 1c defines 5 mutually exclusive Income ranges. Using these Income ranges, each of the three Income column partitions in Fig. 1a can be encoded using a bit strings of length 5 in Fig. 1b. For instance, the Income column for partition P₃ is encoded as 10000. This is because this partition only contains values 15 and 16, which fall in the range [15-16] of the GRT table in Fig. 1c. As range [15-16] has index 5, only the fifth bit is set. Now consider the query $\text{Income} \leq 12$. This query intersects with three ranges from the GRT, namely [1-3], [5-9], and [11-12]. Therefore, the query can be encoded as 00111. Comparing the bit string of the query with that of the encoding column in Fig. 1c, one can verify that $00111 \wedge 10000 = 00000$, hence partition P₃ can be pruned safely. The bit string encoding preserves more gap information, compared with MINMAX, e.g. encoding P₁ as [1-13] implies that [11-12] is included. The bit string excludes this range.*

Conceptually, the global range table is a set of ranges on column partitions. The extraction of these ranges can be performed in either a single-phase process from all column partitions at once, or in a two-phase process by integrating the ranges from partitions. The two-phase approach has several advantages:

- **Memory consumption:** the single phase approach requires every column partition to be loaded into memory. The alternative way reduces the memory footprint by integrating ranges extracted from independent partitions.
- **Performance enhancement:** the two-phase approach can be implemented within the MAPREDUCE framework, with the MAP phase applied to independent partitions (Sec. 4.1) and the REDUCE step to integrate ranges (Sec. 4.2).
- **Capturing gaps:** ranges extracted from all data might not capture gaps inside partitions. Our two-step approach avoids this by regarding gaps in partitions as constraints, penalized in the goodness measure for ranges (Eq. 3).

4.1 The Sub-Partitioning Step

This step produces a set of ranges from each partition. Once the set of all ranges have been created, they will be integrated to construct GRT (Sec. 4.2). Given a set of values V , integer k , and cost function of Eq. 2, the sub-partitioning problem is to find an optimal selection of non-empty subsets S_1, \dots, S_k , s.t. $\cup_{1 \leq i \leq k} S_i = V$. As the order of values is not represented in a set, we re-order the rows in each column partition when extracting ranges and consider subsets with consecutive members. That leads to a simplified problem: given an ordered list of values V , we find the optimal k mutually exclusive sub-lists $V_1 = V[1 : i_1], \dots, V_k = V[1 + i_{k-1} : i_k]$, with $i_1 \leq j \leq k$ being indices of sorted value list.

4.1.1 *Sub-Partitioning Cost Model.* A column value is popular if it can satisfy a large fraction of queries in the recent workload¹. The more query predicates a value can satisfy, the higher its popularity ranking is. For example, suppose we have two predicates $1 \leq x \leq 5$ and $4 \leq x \leq 10$ on an integer column. Values 4 and 5 can satisfy both predicates while the other values between 1 to 10 satisfy only one predicate each. In this case, 4 and 5 are more popular than 1,2,3,6-10. Let $|Pred|$ denote the total number of predicates in the workload and let V be the set of column values. We define the popularity of a column value $v \in V$ (denoted by $C[v]$) to be the ratio of predicates from the recent workload satisfied by v . $C[v]$ is between 0 and 1, inclusive. A value is popular if it satisfies many predicates. If a popular value is in a gap within a partition, a query for this value returns nothing². Thus, we observe that the probability of false positives depends directly on the popularity of the value(s) in gaps. Let G be a gap and V_G be the set of values included in G . We define the cost of gap for G to be the sum of the popularities of the values it contains:

$$\text{Cost}(G) = \sum_{v \in V_G} C[v]. \quad (1)$$

For each sub-partition s , let V_G^s be the set of values of the gaps that are included in s . If a popular value $v \in V_G^s$ (i.e. v does not exist in sub-partition s), then those predicates that v satisfies will cause false positives on the partition to which sub-partition s belongs. The reason is that the sub-partition value range will indicate the existence of v , but it is not true (i.e. false positive). Therefore, the sub-partitioning cost of a partition is the sum of gap costs included in any created sub-partition. Let Sub_p be the set of sub-partitions in the partition p . Then,

$$\text{SubCost}(P) = \sum_{s \in \text{Sub}_p} \sum_{v \in V_G^s} C[v]. \quad (2)$$

This measure gives the likelihood that the sub-partitioning scheme will create false positives for a partition, for values that do not actually exist in the partition. Thus, creating sub-partition value ranges that include popular gaps yields a high false positive rate. Intuitively, the lower the cost is, the better the sub-partitioning scheme is. When the cost is 0, that means there is no sub-partition that produces false positives on any predicate. Thus, we would like to minimize this measure. To normalize this cost, we divide it by the maximum number of possible distinct values that the partition can take. To summarize, the normalized cost penalizes gaps that cause false positives in a set of ranges extracted from each partition. The ranges are extracted via sub-partitioning.

¹We base our approach on *predicate stability*, i.e. popular column values continue to satisfy many predicates in future queries. If predicates are not stable, our approach will remain valid but sub-optimal considering the false positive rates.

²However, a MINMAX synopsis would incur false positive on this gap.

4.1.2 The Largest Gap Greedy Algorithm. Sub-partitions with fewer gaps reduce the cost of the ranges extracted from each partition. Therefore, if we exclude popular gaps from each sub-partition, the cost would be toward optimal. The main idea of our greedy algorithm is to find top $(k-1)$ popular gaps. We use a min-heap to keep track of the top $(k-1)$ popular gaps (i.e. with largest costs). For each node of the min-heap, we keep the gap cost (i.e. Eq. 1; the gap popularity) and the index of the gap. The index of the gap is defined as the identifier of the value immediately before the gap. The min-heap property is maintained with respect to the costs stored in nodes. We go through the sorted list of distinct values of the partition and manage the top $(k-1)$ popular gaps as well as the indices of those gaps in the heap. At the end, the indices determine sub-partition boundaries. At the beginning, there are $N_V^p - 1$ candidate boundary points in partition p with N_V^p distinct values. Our algorithm selects $(k-1)$ positions to minimize the sum of the costs of sub-partitions (i.e. Eq. 2) in $O(N_V^p \log k)$ time. We omit algorithm detail and proofs for brevity.

4.2 Extracting GRT And Optimizations

The sub-partitioning step produces k value ranges per partition. Integrating at most kN_p ranges into a single list may have overlapping ranges, as well as duplicates. In this step, a value-range list global to all partitions is produced, with the primary goal to reduce false positive rates. To achieve this, we extend Eq. 2 to quantify the quality of a global range table GRT, as opposed to one partition:

$$\text{Cost}(GRT) = \sum_{r \in GRT} \sum_p \left(C[v] : v \in V_G^p \cap r \text{ s.t. } V_G^p \cap r \neq r \right). \quad (3)$$

We first integrate kN_p ranges (k ranges for N_p partitions) into one list, and call this rGRT (for raw GRT). We refine rGRT in two steps. First, we remove duplicate ranges and value range overlaps (Sec. 4.2.1). Then, for a given a memory budget, we show how to merge ranges effectively and derive a reduced list (Sec. 4.2.2).

4.2.1 Mutually Exclusive GRT. Starting from rGRT, the goal is to make every pair of ranges mutually exclusive. For this, we propose an approach based on the greedy algorithm proposed for the interval scheduling problem [3], where the range with smallest endpoint from the list is picked and inserted into the result list, if it does not intersect with any other ranges already in the result list. The range is discarded if it is in conflict with at least one range in the result list (i.e. cannot be scheduled together). In our approach, whenever the value range overlaps with some value range already in the result list, we split the to-be-inserted range into smaller ranges instead of discarding it. Each smaller range is either mutually exclusive or a duplicate (i.e. already completely covered) of the ranges in the result list. Then, we discard those duplicates and insert the others. For example, assume that we want to insert value range [2-18] to the list of ranges $R = \{[1-4], [7-10], [15-16]\}$. In our approach, we split [2-18] into six smaller ranges: [2-4], [5-6], [7-10], [11-14], [15-16], and [17-18]. This is done based on the overlap of [2-18] with the ranges in R . We process each sub-range separately. Because [2-4], [7-10], and [15-16] are already present in the result list, we discard them and insert [5-6], [11-14], and [17-18]. We iterate this split-and-insert process for every range in rGRT and obtain a mutually exclusive global range table (xGRT) in time linear to the number of ranges in rGRT. In this process, the ranges are refined and Eq. 3 reduces, but the number of ranges grows. This increases the number of bits needed to encode each partition.

4.2.2 Greedy Merge Algorithm. A synopsis is expected to have a small memory footprint. We propose a greedy algorithm to merge ranges and reduce the size of xGRT while keeping the GRT cost low. Merging t ranges R_1, \dots, R_t has two overheads: the extra range cost³ and the cost of the newly introduced gaps.

EXAMPLE 4.2. Suppose partition $P = \{1, 3, 6, 8, 9, 13\}$ and a given xGRT. Suppose we select two ranges [8-9] and [11-12] to merge, and let [11-12] be a range from another partition. The ranges [8-9] and [11-12] would merge into [8-12]. After this merge, the popularities of value 11 and 12 contribute to the GRT cost against partition P while it would not before. This is the extra cost of the range [11-12]. Before merging, the query $11 \leq x \leq 12$ would not have any match on this partition since the GRT would tell that this partition has no match. However, after merging, the GRT would suggest to load the partition since this partition has data within [8-12]. Because there is a gap between the two ranges (i.e. value 10 is missing), the cost of the gap contributes to the extra cost of merging, which comes from the popularities of 10, 11, and 12.

The greedy merge algorithm must maintain cost matrix EC , with $EC_{i,j}$ being the extra cost of merging ranges r_i, \dots, r_j in xGRT. After merging ranges r_u, \dots, r_v , all entries at row v or column v are invalidated, and every entry $EC_{i,j}$ at row u or column u must be recomputed. We continue picking the lowest extra cost and updating EC , until only m ranges remain. However, we notice that if a larger merging fully contains a smaller one, then it is guaranteed that the smaller merging has a lower (or equal) cost than the larger one since the extra-cost is non-negative. Therefore, we simplify the algorithm to use a 1-dimensional list of extra-cost, with EC having $N_R - 1$ entries. In this case, EC_i denotes the extra-cost of merging the i -th range with the next one in xGRT. At each iteration of the algorithm, we pick the lowest extra-cost, EC_u , and merge the u^{th} range with the $(u+1)^{th}$ range and update EC : we invalidate EC_{u+1} and range $(u+1)$ in xGRT. If EC_u is the last entry, then EC_u itself is invalidated. On the other hand, we at most need to update two entries of EC . If EC_u is not the first or the last entry, we re-calculate EC_{u-1} and EC_u using the updated xGRT. Note that EC_u now stores the extra-cost of merging the u^{th} and $(u+2)^{th}$ ranges as the $(u+1)^{th}$ entry has been invalidated. If EC_u is the first (the last) entry, then we only re-calculate EC_u (EC_{u-1}). We iterate until only m ranges remain. We name the result list cGRT (for compact GRT). Our algorithm takes $O((kN_p - m)N_p \log(kN_p))$ time to find cGRT.

4.3 Partition Encoding and Elimination

Encoding partitions. Once the GRT is constructed with m mutually exclusive ranges, each column partition can be encoded using a bit string of length m . The bit i is 1 if and only if the partition has at least one value within the value range r_i in the GRT. This is a pre-processing step. For each partition, the encoded bit string serves as its compact synopsis, which is kept in memory.

Encoding query. At query processing time, each query is encoded as a bit string. The i -th bit is set to one if at least one value in the range r_i of the GRT satisfies the query predicate.

Partition pruning. The encoded query is compared against the encoded bit string for each partition, using bitwise AND operation. If the result bit string has at least one set bit, there might be some value(s) in the corresponding partition that satisfy the query predicate. Otherwise, no record in the partition will satisfy the query predicate, and the partition can be safely pruned.

³I.e. the range cost of merging R_1, \dots, R_t but excluding R_t .

Figure 2: Experiments on 1M rows

5 EXPERIMENTAL EVALUATIONS

We conducted experiments on a machine with Intel Core i7-4770 CPU. The dataset is from a real SAP application. We range-partitioned the table based on a date column, and extracted synopsis (MINMAX or GRT based) from the document identifier (SAP UUID) of each partition. The distribution of values in this column was sparse with many gaps. Fig. 2a compares GRT encoding with MINMAX based on the ratio of gaps preserved. For each column partition, the measure quantifies the ratio of values in column partition’s MINMAX range, that 1) do *not* appear in the column partition, and 2) can be excluded using the column synopsis. This ratio is between 0 and 1, with larger value more desirable; it indicates better pruning. This measure is zero for MINMAX; none of the values appearing in a column partition gap can be excluded by the minimum and the maximum range. The memory overhead for MINMAX for each partition is a pair of minimum and maximum values. For GRT based encoding, the memory overhead is one bit string per partition, plus one global range table for all partitions. Note that we need to have values (i.e. value pairs for MINMAX and value ranges in GRT) in memory, instead of dictionary value identifiers. This is mainly because the pruning is performed without accessing each column and its data structures (i.e. encoded data vector and dictionary).

Using GRT based encoding (Sec. 4.2.2), one can preserve more gaps as “zero” bits of the synopses to demonstrate values in the gap that are not included in a partition. The number of gaps preserved decreases when the number of bits dedicated to each synopsis reduces; merging GRT ranges produce wider the ranges in the target GRT table. This reduces the number of zeros as well as pruning opportunity. Fig. 2b reports the normalized GRT cost for no merge (xGRT of Sec. 4.2.1) and cGRT (Sec. 4.2.2). With reduction in the number of bits, the overhead of merge is observed as increase in the normalized GRT cost and in the construction time (Fig. 2c). For both xGRT and merged GRT, the normalized GRT cost decreases when the dataset size increases (Fig. 3a,b). The reason is that partitions become larger and the number or the size of gaps reduces in each partition. Therefore, the number of split ranges in xGRT decreases. Consequently, the time spent to merge these ranges reduces.

(a) Normalized GRT cost, varying the number or rows

(b) GRT construction time (seconds), varying the number or rows

6 CONCLUSION AND FUTURE WORK

We introduced GRT, a compact data structure to achieve partition pruning. GRT is a list of ranges which we use to encode partitions and predicates. Bit string encoding is compact (compared to original partitions) and can be used for efficient partition elimination. This encoding is superior to MINMAX zone maps. In particular, when the distribution of values in column partitions is sparse and value gaps appear, pruning by MINMAX becomes less effective; false positives demand for extra candidate check [7]. Encoding partitions using global range tables, as opposed to local range tables optimized per partition (e.g. [9]), has the advantage that partition elimination can be performed without re-encoding the query per partition. Our results confirm the effectiveness of our approach, in preserving gap information. We studied the application of GRT in the context of query processing on cold partitions. However, its application can be extended to other use cases, e.g. semi-join reduction and enforcing the uniqueness constraint. Our encoding is reminiscent of Bloom filters [2]; we set bits using a global range table common to all partitions, to assist point and range queries. Designing GRT to offer bounds on false positive rates is an interesting future research direction. We plan to assign different sub-partitioning quota for dense vs. sparse partitions (non-homogeneous sub-partitioning). Sparse partitions should receive more encoding space than dense and uniform partitions, to reduce false positive rates.

ABSTRACT

Modern persistent Key/Value stores are designed to meet the demand for high transactional throughput and high data-ingestion rates. Still, they rely on backwards-compatible storage stack and abstractions to ease space management, foster seamless proliferation and system integration. Their dependence on the traditional I/O stack has negative impact on performance, causes unacceptably high write-amplification, and limits the storage longevity.

In the present paper we present NoFTL-KV, an approach that results in a lean I/O stack, integrating physical storage management natively in the Key/Value store. NoFTL-KV eliminates backwards compatibility, allowing the Key/Value store to directly consume the characteristics of modern storage technologies. NoFTL-KV is implemented under RocksDB. The performance evaluation under LinkBench shows that NoFTL-KV improves transactional throughput by 33%, while response times improve up to 2.3x. Furthermore, NoFTL-KV reduces write-amplification 19x and improves storage longevity by imately the same factor.

1 INTRODUCTION

Over the last decade, various specialized DBMSs have been intensively investigated to meet the demand of new workloads, applications or data models. Persistent Key/Value stores (KV-stores) are specialized for high-throughput and predominantly update-intensive, OLTP-style workloads.

KV-stores exhibit a characteristic *lightweight architecture*, simplifying the deployment and integration process for large infrastructures and lowering maintenance demand in production. *Scalability* is intrinsically supported in terms of partitioning and distribution schemes, making KV-stores an excellent choice for current data-center architectures. The *simplicity* of their interface (with *put* and *get*) as well as data model matches wide range of modern insert and update intensive applications running high-throughput OLTP-style workloads. Last but not least, the ability to *serve as DB-Engines* in traditional and modern NoSQL databases (e.g. MyRocks[13] or MongoRocks), allows for the *integration* as meta stores into applications and distributed file systems (e.g. Ceph[10]), or serve as a backend for OLTP services.

Persistent KV-stores leverage the properties of modern hardware due to the lean architecture, interface and flexibility, yet native hardware support is rare. The majority of such KV-stores rely on backwards-compatible storage, to ease administration and foster proliferation. Furthermore, the use of file systems simplifies space management, support for various storage architectures and the embedding in existing data center environments. *The underlying assumptions are that: (1) files and file-based I/O are the appropriate storage abstractions, and (2) use of standard/compatibility interfaces (and abstractions) on each individual layer of the I/O stack does not harm performance.*

The traditional I/O stack was developed with the characteristics of HDDs in mind, with the block-device interface, block I/O operations and files as abstractions. New storage technologies such as Non-Volatile Memories or Flash exhibit very different characteristics. However, to utilize them, persistent KV-stores require multiple layers of backwards compatibility, having a negative impact on performance and longevity. (1) Hardware resources are not fully exploited because of the hardware-oblivious abstractions. (2) DBMS access patterns result in suboptimal physical I/O patterns due to the presence of multiple abstraction layers along the critical I/O path. (3) KV-store information about the current workload cannot be used for better physical data placement. (4) Functionality along this critical I/O path is redundant. Significant write-amplification and suboptimal performance are the inevitable consequences.

Figure 1: Write-Amplification along a traditional I/O stack in contrast to NoFTL-KV.

To verify the above claims we perform an experiment under RocksDB running LinkBench and measure the end-to-end write-amplification along a backwards-compatible, file-system based stack. The results (Fig. 2a) indicate a 19x physical write volume increase, lower performance and longevity.

In this paper we present NoFTL-KV (Fig. 1), an approach that avoids backwards compatibility and targets the above disadvantages by controlling the underlying physical storage directly. NoFTL-KV integrates physical storage (Flash) management natively in the KV-store. Subsequently, it opens up ways for workload adaptability within the storage layer and new abstractions for native storage.

The main contributions of this paper are:

- (1) The extension of the concept of native storage management (NoFTL) to persistent KV-stores. We show that by coherently integrating address mapping, data placement, GC and free space management into the KV-store, storage characteristics, on-device parallelism and wear-leveling are addressed.
- (2) NoFTL-KV is implemented under RocksDB.
- (3) The performance evaluation under LinkBench[1] shows that NoFTL-KV improves the transactional throughput by 33%, while the response times improve up to 2.3x. Furthermore, NoFTL-KV improves physical storage management. In terms of *write efficiency*, NoFTL-KV performs 87% less physical page writes (including maintenance I/O and GC). Moreover, NoFTL-KV performs 19x less erases, improving the endurance by approximately the same factor.

The rest of the paper is structured as follows. NoFTL-KV and the integration into RocksDB are described in Section 3. Experimental results are discussed in Section 4. We conclude in Section 5.

2 RELATED WORK

Modern workloads (Social Media, Big Data or IoT) not only have become write-intensive and require high sequential throughput, but also demand low latencies [16]. *Read- and Write-Amplification* are major performance factors [16].

These can either be approached by utilising compression to decrease I/O in general [5] or by aligning better with the characteristics of modern storage devices. The latter is addressed in terms of either new data structures [3, 4, 19], or new software interfaces [2] as well as Flash interface extensions [9, 12, 14]. However, neither of those takes the issues with the *cooked stack* into account. [6] and [7] present a full integration of native storage support within traditional DBMS. A few lightweight KV-stores address the concept of direct native storage integration [8, 15, 17, 18] by moving the entire KV-store onto the device. Yet, physical storage management is only partially addressed.

With NoFTL-KV we address the deep integration of native storage management to tackle all issues regarding the traditional cooked stack while avoiding to overload the device controller with database functionality and maintaining a mature KV-store.

3 NOFTL-KV: NATIVE STORAGE KV-STORE

We investigate the concept of native storage management and NoFTL under persistent KV-stores to address and evaluate the above mentioned claims. RocksDB exhibits an append-only I/O pattern for various write-intensive workloads, because of its LSM-Tree-based persistent storage. LSM-trees perform regular compactions to remove old records, to ensure optimal tree structure and to perform hot-cold-separation. Compactions reorganize

levels of the LSM-Tree, removing updated or deleted KV-Pairs, at regular intervals or given a certain threshold. As a consequence, frequently changing data is placed in the upper levels of the LSM-Tree, while the lower levels contain the cold data.

Under NoFTL-KV we pursue coherent integration of Flash management into existing modules of the KV-store as shown in Fig. 3. Firstly, NoFTL-KV has direct control over hardware resources through a native storage interface (NSI). NSI allows the DBMS to operate with I/O operations, in granularity and with addressing schemes supported by the underlying storage technology. Furthermore, NSI eliminates the need to support backwards compatibility. Secondly, we revisit hardware-oblivious abstractions and propose using physical storage abstractions such as *Regions* to: (a) reduce read/write amplification along the I/O path, (b) utilize available I/O parallelism more efficiently, (c) provide better hot-cold data separation to (d) improve space management and (e) increase longevity.

Moreover, unnecessary DBMS data transfers can be reduced by pushing tasks down to the storage device. For instance, parts of garbage collection and compaction can be planned by the NoFTL-KV storage manager for certain Regions, but are executed onto the device to reduce I/O contention and data transfers. Likewise, queries, i.e scans, can be pushed down and executed on the storage device. Especially in combination with Regions, such queries can profit by the involved address mapping and level of on-device-parallelism. Also worth to mention is that processors on such storage devices usually exhibits the characteristics of common co-processor (ASIC or FPGA). These are perfectly aligned to the characteristics of modern storage technology (Flash, NVM) e.g. in respect to parallelism.

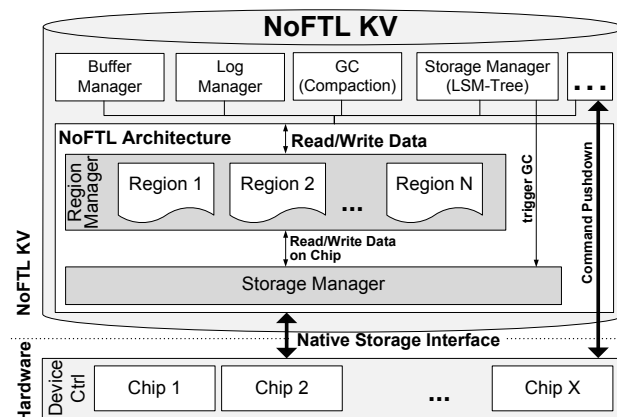

Figure 3: NoFTL-KV: Design of a deep integration of the NoFTL concept within an entire KV-store for native storage management

By integrating address mapping into the storage manager of the KV-store, the latter gets control over the physical data placement on Flash. Hence, the KV-store can utilize available information about data semantics, statistics and the access pattern (e.g., desired level of I/O parallelism) to perform efficient placement. Individual levels of the LSM-Tree can be physically separated on different chips to improve I/O throughput and parallelism since I/O-heavy compaction jobs do not block the entire device. Consequently, new storage abstractions can be defined besides files.

(a) Amount of data written by the DB, FS and FTL during the load and request phases of LinkBench shows the write-amplification of RocksDB in contrast to NoFTL-KV

	NoFTL-KV		RocksDB		Speedup
	Mean	StDev	Mean	StDev	
GC Calls	1	3	4769	2434	
GC Page Write	0	0	1932263	737453	
Block Erase	1127	3564	21389	7792	18.98x

(b) Number of logical page writes of the DB's compaction and physical page writes of the device over 10 request phases demonstrates write-amplification and inconsistent logical to physical page write ratio.

(c) Throughput: The average number of executed operations over the last 7 request phases demonstrates that NoFTL-KV outperforms RocksDB

(d) Response Time (the lower the better): Average operation latencies and std. dev. are better and more stable under NoFTL-KV vs. RocksDB

Figure 2: Results of the experimental evaluation of NoFTL-KV using LinkBench

We introduce *Regions* as physical storage abstractions spanning multiple chips/dies (i.e. parallel unit of the storage device). They can be effectively optimized for different access patterns (sequential, random, append) of various KV-store components (e.g. Levels of LSM-Tree and Log Manager). Regions allow for flexible physical storage management as the parameters of hot-cold data separation, garbage collection etc. are part of the definition. The level of supported I/O parallelism per Region can be defined in terms of the number of chips/dies it spans or whether these run in pseudo SLC, MLC or TLC Flash mode. Region definitions are not static, but can evolve over time to reflect properties of the workload.

```
CREATE REGION rgBlockMapping (
  MAX_CHIPS=4, MAX_CHANNELS=4, ..., ADDR_MAPPING=BLOCK,
  NAND_MODE=MLC, ...);
CREATE TABLESPACE MyRocks.tb1Block (
  REGION=rgBlockMapping, UNIFORM EXTENT SIZE 128K );
CREATE TABLE MyRocks.nodetable(...)
  TABLESPACE MyRocks.tb1Block;
```

Furthermore, the functional redundancy along the *cooked I/O stack* is reduced. While, the file-system and the FTL distort the append-based access pattern and amplify the read/write data volume, NoFTL-KV simplifies the critical I/O path, exhibits a physically sequential I/O pattern, and offers better physical storage management. Consequently, write-amplification is significantly reduced. Similarly, the integration of the garbage collection within the compaction process of the LSM-Tree, allows for

elimination of the time and resource-expensive merges common for traditional FTL-based SSDs. As a result, the KV-store is able to trigger the GC only when necessary and under the current workload. Higher longevity through less block erases and better throughput are the consequence.

4 EXPERIMENTAL EVALUATION

Testbed. Our testbed comprises a server equipped with an Intel Xeon E5-1620 v3 3.50 GHz CPU-core, 32GB RAM and an Intel DC 3600 SSD under Ubuntu 12.04 LTS, kernel 3.13.0.

The Flash storage device for the NoFTL-KV data is emulated by our real-time Flash Simulator[6], which is running as a kernel module. Configured with common latencies for reads, writes, and erases of current SLC NAND Flash it is able to simulate a modern enterprise SSD with either block- or char-device interfaces. For the block device, FASTER[11] is utilised as FTL with an over-provisioning area of 14%. In our setup, the simulator consumes 24 GB of memory to emulate an SSD of the same capacity with 256 pages (4KB) on 24576 blocks. The level of parallelism (emulated NAND chips/dies) is limited by the number of hardware threads. For our experiments we configured NoFTL-KV to only store RocksDB LSM-Tree files on the emulated device and the remaining files on the Intel DC 3600 formatted with an ext4 file system.

LinkBench. The experimental evaluation is performed using LinkBench[1], which is an OLTP-style workload on large updatable graphs. Under LinkBench the working data set size is an order of magnitude larger than the database buffer. The request phase of LinkBench comprises common graph queries like adding, getting, counting, deleting, updating nodes or edges on the graph. The experimental dataset is a graph of 15M nodes (initial), amounting to 15GB raw data. The number of requests and duration vary depending on the experiment. The baseline utilises the same configuration (ext3, 4KB blocksize, active journal) for MyRocks with RocksDB, hereinafter referred to as RocksDB.

Write-Amplification. To measure write amplification, hooks are placed in the storage engine of RocksDB (DB), the file system (FS), and the Flash emulator (FTL), i.e., in all layers along the I/O path. The number of requests is limited to 1M per thread with sufficient time (10h) to be executed completely. This ensures that, at the end, both variants have executed the same number of operations. The results (Fig. 2a) for NoFTL-KV and the baseline RocksDB represent average values of multiple runs.

Not surprisingly, the significant write amplification of the cooked stack becomes evident. The 26 GB of raw data, bulk-loaded during the *load phase*, swells up by more than 14 times to 383 GB. On top of that, the file system adds about 225 GB and the FTL increases this again by 132 GB. During the *request phase*, the disadvantages of the cooked I/O stack become even more visible. The average write-amplification here is more than 19x. This creates enormous I/O overhead, which is clearly reflected by the metrics to follow.

Throughput. The mean number of executed operations and their errors for every operation type is shown in Fig. 2c. NoFTL-KV outperforms RocksDB in every type of query. This is because of the smaller data volume to be written, and the better utilisation of available Flash parallelism. The workload of LinkBench has a high write-intensity over the complete duration. Consequently, the throughput increases about 31% across all operation types. The performance stability across different runs, indicated by the error bars increases by an order of magnitude.

Response Time. To investigate the impact on response time for common operations, we perform further experiments with 1M requests per thread. Fig. 2d shows the average duration, while the error bars indicate the standard deviation.

One can clearly see that the latency is lower under NoFTL-KV. Especially reading operations like *GetNode()*, *GetLinksList()*, and *MultigetLink()* perform significantly better. This is even more relevant, since about 22% of these could not be served by database buffer (cache miss rate) and are read from the persistent device. On the other hand, inserting and updating operations like *AddNode()*, *AddLink()*, and *UpdateLink()* complete directly after pushing the data into an in-memory buffer and the WAL. This buffer is persisted only after a compaction, which is not taken into account for the operation latency. This explains the similar performance for both RocksDB and NoFTL-KV. The only exception is *UpdateNode()*, which might result in multiple gets that are slower with the traditional I/O stack.

Erases and Longevity. Write-amplification on Flash devices inevitably leads to more physical Flash erases, which has negative impact on device longevity. Table 2b captures the GC activity in terms of physical page writes and block erases during the benchmark runs of the previous experiment.

RocksDB performs almost 19 times the physical block erases than NoFTL-KV, which is primarily due to (i) the journal of the file system, which doubles Flash page writes, and (ii) FASTER's

hybrid address mapping scheme. It is worth noting that the erase overhead of FASTER would also be present in other FTLs, which utilize hybrid address translation (common for current SSDs). As soon as the so-called log block area of the device runs out of space, the GC kicks in and merges the updated data with the corresponding Flash blocks in the data block area. Each of those merges requires multiple page migrations (on-device write amplification), and one or two erase operations (partial or full merges). NoFTL-KV is configured to use BLM, which matches the append-only LSM-Tree based storage management of RocksDB.

5 CONCLUSION

In the present paper we propose NoFTL-KV, an approach that results in a lean I/O stack, integrating physical storage management natively in the Key/Value store. NoFTL-KV eliminates backwards compatibility, allowing the Key/Value store to directly exploit the characteristics of modern storage technologies. NoFTL-KV is implemented under RocksDB and evaluated using LinkBench. The transactional throughput improves by 33%, while response times improve up to 2.3x. Furthermore, NoFTL-KV reduces write-amplification 19x and improves endurance. In addition, our current integration on the file-based LSM-Tree can be further improved by a deeper integration into the KV-store's data structure in future work to gain additional performance improvements.

Towards Hypothetical Reasoning Using Distributed Provenance

Daniel Deutch, Yuval Moskovitch, Itay Polack Gadassi and Noam Rinetzky
Tel Aviv University

ABSTRACT

Hypothetical reasoning is the iterative examination of the effect of modifications to the data on the result of some computation or data analysis query. This kind of reasoning is commonly performed by data scientists to gain insights. Previous work has indicated that fine-grained data provenance can be instrumental for the efficient performance of hypothetical reasoning: instead of a costly re-execution of the underlying application, one may assign values to a pre-computed provenance expression. However, current techniques for fine-grained provenance tracking are ill-suited for large-scale data due to the overhead they entail on both execution time and memory consumption.

We outline an approach for hypothetical reasoning for large-scale data. Our key insights are: (i) tracking only relevant parts of the provenance based on an a priori specification of classes of hypothetical scenarios that are of interest and (ii) the distributed tracking of provenance tailored to fit distributed data processing frameworks such as Apache Spark. We also discuss the challenges in both respects and our initial directions for addressing them.

1 INTRODUCTION

Data analytics often involves *hypothetical reasoning*; repeatedly modifying the database according to specific scenarios, and observing the effect of such modifications on the result of some computation. A naive way to perform such an analysis is to create a copy of the data, modify it, and recompute the results for the inspected scenario. However, this approach can be very costly when the computation involves access to large-scale data. A more efficient method is to use *provisioning* [4, 6]: compute a symbolic *provenance expression* (PE) which encodes the result of the computation under any possible scenario. Then, the user interacts with the PE for efficient exploration of the scenarios. Creating the PE incurs a *one-time* overhead over the evaluation of a specific query. However, if the analyst inspects multiple scenarios, the creation of the PE may pay off in an inspection which is orders-of-magnitude more efficient than a naive recomputation.

Example 1.1 (Running example). Consider a database of a telephony company containing the number, name, zip code, and call plan of every customer, the *price per minute* (*ppm*) of every plan, and a log of the duration and date of every call (see Fig. 1). The following query computes the company revenues (this example is inspired by the one used in [6]):

```
SELECT Calls.Mo, SUM(Calls.Dur * Plans.Price)
FROM Calls, Cust, Plans
WHERE Cust.Plan = Plans.Plan
      AND Cust.Num = Calls.Num
GROUP BY Calls.Mo
```

The query computes the monthly revenues by summing the per-call-revenue, computed by multiplying the duration of every call

Cust				Plans	
Num	Name	Zip	Plan	Plan	Price
555-777	Bob	10001	Plan1	Plan1	0.1
555-942	Alice	10002	Plan2	Plan2	0.2
555-465	Dave	10003	Plan2		

Calls					
Num	Mo	Dur	Num	Mo	Dur
555-777	Jan	21	555-942	Feb	33
555-777	Jan	8	555-942	Feb	27
555-777	Jan	14	555-942	Feb	32
555-777	Feb	7	555-942	Feb	16
555-777	Feb	17	555-465	Jan	9
555-777	Feb	33	555-465	Jan	7
555-942	Jan	28	555-465	Jan	8
555-942	Jan	20	555-465	Feb	33
555-942	Jan	23	555-465	Feb	14
555-942	Jan	21	555-465	Feb	12

Figure 1: Example database

by the *ppm* of the customer’s plan and grouped by month. An analyst may be interested in the effect of possible changes to the call price on the company revenues. For example, the analyst may wish to compute the revenues under (some combination of) the following hypothetical scenarios:

- HS1 What if the *ppm* is decreased by 10% in calling plan 1 and set to \$0.3 in calling plan 2?
- HS2 What if all the customers with vanity phone numbers were subscribed to plan 1?
- HS3 What if the *ppm* for costumers in Boston is set to \$0.3?
- HS4 What if a 25% discount is given to calls which took less than ten minutes?

Computing a PE for the query of Example 1.1 and the scenario HS1 is relatively straightforward for small-scale data [4, 6] (see Section 2.1). Scenario HS2 is more challenging, since it involves changes to the parts of data that is in a comparison in the query. This may be handled in a c-table-like construction as mentioned in [6] (see Section 2.2). The two other scenarios involve changes that may not be directly applied to input data, but rather only to some views over it; we discuss the semantics of such scenarios and the questions that arise in Section 2.3. Further, for all scenarios, there is the concern of space and time overhead incurred by provenance tracking. We propose distributed provenance representations to address this, in Section 3. Specifically, we present two different methods for representing fine-grained provenance in a distributed manner: a *combined representation* that stores each polynomial as a single tuple in the output table comprised of a collection of monomials, and a *separated representation* that stores separately each monomial. Our preliminary results, based on an implementation in *Apache Spark* [12, 14, 15], indicate that the combined approach allows for more efficient exploration, provided that the provenance expression is relatively small, while the separated approach scales better as it is more suitable to the

distributed model, however it incurs a non-negligible overhead over the combined approach where the latter can be used.

Related Work. Data provenance has been studied for different data transformation languages, from relational algebra to Nested Relational Calculus, with different provenance models and applications and with different means for efficient storage. Particularly relevant are systems that support provenance for distributed systems [3, 5, 9, 11, 13]. We note that the Spark framework already supports a provenance-like logging mechanism that allows for fault tolerance. Unlike those existing works, we focus on cell-based provenance, where polynomials replace individual values, which is necessary for answering what-if questions. The use of data provenance for hypothetical reasoning has also been studied in e.g., [4, 6, 7], but without targeting big data and addressing the scalability issues that consequently arise.

2 PROVISIONING IN A NUTSHELL

Provisioning, i.e., *hypothetical reasoning* using provenance, is a two step process: First, the analyst *parameterizes* some entries in the input database. Then, she explores the effect of hypothetical modifications by instantiating the parametrized entries with specific values [4, 6]. Technically, parametrization entails instrumenting entries using *symbolic variables*, e.g., by (symbolically) adding or multiplying them with the original numerical values. When the provisioning engine runs an SQL query, it treats the parameterized entries in a symbolic way, and creates a *provenance expression* (PE); an *output table* which may contain symbolic values. The symbolic representation allows the analyst to explore multiple scenarios by *evaluating* the PE using a specific *assignments of concrete values* to symbolic variables. Different types of scenarios lead to different challenges as we next explain.

2.1 Basic Provisioning

We start with the case where the parametrization involves a single table and the program does not perform selection or join over parameterized attributes. In this case, the semantics of provisioning is fairly straightforward. First, the parameterized data entries are annotated with variables which, roughly speaking, replace every parameterized data by a *multivariate polynomial*. Second, a query Q is executed according to its standard semantics except that summations and multiplications are executed symbolically to produce polynomials instead of concrete values. As for aggregation, we simply combine the polynomials in the provisioned attributes using a symbolic plus (+) operator. The analyst uses the generated provenance expression to explore a specific scenario by providing an *assignment* ρ which defines a (concrete) valuation for each symbolic variable and computing the value of the polynomial under ρ . It is straightforward to observe that this computation produces the same results as the re-execution of Q on a correspondingly modified database.

Example 2.1. Reconsider our running example query and scenario HS1 from the Introduction. To generate a PE for them (where we wish to support a generalized version of HS1), we first parameterize the input database as shown in the Plans table of Figure 3. In this example, the price for plan 1 is multiplied by a variable p_1 and the price for plan 2 is both multiplied by a variable p_2 and added a variable s_2 , the latter allowing for its replacement by a different value. Evaluating the running example query using these symbolic values results in the output table and provisioning expressions shown in Figure 2.

Provenance expression		Output	
Mo	Revenues	Mo	Rev.
Jan	$43 \cdot (0.1 \cdot p_1) + 116 \cdot (0.2 \cdot p_2 + s_2)$	Jan	38.67
Feb	$57 \cdot (0.1 \cdot p_1) + 167 \cdot (0.2 \cdot p_2 + s_2)$	Feb	55.23

Figure 2: A PE and the results of its evaluation according to scenario HS1 (i.e., $\rho = [p_1 \mapsto 0.9, p_2 \mapsto 0, s_2 \mapsto 0.3]$)

2.2 Conditional Provisioning

Hypothetical scenario HS2 in Example 1.1 is a particular member in a family of scenarios which enable computing the company’s monthly revenues under different reassignments of customers to plans. A PE which allows inspecting the scenarios in this family can be generated by the techniques of [4, 6]. In our example, this entails parameterizing the Plan attribute in table Cust by replacing its content in every entry by a customer-unique symbolic variable, and then representing the join of Cust and Plans over the parameterized attribute using a c-table [10].

Example 2.2. Reconsider Figure 3, and now note that the Cust table is also parameterized, adding the parameters n_{777} , n_{942} and n_{465} for HS2. Each of these may be assigned to Plan1 or Plan2. The resulting PE for January in this example is

$$43 \cdot (0.1 \cdot p_1) \cdot [n_{777} = \text{Plan1}] + 43 \cdot (0.2 \cdot p_2 + s_2) \cdot [n_{777} = \text{Plan2}] + 92 \cdot (0.1 \cdot p_1) \cdot [n_{942} = \text{Plan1}] + 92 \cdot (0.2 \cdot p_2 + s_2) \cdot [n_{942} = \text{Plan2}] + 24 \cdot (0.1 \cdot p_1) \cdot [n_{465} = \text{Plan1}] + 24 \cdot (0.2 \cdot p_2 + s_2) \cdot [n_{465} = \text{Plan2}]$$

Expressions in brackets are mapped to 1 or 0 based on their truth value upon assignment of values to the variables. If we are still interested in exploring HS1, we simply assign to the n variables their original values, and proceed to assigning the other variables as in the previous example. But we can also, e.g., assign Plan2 to n_{777} , intuitively switching the plan of Bob to be Plan2; then the expression $[n_{777} = \text{Plan1}]$ is evaluated to 0 and $[n_{777} = \text{Plan2}]$ to 1, so that Bob is given the price of Plan2.

2.3 View-Based Provisioning

The parameterization of the database in Examples 2.1 and 2.2 is done over a single table for each hypothetical scenario. However, the symbolic representation needed for capturing scenarios HS3 and HS4 require the pre-generated views produced by joining tables Cust and Plans and tables Cust and Calls, respectively. The view is required because Price is parameterized based on the customer’s Zip code in HS3 and the call’s duration (Dur) in HS4. We can parameterize a view as if it is a single (albeit joined) table, and use it to generate a provenance expression as described in Section 2.1. However, the use of a parameterized view may render some queries as undefined for hypothetical reasoning as the following example shows.

Example 2.3. Retrieving the *ppm* of Plan1, using the parameterized view generated for scenario HS3 does not make sense because the price of the plan depends on the customer’s zip code. Conversely, determining the monthly revenues over this view is

Cust				Plans	
Num	Name	Zip	Plan	Plan	Price
555-777	Bob	10001	n_{777}	Plan1	$0.1 \cdot p_1$
555-942	Alice	10002	n_{942}	Plan2	$0.2 \cdot p_2 + s_2$
555-465	Dave	10003	n_{465}		

Figure 3: Data with provenance annotation

well defined, and can be computed using, e.g., a rewrite of the query shown in Example 2.1.

The problem of using views for hypothetical reasoning is highly related to the problem of answering queries using views [8]. One notable difference between the two problems is that a query may be well defined under an hypothetical scenario also if it only relies on tables that are *not* used in the views; the problem arises only when the query uses the same pieces of data affected by the parameterization, but does so in a “different” way. Formalizing and studying the properties that make a query answerable under a definition of hypothetical scenarios over views is an intriguing problem for investigation.

3 DISTRIBUTED BASIC PROVISIONING

Provisioning large-scale data is challenging: computing and maintaining provenance expressions may lead to large overheads in terms of both memory and time. We propose a partial remedy to this problem via an adaptation of basic provisioning to the distributed setting, and report on initial promising experimental results obtained in the context of *Apache Spark* [12, 14, 15].

Simplifying assumptions. We focus on basic provisioning and further assume that only numerical attributes may be parameterized and that the parameterization is performed on each *record* separately—parameterization based on information located at multiple tables requires creating an appropriate (unparameterized) view at a preliminary stage.

3.1 Apache Spark

Apache Spark is a popular framework for writing large scale data processing applications. *Spark* provides operations such as *map*, *filter* and *fold* which can be seen as extensions to the standard database operations *project*, *select* and *aggregation*, respectively, with arbitrary UDFs applied. In addition, *Spark* provides a *natural join* operation between multisets indexed by a common (possibly non-unique) key and *foldByKey* operations which, analogously to the *groupByKey* operation in databases, aggregates together the values pertaining to the same key.

Spark programs are executed on a cluster comprised of a single *master* node, which coordinates one or more *worker* nodes. Roughly speaking, a *spark* program operates as follows: It first partitions the data across the cluster nodes. *map* and *filter* operations are executed by each node, and on each partition in parallel. *fold* operations are executed in two stages: Every worker node aggregates the values in its partitions and sends the partial result to the master node which aggregates them together. *foldByKey* and *join* operations may require a preliminary (expensive) *shuffle* stage where records are exchanged between working nodes according to a strategy determined by the driver. At the end of the shuffle stage, all the records pertaining to any key are located in the same partition. This allows to compute the (by-key) *fold* and *join* operations by every working node separately.

3.2 Distributed Provenance Expressions

Representing and interacting with a provenance expression can be computationally expensive when it is generated from large-scale data. Specifically, two challenges may arise: (i) the table may contain many polynomials, thus representing it would consume a lot of space, and (ii) every polynomial may be comprised of a large number of monomials, thus designing efficient ways to represent and evaluate large polynomials is required.

Key	Value
(Jan, p_1)	$43 \cdot 0.1$
(Jan, p_2)	$116 \cdot 0.2$
(Jan, s_2)	116
(Feb, p_1)	$57 \cdot 0.1$
(Feb, p_2)	$167 \cdot 0.2$
(Feb, s_2)	167

Figure 4: Separated provenance representation.

Handling challenge (i). Using a *polynomial-level distributed representation*, which we refer to as the *combined representation*. In this representation, the provenance expression is spread across the cluster so that different nodes manage different polynomials (and each node manages a whole polynomial). Technically, the *combined representation* stores every polynomial as an additional attribute of each relation. The attribute is an array of *monomials*, where every monomial is a pair comprised of a coefficient and an array of symbolic variables. The symbolic execution of an aggregation operation amounts to combining the monomials coming from different polynomials by performing algebraic simplifications to compute the coefficients. For example, the provenance expression shown in Figure 2 is in the combined representation. Evaluating the provenance expression is done by an invocation of a map operation that evaluates every polynomial for the given assignment in the standard way.

Handling challenge (ii). Using *monomial-level distributed representation*, which we refer to as the *separated representation*: We split every polynomial into its constituent monomials and store each monomial in its own record. Technically, every monomial is represented as a key-value pair, where the value is the monomial’s coefficient and the key is a combination of a unique identifier of the polynomial that the monomial belongs together with the product of its variables. For example, Figure 4 depicts a separated representation of the PE shown in Figure 2. Under the separated representation, the (symbolic) execution of an aggregation operation does not combine different symbolic values into a single polynomial. Instead, when evaluating the provenance expression, a map operation evaluates the value of every monomial and a *foldByKey* operation computes the value of every polynomial.

3.3 Experimental Evaluation

We have performed a preliminary evaluation of our approach, and show two basic experiments based on our running example and a synthetically generated database. In the first experiment, we have joined the *Cust* and *Plans* tables, and parameterized the *Price* attribute of every customer record by multiplying it with a unique customer-unique variable. We ran the query using a *Cust* table that contained 2^{18} (262,144) customers, identified by their unique phone number, and uniformly distributed across the 41,668 US zip codes, and eight call plans. This resulted in a provenance expression comprised of 1536 polynomials. We considered different sizes of the input data by populating the *Calls* table with either 128, 256, 512, 1024, or 2048 calls for every customer. The resulting sizes of the *Calls* tables are in the range of 500 MB to 9.1 GB.

Creating the provenance expressions was up to $\times 2.1$ slower than the computation of the non-provisioned query. Evaluating the queries, on the other hand, up to $\times 385$ time faster than a naive recomputation. Figure 5 depicts the provenance evaluation time

Figure 5: Experiment 1 (Assignment time)

Figure 6: Experiment 2 (PE generation time)

for the *smallest* database¹. We made sure that changing the size of the data only affected the value of the coefficients, specifically, it did not change the number of monomials in any of the polynomials. As a result, the time it took to evaluate the provenance expression was independent of the size of the database.

In the second experiment, we evaluated the efficacy of the different representations using polynomial of different sizes by generating a provenance expression that comprised of a single polynomial with different number of monomials. We joined the Cust and Plans tables, and parameterized the Price attribute of every customer by multiplying it with a symbolic variable. We used the same database as in the first experiment using a Calls table with 32 calls for every customer. We ran the experiment nine times, where in the i th experiment, for $i = 0..8$, we used the same variable for all the customers whose phone numbers ended with the same $10 + i$ bits. Thus, the smallest polynomial contained 1024 monomials, and the biggest one had 262144. Figure 6 depicts the time it took to generate the provenance expressions. It shows that the Combined approach has the upper hand for small polynomials, yet it quickly becomes much slower than the Separated approach, up to the point of being prohibitively expensive.

Analysis. The Separated representation has an advantage for big polynomial whereas the Combined approach is better when the polynomials are small. We believe that the reason for this is that the Separated representation allows to store and evaluate a

¹We ran our experiments on Amazon EC2 public cloud [2] using a cluster comprised of nine m4.xlarge virtual machines. Eight machines were used as workers and one as the cluster’s driver. Each virtual machine has four virtual CPUs, 16GB memory. (The physical CPU used for an m4.xlarge virtual machine is a 2.4GHz Intel Xeon E5-2676 v3 processor, where every virtual CPU is a hyperthread of an Intel Xeon core.) We ran Spark version 1.6.2 over Amazon Linux AMI 2016.03, with Linux kernel 4.4.11, Java runtime 1.8.0_101, and Scala version 2.10.5. The UDFs were implemented in Scala, and the data was stored in Amazon Simple Storage Service (S3) [1].

single polynomial concurrently using multiple nodes. Furthermore, this representation is particularly beneficial in the context of Spark which handles tables containing a large number of records very efficiently, but struggles when it is asked to process large records due to its in-memory representation of the data and its single-threaded record processing.

4 OPEN PROBLEMS AND FUTURE WORK

We briefly discussed in this paper the problem of provisioning for big data, highlighting semantic and scalability issues, and proposing partial solutions in the context of Apache Spark. Both facets of the problem require extensive investigation, which is the subject of our on-going work. On the semantic side, a notable omission in the current literature is a formal language for specifying hypothetical scenarios (the need for such language is also mentioned in [4]); then, given a formal specification, can we efficiently decide whether an hypothetical is “answerable” (as in the view-based examples we have shown, this is not a given) and if so efficiently generate the PE? In terms of efficiency, we plan to extend our Spark-based implementation to allow for conditional provisioning. In addition, we are interested in exploring the benefits of a *hybrid* method for representing distributed provenance which combines the methods Separated and Combined we have presented by maintaining every polynomial as a table of sub-polynomial instead of single monomials. Last, we plan to investigate possibilities of “approximate provisioning”, where we lose some granularity of the possible assignments to variables but gain in performance.

On Answering Why-Not Queries Against Scientific Workflow Provenance

Khalid Belhajjame

Université Paris-Dauphine, PSL Research University, CNRS, [UMR 7243], LAMSADE
Paris, France

Khalid.Belhajjame@dauphine.fr

ABSTRACT

Why-not queries help scientists understand why a given data item was not returned by the executions of a given workflow. While answering such queries has been investigated for relational databases, there is only one proposal in this area for workflow provenance, viz. the Why-Not algorithm. This algorithm makes the assumption that the modules implementing the steps of the workflow preserve the attributes of the input datasets. This is, however, not the case for all workflow modules. We drop this assumption, and show in this paper how the Web can be harvested to answer why-not queries against workflow provenance.

1 INTRODUCTION

Scientific workflows have been shown to facilitate and accelerate scientific data exploration and analysis in many areas of sciences [6]. A workflow can be viewed as an acyclic graph in which the nodes are modules that can be executed locally or remotely, and the edges specify the data dependencies between the constituent modules. Workflows have been utilized to model and enact in-silico experiments in a range of scientific fields, including proteomics, transcriptomics, metabolics, plant phenotyping, astronomy, and bio-medicine.

Fig. 1 illustrates an example of a simple workflow used for identifying the pathway associated with a given input metabolite (compound). Given a compound identifier, the first module returns a compound name, which is used to feed the second module to obtain the corresponding pathway.

Figure 1: Example workflow.

Major workflow systems are instrumented to capture provenance information that records the data items used and generated by the workflow modules together with information specifying the lineage of such data items across the workflow execution.

Workflow provenance information can be utilized in a range of applications [8]. For example, it can be used to i)- estimate the quality of data based on the source data, ii)- determine the entity (author) to whom a given data item should be attributed, and

iii)- debug errors in the workflow execution. In this work, we focus on an application that has received little attention within the workflow provenance community, namely why-not queries. Given the provenance traces of workflow executions, the scientist may want to understand why a given result, e.g., his/her favorite protein, does not appear in the result of workflow executions.

1.1 Related Work

We distinguish between two classes of proposals for answering why-not queries: instance-based and module-based.

Instance-based. Proposals that fall into this category attempt to find the data items in the inputs that are responsible for the non appearance of a given data item in the result. More specifically, they determine the changes that need to be applied to the input datasets for the data item provided by the user to appear in the result. Artemis [9] and Missing-Answers [10] are examples of algorithms for processing instance-based why-not queries over relational databases. There is no proposal in the state of the art that investigates instance-based why-not queries for workflow provenance.

Module-based. Proposals in this class attempt to identify the modules that are responsible for the non-appearance of a given data item in the workflow results. The only proposal in this category for workflow provenance is the Why-Not algorithm proposed by Chapman and Jagadish [4]. Indeed, while why-not queries have been investigated in databases, where datasets are manipulated using (white boxes) query operators with known operational semantics, this is not the case for scientific workflows, where the steps of the workflow are implemented by black boxes, the behavior of which is not necessarily known. Using the Why-Not algorithm proposed by Chapman and Jagadish, the user query is expressed as a set of atomic predicates that are combined using AND and OR. An atomic predicate is evaluated over a single attribute of the Input datasets of the workflow. Chapman and Jagadish make the assumption that the attributes of the input datasets are preserved by the modules that compose the workflow. This is not the case, however, in the general case. For example, the modules in the workflow illustrated in Fig. 1 do not preserve the attribute of the input, viz. Compound – ID, in that the output of the first and the second module do not contain information about the compound identifier.

As well as identifying the reason why a result is missing, a number of proposals investigated changes that can be made to the query to include known missing results (see e.g., [1, 5]).

In this work, we focus on explaining why a data item is missing from the results of a data-driven workflow. In doing so, we drop the assumption made by Chapman and Jagadish, and propose a solution that can be utilized for answering why-not queries for workflow with modules that do not preserve attributes of the input datasets. Furthermore, unlike the Why-Not algorithm which is module-based, our proposal is hybrid in that it seeks

to answer instance- and module-based why-not queries. This makes our solution the only hybrid solution targeted for workflow provenance.¹

In the rest, we start by laying down the foundations in Sect. 2. We sketch our algorithm in Sect. 3. We then focus on operations that are central to our algorithm, namely determining if a module is picky, i.e., responsible for the non-appearance of an output data item, and determining the missing input data item for a given module in Sect. 4. Finally, we report on the results of a feasibility study that we conducted, and conclude the paper in Sect. 5.

2 FOUNDATIONS

We define a workflow WF as a directed acyclic graph in which the nodes correspond to modules, and the edges specify data flow dependencies. A data link connecting a module M_1 to a module M_2 specifies that the output produced by the invocation of the first is used as input to feed the execution of the latter.

The invocation of a module M , which we call module instance and denote by m , takes one or more data items as input and produce a data item as output. We write $m(d^{I_1}, \dots, d^{I_n}) = d^O$, where I_1, \dots, I_n represents the domain of values of the inputs of M and O the domain of values of the output. For the purpose of this work, we consider that the modules of a workflow are functions, in that they return the same output data item given the same input data items.

The execution of a workflow WF gives rise to a workflow instance wf, which takes one or more data items and produce as a result a data item. Major scientific workflow systems are instrumented to capture provenance information of workflow instances specifying the data items used and generated by the workflow, which can be utilized to track the lineage of the workflow results.

Typically, a scientist would execute a workflow WF multiple times, and then proceed to the exploration and analysis of the results. We are, therefore, interested in querying the datasets used and generated as a result of multiple executions (instances) of WF. We write $WF(D^{I_1}, \dots, D^{I_n}) = D_0$ to denote that collectively the instances of the workflow WF, took as input the datasets D^{I_1}, \dots, D^{I_n} and generated the dataset D_0 . Similarly, we write $M^{WF}(D^{I_1}, \dots, D^{I_n}) = D_0$ to denote that the invocations (instances) of the module M that took place with the instances of the workflow WF used the datasets D^{I_1}, \dots, D^{I_n} and generated the dataset D_0 .

Inverse of a Module. Central to our solution is the notion of the inverse of a module. The inverse of a module M , which we denote by M_{inv} takes as input data items that are type-compatible with the output of M , and delivers data items that are type-compatible with the inputs of M .

Picky module. A module M is picky with respect to a data item d if M_{inv} does not accept d as input. More specifically, M_{inv} throws an illegal input exception when its execution is fed d .

3 ANSWERING WHY-NOT QUERIES

3.1 Why-Not Queries

A user specifies a why-not query by specifying a data item, which has the same data type as the output of the last module of the workflow. Let such a module be $M^{WF}(D^{I_1}, \dots, D^{I_n}) = D_0$. Consider for the sake of simplicity that such a module output data items that are characterized by the attributes $\langle a_1, \dots, a_m \rangle$. A why-not query is a data item $\langle v_1, \dots, v_m \rangle$ that was not generated by M

¹There are existing hybrid solutions, but they are targeted for relational databases (see e.g., [2]).

when invoked within the workflow WF. That is, $\langle a_1, \dots, a_m \rangle \notin D_0$. We denote such a data item in what follows by $d_{\text{why-not}}$. Note that, in the general case, a workflow may have multiple final modules. Our solution is applicable to those workflows. To do so, our algorithm is applied to each output data item (why-not query) provided by the user.

3.2 Processing Why-Not Queries

To answer a why-not query, the modules of the workflow are explored from the sink to the source in a breadth-first fashion. To do so, we group the workflow modules into levels as illustrated in Figure 2. A module belongs to a level i if its outputs are connected to modules in levels $\leq i - 1$. Of course, this does not apply to the modules in level 0, the outputs of which carry the results of the workflow execution. The modules of a given level can be examined only if the examination of the modules of the previous level has completed.

Figure 2: Workflow levels.

Algorithm 1, which we named Why-Not Detective, sketches the evaluation of a why-not query. It takes as input a data item $d_{\text{why-not}}$ specified by the user, and the workflow modules organized into levels starting from the sink WF_Modules. The modules of each level are examined to identify if the module is picky. Specifically, the inverse of the module in question M is examined to check if:

- It does not accept the corresponding data items that were generated by the inverse of the modules in the previous level. By corresponding data items, we mean data items generated by module parameters in the previous level, if any, that are connected to the output of the M module. The module M is flagged in this case as picky.
- It accepts the corresponding data items that were generated by the inverse of the modules in the previous modules. In this case, the data items the inverse of M produces are saved to be used to feed the inverse of the modules in the succeeding levels, if any. Notice here that the provenance of the workflow subjects to analysis will not contain such data items, otherwise, the workflow would have produced $d_{\text{why-not}}$.

The algorithm iterates over the modules of each level until i)- it finds modules of a given level that are picky, or ii)- it does not find any picky modules. In the first case, the algorithm stops (see line 15). Indeed, the modules of the succeeding level, or at least subset thereof, cannot be examined. This is because we will not have data items to probe the inverse of such modules with. The picky modules are therefore returned by the algorithm as the source of the non appearance of $d_{\text{why-not}}$ in the results. Note here that

our notion of picky module corresponds to the notion of *Frontier Picky Manipulation* in the Why-Not algorithm by Chapman and Jagadish [4]. In the second case (ii), the datasets used as input to the execution of the workflow are designated as the source of the non-appearance of $d_{\text{why-not}}$ in the results. Specifically, the data items returned by the inverses of the modules in the last level are designated as missing in the inputs datasets.

Example 3.1. Consider our example workflow in Fig. 1, and suppose that the scientists did not find the pathway identified by map00220 in the results of the provenance of the workflow. In this simple example, we have two levels composed of one module each. The algorithm starts by examining the getPathway module. The inverse of this module accepts the value map00220 and provides the compound name L – Argentine. This compound name is accepted by the inverse of getCompoundName, which in turn delivers the compound identifier cpd : C00062. The Why-Not detective concludes, in this case, that none of the modules is picky, and that the non appearance of the pathway map00220 in the results is due to the missing input data item cpd : C00062.

Algorithm 1 Why-Not Detective

Input: WF_Modules = $\{L_0, \dots, L_k\}$ // workflow modules grouped into levels (breadth) from the sink to the source.
 $d_{\text{why-not}}$ // missing workflow result.
Output: PickyModules // set of picky modules
MissingInputData // set of data items missing in the workflow input dataset

```

1: PickyModules =  $\emptyset$ 
2: MissingInputData =  $\emptyset$ 
3: Dcurrent =  $\{d_{\text{why-not}}\}$ 
4: Dcurrent+1 =  $\emptyset$ 
5: for Level in WF_Modules do
6:   for M in Level do
7:     if accept(inv(M), getInput(Dcurrent)) then
8:       datacurrent+1 += getResult(inv(M), getInput(Dcurrent))
9:     else
10:      PickyModules +=  $\{M\}$ 
11:    end if
12:    Dcurrent+1 += getResult(inv(M), getInput(Dcurrent))
13:  end for
14: if PickyModules  $\neq \emptyset$  then
15:   breakall
16: end if
17: Dcurrent = Dcurrent+1
18: end for

```

4 DETERMINING THE OUTPUT OF THE INVERSE MODULE

The central operations, which are repeatedly performed in the above algorithm, are the test of acceptance of data items by the inverse of a given module M , and the calculation of the results (data items) returned by the invocation of the inverse module.

To assess whether a module M_{inv} accepts a given data item d , we need to invoke M_{inv} using d . If the invocation of M_{inv} terminates successfully, then we can conclude that M_{inv} accepts d . Otherwise, if the execution of M_{inv} raises an illegal input exception, then we can conclude that M_{inv} does not accept d .

Unfortunately, we cannot perform this test, because we do not have access to M_{inv} . To address this issue, we harvest the (probably) biggest source of information, namely the Web. There are several proposals in the literature that attempted to extract

relational data from tables on the Web (see e.g., [3, 11]). Our objective is, however, different. We do not seek to transform all tabular HTML data into a structured format, but instead, identify the input data items that may be candidate for producing a given data item when used to feed a given module.

We adopt for this purpose a process, composed of three steps: i)- identifying candidate pages, ii)- extracting candidate input data items, and iii)- examining the candidate input data items.

4.1 Identifying Candidate Web Pages

To identify the web pages of interest, we make use of semantic annotations describing the input and output parameters of the module M . Indeed, a number of scientific modules are annotated with ontological concepts informing the semantic domain of the input and output parameters of the module, see e.g., bio-tools². We make use of semantic annotations, because often the names of the input and output parameters are non-informative and take values like in or out. Semantic annotations provide a crisper description of parameter types.

Consider for example that M has an input with a semantic domain c_{in} and an output of a semantic domain c_{out} . We issue a query with the following keywords: $\{c_{\text{in}}, c_{\text{out}}, d\}$ against a Web search engine. We are interested in finding the web pages W_c that contains all of the keywords. We call W_c candidate web pages. If the set W_c is empty, then M_{inv} is likely not to accept the data item d . Note that we say *likely*. This is partly because the Web, albeit a large data source, there is no guarantee of it being complete, and partly because the keywords used may fail to locate a Web page that contains the desired information, even if such a page exists.

4.2 Extracting Candidate Input Data Items

For each web page in W_c , we apply information extraction algorithms to retrieve data items that have c_{out} as a semantic domain. The problem we face here is that Web pages are unstructured. Solutions that have been proposed for information extraction, e.g., [3, 7, 11] can be used for this purpose.

As well as the above proposals, in the context of our work, we use recognizers. Indeed, many of the semantic domains, e.g., pathways, enzymes, proteins, etc., in the scientific fields are associated with recognizers, able to identify the semantic domain of a given raw text/string. This applies particularly to accessions, which can be seen as scientific identifiers for entities such proteins, RNAs, etc., as well as other more complex structures such as sequence entries, e.g., Fasta format, IPR entry, etc. Therefore, if c_{out} is associated with a recognizer, then we apply the recognizer to each of the web pages in W_c . This will result in a list of candidate data items D_{in}^c .

4.3 Examining Candidate Input Data Items

We use the data items in D_{in}^c to feed the execution of the module M . If an execution that takes an input data item d_{in} yields a successful execution of M and produces a result d , then we can conclude that the inverse M_{inv} accepts d and it delivers as a result d_{in} . Note that in the general case, multiple input data items can be associated with d . For the purpose of this work, however, we assume that the module M and its inverse are functions.

If, on the other hand, none of the candidates in D_{in}^c yields d when invoking M , then we conclude that M_{inv} is likely not to accept d .

²<https://bio.tools>

5 FEASIBILITY STUDY

The approach we have just described raises the following question. *Is the algorithm proposed able to identify the reason why a given data item does not appear in the workflow results?* More specifically, *How effective is our solution in identifying picky modules and missing input data items?*

To answer the above questions, we run a feasibility experiment, in which we used a sample of 6 real-world workflows from the myExperiment repository³. We selected workflows that involve deterministic modules, which mean modules that deliver the same result (if any) given the same input. We did not consider workflows that include modules performing data mining operations, for instance. We have also selected workflows for which the inverse modules are also deterministic functions.

5.1 Set-up

We have executed each workflow using example data inputs provided by the workflow authors. In doing so, we used the Taverna workflow systems [12]. We then specified two kinds of queries for each workflow:

- Instance-based why-not query. To assess the ability of the algorithm in answering this type of queries, we randomly selected an output data item d that was returned by the workflow executions. Next, we used our algorithm to see if it is able to reconstruct the lineage of d by harvesting the web to identify the input data items that were responsible for its derivation. We then compared the lineage reconstructed for d with the lineage available in the provenance of the workflow executions previously recorded by the workflow system. This allows us to see if our algorithm was able to successfully identify the input data items responsible for the derivation of d .
- Module-based why-not query This kind of query is used to assess if the algorithm is able to identify picky modules. That is modules that are responsible for the non deliverance of a given data item d by the workflow executions. To do so, for each workflow, we identified a data item that we know it cannot be delivered by the workflow because of a given (picky) module. We then used our algorithm to assess if it is able to identify such a module.

In total we had 6 queries of the first kind, which we denote by $\{q_1^+, \dots, q_6^+\}$, and 6 queries of the second kind, which we denote by $\{q_1^-, \dots, q_6^-\}$. The + sign indicates that we should be able to reconstruct the provenance of the why-not query up to the workflow input, and the - sign indicates that we should not be able to do so, and instead identify the picky module.

5.2 Results

Of the queries $\{q_1^+, \dots, q_6^+\}$, our algorithm was able to successfully constructs the provenance of the why-not query up to the workflow input for 3 queries. Most of the modules composing these workflows, namely 8 out of 11, provides information about the input and output datasets on the Web using Tabular formats.

After examination of the three remaining workflows, we found that one them utilizes proprietary data sources, the content of which is not accessible on the surface web. The last two workflows, on the other hand, contain modules that manipulate excerpt from HTML web pages. Because of this, our algorithm was not able to find the content on the Web of the input and output

of those modules. However, we made a key observation thanks to these two workflows that will allow us to improve the quality of the results delivered by our algorithm. Indeed, these modules that were problematic for our algorithm perform format transformation, which we refer to as Shims in scientific workflows. Such modules could be ignored (skipped) by our algorithm. For example, once ignored, our algorithm was able to identify the inputs data items of the remaining modules in the workflows.

We also measured the number of Top-k web pages that needed to be examined to identify the input data item corresponding to a given output data item. On average, we needed to examine the content of the 4 top web pages returned by the key-word search engine⁴. In several cases, however, the top web page was the right one, in the sense that it contained the input data item we are after.

Regarding the queries $\{q_1^-, \dots, q_6^-\}$, our algorithm was more successful in the sense that it was able to correctly identify 4 picky modules out of 6. For two remaining workflows, the module that was identified as picky by our algorithm was not the correct one. After examination, it transpired that for certain modules the corresponding data item could not be found on the web. Again this issue was due to shims modules the input and output data items are not published on the Web.

To sum up, this small feasibility study has shown that our method is promising. It has also brought some insights into the way our solution can be improved. Our ongoing work includes: i)- tuning our algorithm to deal with shims modules in a workflow, ii)- explore new source of information for identifying picky modules, iii)- extending our solution to cases where the inverse of a module is not a function, and iv)- an experiment involving a large number of scientific workflows.

ABSTRACT

The rapidly growing size of RDF graphs in recent years necessitates distributed storage and parallel processing strategies. To obtain efficient query processing using computer clusters a wide variety of different approaches have been proposed. Related to the approach presented in the current paper are systems built on top of Hadoop HDFS, for example using Apache Accumulo or using Apache Spark. We present a new RDF store called PRoST (Partitioned RDF on Spark Tables) based on Apache Spark. PRoST introduces an innovative strategy that combines the Vertical Partitioning approach with the Property Table, two preexisting models for storing RDF datasets. We demonstrate that our proposal outperforms state-of-the-art systems w.r.t. the runtime for a wide range of query types and without any extensive precomputing phase.

1 INTRODUCTION

Organizations and institutions increasingly see a need to represent their data in a semantically-structured way [7] and, thus, rely on the RDF data model. As the data represented in RDF constantly grows in size, storing and querying these very large RDF graphs becomes a major challenge. In order to increase the query efficiency, many different approaches have been proposed e.g. [1, 10, 13, 15]. Most of the current solutions use DBMS-based systems and map SPARQL queries to SQL queries for the retrieval. Besides the systems which are implemented for single-node machines, such as RDF-3X [11], Sesame [6] and Jena [16], systems designed for distributed environments are increasingly being used. They allow to scale up the storage and to provide parallel query execution capabilities, which is essential to handle very large data. Systems of distributed environments use in particular Hadoop technologies: S2RDF [15] and SPARQLGX [8] are implemented on top of Apache Spark, Rya [13] on top of Apache Accumulo, and Sempala [14] on top of Impala.

Typically, these systems are optimized for specific query patterns and their data loading times are often sacrificed for better querying performance. Thus, there is need for a distributed RDF store with better performance on a wide range of query types, without renouncing a rapid loading phase.

In this work, we describe the approach of PRoST¹ (Partitioned RDF on Spark Tables), that aims to improve the efficiency of queries on RDF data, thereby covering a wide range of query types. Instead of building a standalone system, such as [12], AdPart [2] or TriAD [9], PRoST is based on reliable Hadoop technologies for storing and processing the data and therefore its

¹The source code of PRoST is online available at <https://github.com/tf-dbis-uni-freiburg/PRoST>.

performance depends more on the general approach than on the details of the implementation (e.g. memory management, network protocols). In this paper, we focus on querying RDF efficiently by means of Apache Spark², as it emerged as an important component of the Hadoop ecosystem: It offers general purpose data processing functions that exploit efficiently the main memory – differently from MapReduce that relies mainly on disk operations. This characteristic makes Spark very fast in practice and able to compute complex queries on large RDF graphs. In particular, it is possible to obtain high querying performances using Spark SQL, a module of Spark that adds well-established DBMS techniques to the distributed computation framework.

Our main contribution is proposing a new storage model for loading RDF graphs into Hadoop, including an appropriate strategy for translating SPARQL queries into Spark execution plans. We show that combining the so far separately applied strategies for representing RDF data in Hadoop – Vertical Partitioning [1] and the strategy of using Property Tables [16] – can be implemented with relatively little effort and leads to superior querying performances in many cases, as our evaluation results show.

The paper is structured as follows: In Section 2, we present an overview of similar systems for querying RDF. In Section 3, we outline our approach for modeling the data, our strategy for translating SPARQL queries, and the techniques for improving the performances of PRoST. We summarize our evaluation results in Section 4 and, in Section 5, we conclude and present ideas for future implementations of PRoST.

2 RELATED WORK

Due to space limitations, in the following we restrict ourselves to Hadoop-based RDF querying approaches, as they are the most similar to our system PRoST. S2RDF [15] is a "SPARQL processor" based on Spark SQL. It introduces a data partitioning approach that extends Vertical Partitioning [1] with additional tables, containing precomputed semi-joins. As a consequence, many intermediate results of queries are already computed and can be used to shorten the retrieval time. However, S2RDF trades off the performances with disk space and loading time. For datasets with a large number of properties (e.g., DBpedia [5]), the time required may make the loading unfeasible.

SPARQLGX [8] is another system for distributed SPARQL queries that uses Vertical Partitioning. SPARQLGX compiles the queries directly into Spark operations. The system relies entirely on its own statistics to optimize the computation, in particular for the order of the joins. Differently from S2RDF and PRoST, SPARQLGX does not use Spark SQL.

Rya [13] is a popular RDF management system, developed by an active open-source community and currently an incubating project at Apache. It is built on top of Apache Accumulo³, a distributed key-value datastore for Hadoop. Since Accumulo

²<https://spark.apache.org>.

³<https://accumulo.apache.org/>.

keeps all its information sorted and indexed by key, Rya stores whole RDF triples as keys. For this reason, single triples or short ranges can be accessed very fast. However, considering that the triple table model of Rya contains three columns, it requires to replicate the data multiple times in order to exploit the indexes over all the possible elements. Rya uses some query optimization, e.g. joins reordering, but it lacks of the powerful in-memory data processing that make, in practice, other systems faster.

3 APPROACH

The main idea behind PRoST is to store the data twice, partitioned in two different ways. Each one of the two data structures can be more beneficial (in terms of performance) than the other regarding certain query types, mainly because of the different location of the data in the cluster. Our system tries to exploit this characteristic. We do not limit ourselves to choose the single best model out of these two for each query, but we split a query in several parts, such that each sub-query can be executed with the most appropriate approach. At the end, all the parts can be joined together to produce the final result. In this way, our approach achieves better performance than when running only on one of the two representations, as it leverages the synergy effects of both models.

3.1 PRoST Data Model

The two data structures we use to store an RDF graph are *Vertical Partitioning* and *Property Table*. *Vertical Partitioning* (VP) is an approach proposed by Abadi et al. [1]. It has a strong popularity among RDF storage systems and it is the main choice of the state-of-the-art approaches S2RDF [15] and SPARQLGX [8]. The main concept is to create a table for each distinct predicate of the input graph, containing all the tuples (subject, object) that are connected by that predicate. The vertical partitioning approach is at the same time powerful and simple, but it has the drawback that it needs a number of joins proportional to the number of triple patterns in the query (precisely, the number of triple patterns minus one). Even with this disadvantage, because the VP tables are narrow and often small, VP is a valid and practical choice.

The *Property Table* (PT) is a data scheme that was introduced in the implementation of Jena2 [16], an influential toolkit for RDF graph processing, and Sempala [14], another SPARQL processor built on top of the Impala framework. A PT consists of a unique table where each row contains a distinct subject and all the object values for that subject, stored in columns identified by the property to which they belong.

The most important advantage of PT, when compared with VP, is that several joins can be avoided when some of the triple patterns in a query share the same subject. In this case, part of the query can be executed by a simpler select operator. Therefore, this approach is beneficial for queries where all the triple patterns have the same subject variable, usually called *star* queries. However, as observed by Abadi et al. [1], the PT has some issues, in particular the number of NULLs and the multi-valued attributes. Since not every possible pair subject-predicate has a corresponding object value, the PT potentially contains a very large number of NULLs. We solve this problem by storing the table in *Parquet*⁴, a format that uses run-length encoding. The other problem of the PT is the presence of multi-valued properties, i.e., when more than one different object value exists for at least one subject. In this case, the values are stored using lists

⁴<http://parquet.apache.org>

Figure 1: Example of a conjunction of triple patterns translated to a Join Tree. The root node uses the Property Table, the others Vertical Partitioning.

that need to be flattened when executing operations on these attributes. This particular situation produces an overhead in respect to the VP model, significant if we use the PT for a single attribute, but negligible if compared to the benefit of avoiding more than one join to compute the same query.

We have several advantages (e.g. efficient compression) in using the columnar format *Parquet* to store the PT, but we then introduce also the undesirable possibility that the data belonging to a single subject could be split into different nodes. In order to keep benefiting from the structure of the property table, we partition horizontally on the subject column. In this way, we ensure that every row is stored entirely in the same node.

3.2 Query Strategies

Having two data structures at the same time requires an abstraction to represent the queries. For this reason, we define an intermediate format that we call *Join Tree*. Each node of this tree represents a sub-query extracted from a VP table or from the PT. Using Spark, PRoST can execute a query by calculating the intermediate results from the nodes and then joining them together in a bottom-up fashion.

We now explain how we translate SPARQL queries into the *Join Tree* format. For the sake of clarity, we consider queries with a unique *basic graph pattern* without filter, which are a conjunction of triple patterns. The triple patterns with the same subject are grouped together and translated into a single node with a special label, denoting that we should use the property table in this case. All the other groups with a single triple pattern are translated to nodes that will use the vertical partitioning tables. An example is shown in Figure 1. There could be a join edge between every pair of nodes that shares a variable, it means that more than one *Join Tree* translation is possible for a single query. Since the tree structure influences the final performances, choosing carefully the *Join Tree* is important for the quality of the system. For this reason, we choose a tree guided by simple statistics, as explained in the following section.

3.3 Statistics-based Optimization

In the context of our work, joins are the most expensive operators because they need large portion of the data to be shuffled across the network. The order of the joins is important to limit this issue, and therefore to speed up the calculation. An effective way is sorting the joins using statistics of the input graph. The *Join Tree* of a query decides indirectly the order in which the operations are computed. For example, the leaves are computed first, and the root node is the final one. The statistics we use, simple but effective in practice, are (1) the total number of triples and (2) the number of distinct subjects for each predicate. They are calculated during the loading phase without any significant overhead.

As a general rule of thumb, we want to compute the joins involving few data or with a high selectivity first (high priority), and finally the ones with many tuples (low priority). The priority value of a node of the Join Tree is decided by the following criteria:

- Triple patterns containing literals are scored with the highest priority. The presence of a literal is a strong constraint that limit the number of resulting tuples. Therefore, it is a good approach to push down these kind of nodes.
- A triple pattern of which the underlying data contains many tuples will be scored proportionally. For instance, a triple with the highest number of tuples will have also the lowest priority and it will be the root of the tree. This number is also adjusted according the number of distinct subjects for that predicate.
- The priority of a node containing data belonging to the Property Table is scored taking in account all its triple patterns. However, the presence of a triple pattern with a literal is weighted heavily.

In addition to our effort, Spark SQL’s Catalyst Optimizer [4] uses its internal heuristics to improve query performances further. The trees are not substantially changed, but Spark intervenes in producing optimized physical plans, since it knows the concrete location of the data on the cluster. In particular, the optimizer can choose the type of joins to perform, for example if one of the relations involved is small, a broadcast join will be performed.

4 EVALUATION RESULTS

4.1 Benchmark Environment

We perform our tests on a small cluster of 10 machines connected via Gigabit Ethernet connection. Each machine is equipped with 32GB of memory, 4TB of disk space and with a 6 Core Intel Xeon E5-2420 processor. The cluster runs Cloudera CDH 5.11.0 on Ubuntu 14.04 and Spark 2.1.0. Since one machine is the master, Spark uses only 9 workers. The executor’s memory is 21GB. We use the WatDiv [3] dataset provided by the Waterloo SPARQL Diversity Test Suite 7. It is developed in order to measure how an RDF data management system performs across a wide variety of SPARQL queries with varying characteristics and has already been applied in the evaluations of the comparable systems. Given WatDiv we generate a dataset containing around 100 Million RDF triples (5.16 GB) and we evaluate PRoST with the given *WatDiv basic query set*. It contains queries of varying shape and selectivity in order to model different scenarios. The queries are grouped into the following subsets:

- **C**: Complex shaped queries.
- **F (F1, F2, F3, F4, F5)**: Snowflake shaped queries.
- **L (L1, L2, L3, L4, L5)**: Linear shaped queries.
- **S (S1, S2, S3, S4, S5, S6, S7)**: Star shaped queries.

4.2 Loading

As we can see from Table 1, the storage size used by PRoST decreases when being stored in HDFS. This is a direct consequence of the compression used by the *Parquet* format.

The database size of S2RDF is the largest in this analysis, since its model not only needs the creation of VP tables, but also many additional ones containing the results of its precomputations. SPARQLGX occupies minimal space because it uses only Vertical Partitioning, where instead PRoST requires double SPARQLGX’s size for having in addition the Property Table. The loading time of

System	Size	Time
PRoST	2.1 GB	25m 32s
SPARQLGX	0.9 GB	20m 01s
S2RDF	6.2 GB	3h 11m 44s
Rya	3.1 GB	41m 32s

Table 1: Size and loading times using WatDiv100M

Figure 2: Querying time for WatDiv100M with only Vertical Partitioning and with the mixed strategy.

PRoST is similar to SPARQLGX and around an order of magnitude shorter than S2RDF. Similarly to what we said before for the database size, S2RDF’s model requires longer times because of its extensive precomputations.

4.3 Vertical Partitioning vs Mixed Strategy

One of our central points is the introduction of the Property Table alongside Vertical Partitioning. As a consequence, we evaluated the impact of this addition on query performances. In Figure 2, we show the times to compare the query set from WatDiv100M with Vertical Partitioning only and with the additional support of the Property Table.

The chart shows clearly that the introduction of the Property Table has a strong positive impact on performances. For almost every type of query this version outperforms abundantly the simple Vertical Partitioning approach. The new strategy is effective for Star queries (S), where most of the triples share the same subject, as well as Complex (C) and Snowflake (F) queries, that have more than one different subject. For some of the Linear queries (L), the results are very similar between the two versions. This result comes from the fact that Linear queries contain mostly triples with distinct subject variables, translated using mostly Vertical Partitioning.

4.4 PRoST vs Other Systems

To better evaluate our system we compared it in the same environment with other similar solutions: S2RDF, Rya and SPARQLGX. In Figure 3 we show the querying times on the WatDiv100M dataset with the other systems and our implementation. Note that we used a logarithmic scale, since the large differences would prevent us from visualizing these results well. Compared to S2RDF, PRoST is faster for the queries F2, S1, S3 and S5 but slower for the remaining queries. In particular, for the complex queries (C) and some of the snowflake ones (F3, F4) the S2RDF’s approach makes it faster by a considerable margin. These differences can be explained with the extensive precomputations of S2RDF, that heavily decrease the processing time for joins between VP tables. However we have to keep in mind that S2RDF can reach

Figure 3: Querying time for WatDiv100M with PROST, S2RDF, Rya and SPARQLGX. The scale is logarithmic.

Queries	ProST	S2RDF	Rya	SPARQLGX
Complex	9,364ms	3,392ms	2,195,322ms	61,363ms
Snowflake	5,923ms	1,564ms	369,016ms	24,046ms

these results because of a possibly large loading time, that, for some datasets, may make it less attractive in practice. In contrast, PROST relies on a faster loading phase and its performances does not depend on the particular input graph, i.e. number of predicates.

For some queries, Rya is very fast and outperforms PROST but in other cases it suffers from significant slowdowns, that are several orders of magnitude slower. Therefore, its average query time is the worst of the systems considered, as shown in Table 2. The queries in which Rya performs very well have in common that their computation involves only few intermediate results. As a matter of fact, Rya uses powerful indexing methods but it lacks of more sophisticated approaches to calculate joins. For SPARQLGX, almost all the queries are computed in around twenty seconds, except the Complex ones (C) that have a higher number of resulting tuples. PROST outperforms SPARQLGX in every case, mostly by around an order of magnitude. Since SPARQLGX uses simple vertical partitioning, this difference confirms further the improvements produced by the introduction of the new data organization approach and also increases the validity of the implementation choices of PROST. The evaluation results presented in [8] are obtained using a virtual cluster of 10 nodes on 2 physical machines. In particular, when SPARQLGX is compared to S2RDF, their results are not consistent with the results from our experiment, obtained on a cluster of 10 physical machines.

5 CONCLUSION AND FUTURE WORK

In this paper, we presented PROST, a distributed system for RDF storage and SPARQL querying built on top of Apache Spark. With PROST we introduce an innovative data structure for partitioning RDF data that, to the best of our knowledge, for the first time combines efficiently two pre-existing approaches, namely Vertical Partitioning and the Property Table. Our evaluations, in which we compare PROST on a Hadoop cluster with some state-of-the-art systems Rya, SPARQLGX, and S2RDF, show that PROST

outperforms Rya and SPARQLGX in terms of querying time to a large extent and that it achieves similar results to S2RDF. Notably, PROST shows consistently good results for every type of query and is not limited to datasets with certain characteristics to keep the pre-computation feasible. Therefore, our approach is in particular appropriate for real-world applications, for which the query type and the dataset are unknown a priori.

For future work, we considered further improvements in terms of both storage and querying performance. For example, a promising step might be to add another Property Table where, instead of the subjects, the rows would be created around objects. This could be beneficial for triple patterns that share the same object. Another possible improvement would be to collect more precise statistics of the input dataset in order to produce better trees and, hence, a less expensive retrieval.

ABSTRACT

We leverage vectorized User-Defined Functions (UDFs) to efficiently integrate unchanged machine learning pipelines into an analytical data management system. The entire pipelines including data, models, parameters and evaluation outcomes are stored and executed inside the database system. Experiments using our MonetDB/Python UDFs show greatly improved performance due to reduced data movement and parallel processing opportunities. In addition, this integration enables meta-analysis of models using relational queries.

1 INTRODUCTION

The ad-hoc nature of data analysis pipelines using complex statistical or machine learning algorithms bundled with large volumes of data quickly leads to a latent need for data management systems [9]: 1) Manually managing large datasets as flat files quickly becomes cumbersome and error-prone, and additionally introduces many difficulties when multiple people are working with the same data or when the data has to be written to or updated. 2) Loading data from structured text files (e.g. XML or CSV) is very inefficient, as the data has to be parsed and converted to native binary formats before being subjected to analysis. Files are read from disk every single time an analysis pipeline is run, significantly increasing the time necessary to run these pipelines. These problems are exasperated as analysis pipelines are evaluated and moved towards production use.

These problems can be solved by using existing relational database management technologies. However, it has traditionally been very difficult to combine analytical tools with relational databases. The standard approach of running a separate database server and connecting with it through a socket connection is very inefficient and introduces severe bottlenecks when working with large amounts of data [15]. On the other end of the spectrum, in-database processing techniques have typically been cumbersome and difficult to use. Rewriting analytical pipelines in plain SQL is non-trivial and the subject of research papers [10]. Traditional scalar user-defined functions (UDFs) as supported by “mainstream” relational data management systems are difficult to utilize for complex machine learning tasks where a view on the entire dataset is required.

Recently, vectorized UDFs [8, 14] have been proposed that allow for efficient and flexible integration of popular analytical tools inside column-store databases. By utilizing these UDFs, existing complex analytical pipelines can be moved inside the

database. This allows us to gain all the advantages of storing data inside a relational database, while still having flexible and easy-to-use analytical tools available.

An additional benefit of training and using machine learning models directly in the database is that it is possible to persist both models and metadata (e.g. classification scores on test sets) in the database. Standard relational queries can then be used to apply the trained models to data. This allows for example to compare and combine output from multiple models, each specialized for certain classification tasks. Also, it is possible to classify the same data using multiple models and use the result of the model that reports the highest confidence.

In this paper we showcase how we can use vectorized user-defined functions to efficiently integrate a complex analysis pipeline inside a columnar database management system. We show how we can train models directly inside the database, and how to store the models and subsequently use them to classify data without having to export the data from the database system.

The main contributions of this paper are:

- We show how traditional classification models can be integrated into a column-store relational database management system.
- We describe how models can be stored inside the database system and how these models can then be used to efficiently and flexibly classify data.
- We experimentally show the performance benefit of directly running the models inside the database system versus loading the data from structured text, binary files or using database client protocols.

Outline. This paper is organized as follows: Section 2 discusses related work. Section 3 presents our integration approach, followed by a concrete use-case and performance results in Section 4. In Section 5 we draw our conclusions and discuss future work.

2 RELATED WORK

There is a variety of related work on combining relational database systems with machine learning pipelines. In this section we will present the most recent related work regarding the integration of machine learning through UDFs and model management systems and compare them with our solution.

2.1 Machine Learning Integration

Integrating existing Database Management Systems and machine learning algorithms has been a long standing problem due to the complexity of implementing the machine learning code inside a DBMS.

Early work [2, 16] on this focuses on rewriting analytical algorithms into portable SQL code. This allows the pipelines to be executed within any database system without requiring database-specific modifications. However, rewriting complex analytical pipelines in SQL requires a lot of manual effort and might not be possible for certain algorithms because SQL is not a Turing complete language.

In Ordonez et al. [12], machine learning algorithms are translated to either C, C++ or C# code (depending on the DBMS language support) and inserted into UDFs. As a consequence they achieve high performance when analyzing large data sets compared to external data analysis tools, as data movement is mitigated. However, these algorithm must be coded in one of the previously listed languages. This often results in the need for rewriting code, because most prominent machine learning libraries are usually available in scripting languages (e.g., Python and R). In our solution we allow the developer to use popular scripting languages *together with their entire ecosystem of data analytics packages* as UDFs in MonetDB.

Other work [4, 6, 7] focuses on more templated approaches for machine learning integration to reduce the necessity of code rewriting. However, the main disadvantage of these methods is that they only work for a limited subset of algorithms, which limits their applicability to general machine learning tasks.

2.2 Machine Learning Model Management

When training and using a variety of models the problem of managing these models arises. This problem is exasperated because most Machine Learning Systems do not provide support for storing and querying their models. Due to these issues, data scientists quickly lose track of their models.

In Vartak et al. [19], a system called ModelDB is introduced that can be used for storing, tracking and managing machine learning models in their native environment. This allows data scientists to use SQL to query their models based on their meta-data (e.g., hyperparameters, parameters) and quality metrics (e.g., accuracy). It also has the option to store the used train/test data sets for each model. However, since ModelDB only stores the models in their native environment, it does not provide a solution for coupling machine learning applications with traditional relational databases.

3 MACHINE LEARNING INTEGRATION

Machine learning pipelines consist of three stages [5].

- (1) **Preprocessing.** In this stage, the raw data is loaded and cleaned. The data is normalized, and any inconsistencies from incorrect or missing measurements are corrected for or removed.
- (2) **Training and Verification.** In this stage, the cleaned data is used to train the model. Typically the training set is divided into parts, and techniques like cross validation are used to prevent overfitting the model.
- (3) **Classification.** In the final stage, the trained model is used to classify new data. In this stage, the model can still be refined further based on new data or new properties of the data.

The preprocessing stage can often be performed entirely within traditional database management systems. Loading data and simple cleaning operations such as missing value removal can be done using standard SQL queries. However, when more advanced

preprocessing such as interpolation is required, user-defined functions can be used to simplify this step.

The real challenge of integrating these pipelines into databases, however, is implementing the machine-learning models. The models rely on complex math operations and iterative refinement, which are not supported by standards-complaint SQL.

There are many libraries and packages in vectorized scripting languages that implement common machine learning and classification models, such as TensorFlow [1] and Sci-Kit Learn [13]. Using vectorized user-defined functions, we can plug these libraries into the database. However, the typical processing pipelines must be adjusted so they can fit into a SQL workflow. In this section, we will describe how these analytical pipelines can be integrated into traditional database management systems through the use of user-defined functions.

3.1 Training

To train a classification model, we take a set of annotated data as input and use the annotations to find patterns in the data. After learning these patterns, the trained model can accurately classify un-annotated data.

The training pipeline therefore takes as input a set of columns representing the data, and a single column representing the classes of the data. This will be the input to our user-defined function. The output of this stage of the pipeline is the trained model, which will be the output of our UDF. The actual creation and training of the model will happen inside the function.

Model Storage. Models exist as in-memory objects within the scripting language. However, they can be serialized to a binary format for persistent storage on disk. In Python, this is done using the pickle library. In order to store the objects in the database we need to serialize the objects to this binary format, after which we can place them in a BLOB field.

Listing 1: Training The Model

```

1 CREATE FUNCTION train(data INTEGER, classes INTEGER,
2   n_estimators INTEGER)
3 RETURNS TABLE(classifier BLOB, estimators INTEGER)
4 LANGUAGE PYTHON
5 {
6   import pickle
7   from sklearn.ensemble
8     import RandomForestClassifier
9
10  clf = RandomForestClassifier(n_estimators)
11
12  clf.fit(data, classes)
13
14  return {'classifier': pickle.dumps(clf),
15         'estimators':n_estimators }
16 };

```

An example of a user-defined function that trains a Random Forest Classifier using Sci-Kit Learn is given in Listing 1. This is a vectorized user-defined function, and as such both data and classes are vectors of integers within the function instead of individual elements. This function can be called from within SQL with the model data, classes and the amount of estimators (i.e., model parameters) as input, and will produce a table containing the trained classifier and its meta-data as output. This table can either be stored in the database, or used directly as input to another function that uses the trained classifier (if no persistent storage is necessary). Note that it is trivial to alter this UDF to train a different model from the Sci-Kit Learn library, as all that is required is importing a different model and using that.

3.2 Classification

After the model has been trained, it is ready to accept unlabeled data and can be used to classify that data. The classification stage therefore takes as input a set of columns representing the unannotated data, and the trained classifier that will be used to classify the data. The output is the set of predicted labels produced by the classifier. Inside the user-defined function, the classifier will again have to be deserialized into an in-memory object, after which it can be used to classify the input data and produce a set of labels.

An example of a user-defined function that classifies a set of data is given in Listing 2. This function can be called from within SQL with the unlabeled data and the classifier as input, and will produce a list of predicted classes.

Listing 2: Classification

```
1 CREATE FUNCTION predict(data INTEGER, classifier BLOB)
2 RETURNS INTEGER
3 LANGUAGE PYTHON
4 {
5     import pickle
6     classifier = pickle.loads(classifier)
7     return classifier.predict(data)
8 };
```

The predict function can be used both to test a trained model and to classify a set of new data using such a model. The model can be tested by predicting a set of data for which the labels are known, and comparing the predicted labels against the new labels. The model can be used to

3.3 Ensemble Learning

In addition to only storing the trained models, we can store additional metadata about the models in the database. This metadata can include information such as parameters used to instantiate the model, or information about the effectiveness of the model obtained through testing it against certain datasets. We can then choose a model to classify new data based on this metadata, or we could classify the data using multiple models that are stored and use the results from the classifier with the highest confidence.

4 EXPERIMENTAL ANALYSIS

In this section, we demonstrate how a real classification pipeline can be integrated into a column-store database, and show how the in-database processing pipeline performs when compared against the same pipeline implemented in a standard scripting language where the input data is loaded from a file or transferred over a database socket connection.

The pipeline we use in our experiments is used to attempt to classify who people from North Carolina will vote for in the Presidential Elections based on data from the 2012 Presidential Election. For this purpose, we use two separate datasets:

- **The North Carolina Voters Dataset** contains the information about the individual voters. This is a dataset of 7.5M rows, where each row contains information about the voter. There are 96 columns in total, describing characteristics such as place of residence, gender, age and ethnicity. Note that we do not know who each person actually voted for, as this information is not publicly available.
- **The Precinct Votes Dataset** contains the aggregated voting statistics for each precinct, (i.e., how many people in each precinct voted Democrat, and how many voted Republican). This dataset has 2751 rows, one for each precinct in North Carolina.

By combining these two datasets we can attempt to classify individual voters. We know the voting records of a specific precinct, and we know in which precinct each person voted, so we can make an educated guess who each person voted for based on this information.

Preprocessing. As we do not have the true class labels for each voter, we have to generate them from the information we have about the precincts. This requires us to join the voter data with the precinct data, giving us the voting records of the precinct that each voter voted in. We then generate a “true” class label for each voter using a weighted random function based on the precinct voting records. For example, if voters in a specific precinct voted for Democrats 60% of the time, each voter in that precinct has a 60% chance of being classified as Democrat and 40% chance of being classified as Republican.

Training. After we have generated the true class labels, we have to train the model using the data and the labels. However, we don’t simply want to use all the data for training. Instead, we want to divide the data into a training set and a test set to prevent overfitting. We then feed the data in the training set to the model using the function shown in Listing 1 and store the resulting model in the database.

Testing. After the model is trained, we want to test how it performs by classifying the data in the test set and looking at the results. We can classify the voters in the test set by running the function shown in Listing 2. After having obtained the predicted class labels, we can test the accuracy of our model by comparing against the known true class labels of the data. However, since we only have the generated class labels of the individual voters, comparing the predicted labels against those would not give us a lot of information about our classification accuracy. Instead, we aggregate the total amount of predicted votes for each party by precinct. Then we compare the aggregated predictions against the known amount of votes in each precinct.

Performance Analysis. To determine how well our in-database processing solution performs compared to ad-hoc analysis pipelines we have implemented the pipeline described above both (1) using MonetDB/Python UDFs and (2) inside Python, using various different methods of initially loading the data. For loading the data in Python, we have experimented with loading from binary files (NumPy [20] files and HDF5 [18] using PyTables), CSV files using an optimized parser, transferring the data to Python through a database socket connection (with PostgreSQL [17], MySQL [21] and SQLite [3] as database servers). For the scenarios where the data is stored inside a relational database, we use SQL to perform the preprocessing steps involving joins and aggregations. Whereas for the pure Python solutions, we use the Pandas library [11] to perform these steps.

The experiments were run on a Fedora (Release 26) machine with 2.6GHz 8-core Intel Xeon processor (Turbo Boost up to 3.2GHz), 20MB shared L3 cache and 256 GB of RAM. All the tests are hot runs. The datasets and source code used for the experiments are publicly available¹.

Results. The results of the benchmark are displayed in Figure 1. The numbers display the total time required to run the entire classification pipeline, whereas the bottom gray bars indicate the time spent loading the initial data into Python and performing the initial preprocessing steps and aggregations.

¹<https://github.com/pholanda/VoterClassification>

Figure 1: Voter Classification Benchmark

We can see that the in-database processing solution using MonetDB/Python is significantly faster than the alternative database solutions. The time spent on initial wrangling of the data is an order of magnitude lower than transferring it over a socket connection using the other database solutions. We also note that loading the data from CSV files is comparable in speed to transferring the data over a socket connection.

Loading the data from binary files is much faster than loading from structured text or transferring the data over a socket connection. However, this introduces additional challenges in managing the data. Especially in the case of NumPy binary files, where each of the 96 columns is stored as a separate file on disk. We do still see that the in-database processing solution spends less time on initial wrangling of the data and runs the entire pipeline significantly faster.

5 CONCLUSION

In this work, we have shown how complex analysis pipelines can be efficiently integrated into column-store databases. Using these pipelines, it is possible to perform preprocessing, training, testing and prediction using complex machine learning models directly on data stored within a relational database. We have demonstrated the efficiency gained from using these in-database processing methods, and shown the additional benefits that come with storing data in a relational database system.

5.1 Future Work

In our pipeline, there is still some unnecessary overhead in the serialization of the models. Whenever a model is stored in the database, we are serializing it to a BLOB. Before it can be used again, it must be deserialized. For larger models, this can have a performance impact. The database system could be extended to directly store snapshots of the in-memory representation of the models to avoid this (de)serialization overhead.

Additionally, we have only experimented with datasets that fit in memory. Additional work could be done on working with

out-of-memory datasets, distributed execution of the UDFs, or applying several models to the data in parallel.

ABSTRACT

Machine learning techniques for data stream analysis suffer from concept drifts such as changed user preferences, varying weather conditions, or economic changes. These concept drifts cause wrong predictions and lead to incorrect business decisions. Concept drift detection methods such as adaptive windowing (ADWIN) allow for adapting to concept drifts on the fly.

In this paper, we examine ADWIN in detail and point out its throughput bottlenecks. We then introduce several parallelization alternatives to address these bottlenecks. Our optimizations lead to a speedup of two orders of magnitude over the original ADWIN implementation. Thus, we explore parallel adaptive windowing to provide scalable concept detection for high-velocity data streams with millions of tuples per second.

1 INTRODUCTION

Machine learning (ML) techniques gain more and more adoption in stream analysis. They enable various use-cases such as theft detection, event classification, and failure prediction. In a nutshell, ML techniques train a ML model and apply that model when they process stream tuples (e.g., to classify them). Concept drifts cause a discrepancy between ML models and reality, which makes concept drifts a crucial challenge for machine learning on data streams. High discrepancies lead to incorrect predictions and wrong results. As a consequence, we need to continuously monitor concept drifts and retrain ML models accordingly. Stream processing engines require scalable solutions for concept drift detection and adaptation to execute ML techniques on high-velocity data streams with millions of tuples per second.

A naive approach to cope with concept drifts is to retrain the ML model periodically on a fixed size batch of recent data. This periodic re-computation is in conflict with the real-time requirement of stream processing applications for two reasons: (i) Models do not yet cover the most recent data when they are applied although the most recent data might indicate a concept drift. (ii) The data, which is reflected in the model, indicates concept drifts leading to deviations between model and reality.

In contrast to the naive solution, a wide range of approaches detects concept drifts on the fly [8]. Some monitor the evolution of different performance indicators [10, 12], while others observe the distributions on two different time-windows [9].

We study the scalability limitations of such approaches on the example of *adaptive windowing* (ADWIN) [2]. In general, ADWIN maintains a *global window* of adaptive size which is the data basis for the model computation. It trades off the variance in the *global window* (i.e., the data variance reflected in the model) against the size of the global window (i.e., the amount of data reflected by the

model). We chose ADWIN because it has proven its capabilities in a wide range of real-world applications: ADWIN was combined with Kalman Filters and demonstrated with Naïve Bayes and k-means clustering [1]. Furthermore, ADWIN is used for an online version of the Bagging method by Oza and Rusell [5] and in a parameter-free variant of the Space Saving algorithm [4]. Moreover, ADWIN is available in the open source MOA framework [3].

In this paper, we present the following contributions:

- (1) We analyze the original ADWIN approach, point out its scalability limitations, and identify its bottlenecks.
- (2) We parallelize ADWIN to overcome its bottlenecks and to provide scalable concept drift adaptation in real-time.
- (3) We evaluate the latency and throughput of our solution. It achieves two orders of magnitude speedup over the original ADWIN implementation and 54 times speedup in comparison to an optimized sequential implementation.

The source code of our implementation is available on GitHub¹.

In the remainder of this paper, we discuss ADWIN and its bottlenecks in Section 2, present our parallel adaptive windowing approaches in Section 3, and evaluate them in Section 4.

2 CONCEPT DRIFT DETECTION WITH ADAPTIVE WINDOWING

In this section, we present the original ADWIN algorithm [2] (Section 2.1), discuss an optimization based on exponential histograms (Section 2.2) and analyze the performance of the open source ADWIN implementation (Section 2.3).

2.1 The ADWIN Algorithm

ADWIN is an algorithm which detects concept drifts on the fly and adapts ML models accordingly. The algorithm maintains an adaptive window which is the basis for computing the ML model. ADWIN grows the window (i.e., adds the most recent tuples) as long as there is no concept drift detected. As a result, the model can rely on growing training data. ADWIN shrinks the window by removing old tuples when it detects a concept drift.

The algorithm does not require users to configure minimum or maximum times between concept drifts in advance because it identifies concept drifts on a per-tuple basis. This removes an important drawback of approaches which use fixed-size windows (i.e., batches) of data to recompute models periodically. In ADWIN, users configure only the confidence value $\delta \in (0, 1)$ to adjust the sensitivity of the concept drift detection.

When processing a stream tuple, ADWIN first adds the tuple to the adaptive window. Then, the algorithm analyzes the content of the adaptive window to identify concept drifts. To that end, ADWIN iterates over all possible combinations of two *large enough* sliding subwindows, as shown in Figure 1. If the value distributions of the two subwindows are *different enough*, ADWIN detects a concept drift and removes the oldest tuple from the

Figure 1: Iterations of the cut check procedure in ADWIN

Figure 2: Exponential histogram: We first assign tuples to buckets of exponential size. We then compress buckets and store sums and variances only.

adaptive window. We call this *cut detection* because it determines when to *cut* the adaptive window in order to remove old data. The cut detection repeats removing old tuples until the content of the adaptive window does not indicate a concept drift anymore.

2.2 Exponential Histograms

A naive ADWIN implementation is computationally expensive because it performs a cut check for all possible combinations of subwindows for each tuple of the input stream. To address this problem, ADWIN uses an *exponential histogram* as underlying data structure of the adaptive window [7]. The exponential histogram assigns input tuples to buckets (Step 1 in Figure 2). Buckets of recent data contain just a few tuples. Buckets of older data contain an exponentially growing number of tuples. Each bucket stores the sum and variance of its tuples only. This reduces the memory consumption of the histogram (Step 2 in Figure 2). In summary, the number of buckets and the respective memory consumption grow logarithmically when the adaptive window grows. The cut check procedure now compares buckets instead of per-tuple subwindows which leads to an $O(\log(n))$ complexity for the cut-check procedure. Thereby, n is the number of tuples in the adaptive window and $\log(n)$ the number of buckets.

Figure 3 shows an overview of the ADWIN algorithm including exponential histograms. The algorithm performs two tasks:

- (1) ADWIN inserts arriving tuples to the adaptive window, i.e., the exponential histogram (Step 1.1 in Figure 3). This occasionally causes bucket compression and fusion of smaller buckets to larger buckets (Step 1.2 in Figure 3).
- (2) ADWIN detects concept drifts with its *cut detection* procedure and potentially removes old data from the histogram.

In the following subsection, we analyze the runtimes of the different tasks and thereby identify the bottlenecks.

2.3 Initial Performance Analysis

As a starting point of our work, we study the original ADWIN implementation, which is also part of the MOA framework [3]. This implementation is not parallel, i.e., it runs in a single thread. As we will show in detail in our experiments in Section 4, the single thread version has a low throughput compared to our parallel approaches which we present in Section 3.

Figure 3: ADWIN overview: New tuples are added to the histogram (1.1), buckets are compressed (1.2), and the cut detection procedure identifies concept drifts (2).

Figure 4: Runtime distribution among ADWIN tasks

In order to identify the bottlenecks of the existing implementation, we use JProfiler² and Java VisualVM³ for performance profiling. In Figure 4, we show the processing time distribution among the tasks performed by ADWIN. A single thread implementation spends about 98% of its runtime with cut checks. In comparison, the time spent on maintaining the exponential histogram is almost negligible as it contributes only 2.2% to the total processing time of a tuple. Although the number of buckets grows logarithmically with the number of tuples contained in the histogram, bucket comparisons dominate the execution effort since they are performed for each tuple. Based on the observations above, we focus our optimizations on parallelizing the cut check procedure because it exhibits the largest saving potential.

In our code analysis, we identified ways to improve the original ADWIN implementation. We did a logically equivalent reimplementa-tion to speedup the execution. The major improvement of our reimplementa-tion is the use of circular array buffers as an underlying data structure for the histogram. This reduces memory copy operations compared to the original implementation.

3 PARALLEL ADAPTIVE WINDOWING

In this section, we introduce several approaches to parallelize ADWIN in order to improve its throughput. We focus on parallelizing the *cut detection* because we identified it as bottleneck in Section 2.3. We discuss single-node parallelization in Section 3.1 and multi-node parallelization in Section 3.2.

3.1 Single-Node Parallelization

In Figure 5, we show in pseudo code how ADWIN processes an input tuple and point out possible single-node parallelizations. We present each parallelization in detail in the following subsections. First, we decouple histogram updates and cut-checks from each other such that cut-checks cannot delay processing input tuples (Section 3.1.1). This decoupling is generally applicable to algorithms that store stream statistics in a separate data structure. Then, we parallelize the cut-check procedure itself which we call *Intra Cut-Check Parallelization* (Section 3.1.2). Finally, we discuss how to perform multiple cut-check procedures in parallel in case ADWIN detects cuts. We call this *Inter Cut-Check Parallelization* (Section 3.1.3). Both parallelizations are generally applicable to all algorithms which use multidirectional iterable datastructures.

²JProfiler: <https://www.ej-technologies.com/products/jprofiler/overview.html>

³VisualVM: <http://visualvm.java.net>

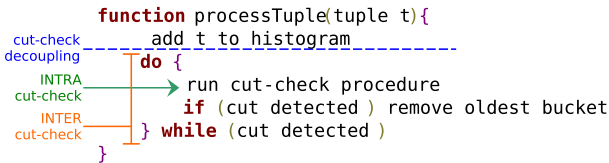

Figure 5: Scope of ADWIN parallelizations.

Figure 6: Optimistic ADWIN Decoupling histogram maintenance and the cut detection procedure.

3.1.1 *Cut-Check Decoupling.* We introduce an optimistic parallelization of ADWIN which assumes that most input tuples do not indicate a concept drift (i.e., a cut). This assumption regularly holds for big data streams, because real-world data follows laws of nature and causes few cuts compared to the number of tuples.

As explained in Section 2, ADWIN performs two tasks: updating the histogram with new tuples and detecting concept drifts with a cut detection procedure. Originally, ADWIN performs these tasks in succession for each tuple. This limits the throughput because the cut detection blocks the processing of the input stream.

In *Optimistic ADWIN*, we decouple histogram updates and cut checks from each other to overcome throughput limitations. The algorithm performs cut checks on a separated *snapshot histogram* and adds new tuples to a *primary histogram* concurrently. We synchronize histograms after each run of the cut check procedure.

We illustrate *Optimistic ADWIN* in Figure 6. One thread adds new input tuples to the primary histogram and a redo log. Another thread creates a deep copy of the primary histogram (step 1) and performs the cut check procedure on this copy (step 2). In case of a concept drift, we initiate a rollback which replaces the primary histogram with the snapshot manipulated by the cut detection procedure (step 3). Finally, we use the redo log to add missing input tuples to the primary histogram again. The overall process repeats continuously. Thereby, the majority of runs does not detect a cut and requires no rollback.

The main benefit of *Optimistic ADWIN* is that the cut detection procedure cannot block the input stream anymore. During one execution of the cut check procedure, new tuples are processed already. It is important to notice that *Optimistic ADWIN* introduces a latency between the insertion of a new tuple in the primary histogram and the notification about a cut. We discuss this effect in detail in Section 4. Our experiments show that we achieve detection latencies below 15 μ s with *Optimistic ADWIN*.

3.1.2 *Intra-Cut-Check Parallelization.* A single thread execution of the cut-check procedure starts to check for cuts at the ending of the histogram and moves towards the beginning (top of Figure 7). Thereby, the algorithm compares sliding subwindows as described in Section 2.1. This comparison requires sums and variances of subwindows, which are aggregates of sums and variances of buckets covered by the subwindows. The algorithm updates the aggregates of subwindow (i.e., the aggregation of buckets) incrementally when moving from one iteration to the next. As initialization for the cut-check iteration, the histogram stores and maintains its overall aggregate.

Figure 7: Half-Cut ADWIN: Parallelisation of the cut check procedure with two threads. Both threads iterate till the middle of the histogram.

We change the cut-check iteration such that two cut checks run in parallel. To that end, we introduce *Half-Cut ADWIN* in Figure 7 (bottom). Since the cut check in each iteration step is independent of cut checks of previous iteration steps, two threads can iterate over the histogram concurrently. Thereby, each thread covers half of the cut-check positions. One thread starts at the beginning and moves towards the end of the histogram and the other thread moves in the opposite direction. Both threads still update subwindow aggregates incrementally in each iteration step. *Half-Cut ADWIN* terminates the cut check procedure when both threads reach the middle of the histogram or when it finds a cut. This leads to a maximal speedup factor of two and halves the latency of the cut detection. It is also easy to add on top of existing histogram implementations.

In general, the concept of *Half-Cut ADWIN* extends to more than two threads. Therefore, the histogram needs to maintain additional aggregates of subwindows as initialization for additional threads. This overhead pays off for large histograms only. Since the number of buckets grows logarithmically, a high degree of Intra-Cut-Check Parallelism pays off seldom considering the overhead for aggregate maintenance in the histogram. *Half-Cut ADWIN* does not have this overhead because it uses the same aggregate as initialization for both threads.

3.1.3 *Inter-Cut-Check Parallelization.* If ADWIN finds a cut, it removes the oldest bucket from the histogram and repeats the cut check procedure till no further cuts are detected. This enables a *pessimistic parallelization* which assumes that we detect further cuts after removing old buckets from the histogram. While thread 1 performs cut checks on all buckets 1..n, thread 2 could already check if there will be another cut after removing an old bucket and perform cut detection on buckets 2..n. This extends to $n - 1$ parallel cut check procedures each of which could also apply *Half-Cut ADWIN*. However, the detection of cuts is usually rare compared to the total number of cut check procedures. Inter-Cut-Check Parallelization is not beneficial when we detect no cut. Respectively, we expect a minimal speedup from this approach. Still, it can reduce the latency of the cut detection, which is valuable for situations with frequent concept drifts.

3.2 Multi-Node parallelization

It is desirable to distribute stream processing applications over multiple nodes in a cluster in order to achieve linear speedup. Common distributed streaming engines such as Apache Flink [6] and Storm [11] achieve data parallelism on multiple nodes with data partitioning. Thus, each node is responsible for processing tuples of certain keys (e.g., user ids, regions, or event classes). *Half-Cut ADWIN* and *Optimistic ADWIN* are complementary to this approach and increase the throughput per partition.

It is also possible to distribute the cut detection procedure on multiple nodes. However, this requires a central shared histogram

or histogram copies with multi-version concurrency control. The coordination and network overhead for these histograms would dominate the processing in our network-bounded cluster and prevent a speedup. However, multi-node parallelization of cut checks can be beneficial if we overcome the network bottleneck with technologies such as InfiniBand.

4 EVALUATION

In this section, we provide an experimental evaluation of *Half-Cut ADWIN*, *Optimistic ADWIN*, and the state-of-the-art. We discuss our setup in Section 4.1 and present our results in Section 4.2.

4.1 Experiment Design

Throughput. The throughput of *ADWIN* depends on the size of the histogram. Large histograms contain more buckets and, thus, require more cut checks. More concept drifts (i.e., cuts) increase the throughput by reducing the histogram size. Our experiment measures the throughput for different histogram sizes.

Latency. We analyze the latency between adding a tuple to the histogram and the completion of the cut check procedure. This corresponds to the detection latency of cuts. We show the worst-case execution time of the cut check procedure which corresponds to finding a cut at the last cut check position. In addition, the latency of *Optimistic ADWIN* includes the waiting time of a tuple in the primary histogram before the decoupled cut check procedure starts. We show a range of latencies which reflects the shortest and longest possible waiting time.

Data. Since the overhead of *Optimistic ADWIN* is negligible, the performance depends on the histogram size only. Therefore, we generate batches of constant values and measure their insertion times. The insertion times include performing cut detections.

Execution Environment. We measure runtimes and latencies with *JMH*⁴ which enables reliable and reproducible microbenchmarks on a Java Virtual Machine. We run all experiments on a machine with 8GB RAM and an Intel Core i5-4210U processor.

Algorithms. We compare four versions of *ADWIN*. The open source version⁵, our optimized sequential version (Section 2.3), *Optimistic ADWIN* (Section 3.1.1), *Half-Cut ADWIN* (Section 3.1.2).

4.2 Results

Throughput. The left plot in Figure 8 shows that our sequential reimplementation is on average 5 times faster than the original implementation. *Half-Cut ADWIN* is 10 times faster than the original implementation. As expected, *Half-Cut ADWIN* is almost 2 times faster than our optimized sequential reimplementation because it reduces the execution time of cut checks by almost 50%. *Optimistic ADWIN* improves upon *Half-Cut ADWIN* by a factor of 27 and is 54 times faster than our optimized reimplementation. This leads to a 274 times speedup compared to the original *ADWIN* implementation. Moreover, *Optimistic ADWIN* decouples the insertion of tuples into the histogram from the cut check procedure. Therefore, its throughput is not directly correlated to the histogram size, which leads to a better scalability.

Latency. In the right plot in Figure 8, we show the latencies of different *ADWIN* versions depending on the histogram size. Our new *ADWIN* versions reduce latencies compared to the original implementation by up to 90% and at least by 50%. *Half-Cut ADWIN* has the lowest latency because it distributes the cut detection procedure on two threads without any snapshot and concurrency

Figure 8: Throughput (left), Latency (right)

control overhead. *Optimistic ADWIN* exhibits the largest variance (10 μ s) among the latencies of different tuples. This is because of the additional waiting time between adding a tuple to the primary histogram and the start of the next cut check procedure. In the worst case, a snapshot of the histogram was taken directly before inserting the tuple. This roughly doubles the latency because we first finish the cut check procedure on the recent snapshot before we do a cut check which includes the new tuple. While *Half-Cut ADWIN* decreases the latency compared to *Optimistic ADWIN* by 70% on average, *Optimistic ADWIN* show a 27 times higher throughput. In general, all latencies are in the range of microseconds which enables fast reactions on concept drifts.

5 CONCLUSIONS

Concept drift detection, with algorithms such as *ADWIN*, is a crucial component of stream analysis. We analyzed the bottlenecks of the *ADWIN* algorithm and discussed several approaches for its parallelization. Our *Optimistic ADWIN* algorithm decouples the concept drift detection and the window maintenance. Its evaluation shows that it has two orders of magnitude higher throughput and an at least 50% lower latency than state-of-the-art solutions.

ABSTRACT

Venue recommendation in location-based social networks is among the more important tasks that enhances user participation on the social network. Despite its importance, earlier research have shown that the accurate recommendation of appropriate venues for users is a difficult task specially given the highly sparse nature of user check-in information. In this paper, we show how a comprehensive set of user and venue related information can be methodically incorporated into a heterogeneous graph representation based on which the problem of venue recommendation can be efficiently formulated as an instance of the heterogeneous link prediction problem on the graph. We systematically compare our proposed approach with several strong baselines and show that our work, which is computationally less-intensive compared to the baselines, is able to shows improved performance in terms of precision and f-measure.

1 INTRODUCTION

The recent interest in location-based social networks (LBSNs) such as Foursquare and Gowalla has generated a high volume of user location information on the Web [17]. This has attracted researchers to analyze social data related to users' point of interests (POI) based on their preferences and personalities, which has the potential to improve the quality of higher-level applications such as civic planning, healthcare, advertising/marketing, and crime prediction [10], just to name a few. The recommendation of a point-of-interest to a given user based on her past activity is one of the applications that has already been explored by several authors [3]. These earlier works primarily use features such as spatial and temporal activity of users where both spatial features (location of venues) and temporal features (time of visit) are taken into account. The spatial features are extracted using the geographical information of the user check-ins, which are longitude and latitude of the venues. The collection of these features are then used to train classifiers to determine and recommend a point-of-interest for a given user.

In our work, we take a different perspective on the same problem of point-of-interest recommendation by formalizing user LBSN information in the form of a heterogeneous graph which consists of different node types including users, venues, venue categories, and geographical regions, among others. We propose that the problem of point-of-interest recommendation can be viewed as an instance of the link prediction problem on heterogeneous graphs. In this paper, we systematically show (1) how a collection of LBSN information including user relationships, past user-venue interaction history, venue category information and

geographical coordinates can be unified into and represented as a heterogeneous graph; (2) how meta-paths can be extracted from such a heterogeneous graph representation in order to identify potential links between users and venues (points-of-interest); and (3) that compared to much more complex baselines that incorporate spatio-temporal information into strong recommender techniques such as matrix factorization models, our proposed approach shows improved performance. We extensively compare our work with several state of the art techniques based on the gold standard dataset from [7] and show that while our heterogeneous link prediction model is quite computationally lightweight, it can offer improved performance over more computationally demanding techniques.

2 RELATED WORK

There has already been strong work on Point-of-Interest (venue) recommendation in the literature. Gamba et al. [4] have proposed an extended version of regular Markov Chains which incorporates the n previous visited venues of users. This model was then used for next location prediction using the users historical location visits. In their work, the next location of the users was predicted using the mobility Markov chain that was built for each individual user. Most of the location recommendation markov based models only use the geographical information of the locations without considering the context of the user footprints.

Matrix factorization has been widely used in location recommendation. In [2], matrix factorization is fused with geographical influence using Multi-center Gaussian Model (MGM) and social influence. In their work, location recommendation is based on the probability of a Gaussian distribution model, which is applied to the checked-in location centers along with the fusion framework with user preferences. However, the rich information of the check-in footprints such as the geographical context are not taken into account. In contrast, Yang et al. [18] have proposed a fusion framework, which exploits both spatial and temporal activity preferences (using tensor factorization) of users to predict their next point-of-interest. For each user, the spatial features are captured by building *Personal Functional Regions*, which are built based on frequented regions that the user visits. This model uses the spatial and temporal features separately for recommendation to users. In their work, each region is assigned with a category that the user is more interested in based on her historical visits. Therefore, when the user is near each region, the category assigned to that region is used for venue recommendation. Also, in this work, the lifestyle behavior of users is observed by using the temporal nature of the check-ins. It should be noted that Yang's model does not recommend venues to users and only recommends location categories.

Supervised learning models were also investigated in [9] for location recommendation. In this work, two supervised methods, linear regression and M5 trees were compared and it was

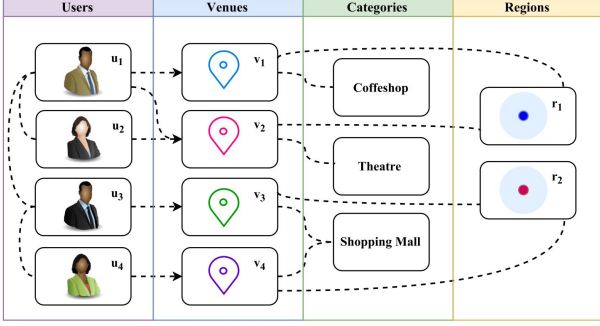

Figure 1: Sample heterogeneous graph representation of LBSN data.

found that M5 trees achieve higher prediction accuracy. Similar to other work, the set of features that were used for learning the classifiers were the user transitions between locations and spatio-temporal features of the check-in footprints. In our work, we have trained our model using the linear regression classifier and have achieved better recommendation accuracy due to using the features collaboratively and not individually compared to the work by Noulas et al. [9]. In [18] and [7], the importance of venue context information such as categories for location recommendation was also investigated. The accuracy of point-of-interest recommendations was improved by using the users' preferences that were based on the location categories they had visited. While in most existing work the current location of the user is needed for location recommendation; in our work, we show improved performance compared to the state of the art without requiring information about the last location of the user.

3 PROPOSED APPROACH

The objective of our work is to recommend a point-of-interest (venue) to a user based on her historical check-in data. Formally, given the check-in profile of a user in time interval t (Definition 1), we aim at recommending a list of venues that the user may be interested in at time interval $t + 1$.

DEFINITION 1. (User Check-in Profile). The check-in profile of user $u \in \mathbb{U}$ at time interval t , with respect to a set of venues \mathbb{V} , denoted by $CP^t(u)$, is represented by a vector of weights over the K venues, i.e., $(f_u^t(v_1), \dots, f_u^t(v_K))$, where $f_u^t(v_k)$ is equal to one if user u checked in at venue v in time interval t and 0 otherwise.

We propose to turn the problem of venue recommendation into a link prediction problem that operates over a heterogeneous graph. In addition to historical check-in data of users, there are other types of data that can be considered while recommending venues, namely venue categories, venue regions and user relationships. In this paper, we combine these data points into a unified heterogeneous graph representation model to consider them simultaneously. An illustration of our underlying representation model G can be found in Figure 1.

As illustrated in Figure 1, our representation model contains four types of nodes and four types of relations. Besides User and Venue nodes and User-Venue relations that represent historical check-in data of users, other types of data that are included consist of the following:

- **Category nodes:** In location-based social networks, venues are organized by a hierarchical category tree which provides a semantic classification of the various venues. For

Figure 2: Network schema of the representation model.

Table 1: Meta-Paths between users and venues.

Meta-Path	Meaning of the Meta-Path
$\mathbb{U} - \mathbb{U} - \mathbb{V}$	A user visits a venue where her friends have visited
$\mathbb{U} - \mathbb{V} - \mathbb{C} - \mathbb{V}$	A user visits venues that belong to the same category
$\mathbb{U} - \mathbb{V} - \mathbb{R} - \mathbb{V}$	A user visits venues located in the same region

example, Foursquare contains a 3-level category hierarchy where categories are grouped into 10 top-level categories, such as Event, Food, Nightlife Spot and Residence. Each top-level category is classified into different subcategories. In our approach, we have infused the categories at the lowest level (Level 3) as our category nodes.

- **Region nodes:** Each region indicates a geographical area. Given the longitude and latitude of existing venues, we use X-means clustering [11] to cluster geographical coordinates and extract different regions.
- **Venue-Category relations:** Based on the hierarchical category tree defined in LBSNs for organizing venues, we assign each venue to its corresponding category in the lowest level of the hierarchy.
- **Venue-Region relation:** To identify the region of a venue, we calculate the Euclidean distance between the venue geographical coordinate (longitude and latitude) and the center of the identified regions and connect each venue to its nearest region.
- **User-User relation:** Users are connected to each other based on the friendship relation among them on the LBSN. By using this relation, potential interaction between users is also taken into account for point-of-interest recommendation.

Having built the representation model G , in order to recommend a point-of-interest to a user $u \in \mathbb{U}$, we formulate a graph-based link prediction problem that operates over G . As our representation model is a heterogeneous graph, the neighbors of an object could belong to multiple types and the paths between two objects could have different meanings. Therefore, it is not possible to apply link prediction strategies such as Adamic/Adar and Common Neighbor, which treat all types of nodes and relations as the same in the form of a homogeneous graph [6].

Sun et al. [16] proposed the concept of heterogeneous information networks and the meta-path concept for heterogeneous information network analysis, which are now widely known and used in different data mining tasks such as ranking [8], clustering

[13], link prediction [1], and influence analysis [12]. In order to solve the problem of link prediction in heterogeneous graphs, Sun et al. [14] proposed the PathPredict method, i.e., meta path-based relationship prediction model to predict links between dissimilar node types. Therefore, to distinguish different types of objects and relations, following the works in [14, 15], we use the PathPredict method to determine the relevance of a point-of-interest $v \in \mathbb{V}$ for a user u . The core of the PathPredict method rests on the idea of *meta-paths*. A meta-path is a path defined over the heterogeneous network schema which can be used to define topological features with different semantic meanings. Figure 2 summarizes our representation model using a meta-structure known as the network schema.

Based on PathPredict, for the target relation $\langle \mathbb{U}, \mathbb{V} \rangle$, we define a set of meta-paths starting with type \mathbb{U} and ending with type \mathbb{V} other than the target relation itself. We extract all such meta-paths by traversing the network schema using Breadth-First Search (BFS) within a fixed length constraint ($\max = 3$). The extracted meta-paths and their semantic meaning are shown in Table 1. For example, The meta-path $\mathbb{U} - \mathbb{V} - \mathbb{C} - \mathbb{V}$, i.e., user-venue-category-venue considers those venues which belong to the same category of the historical check-in venues of a user as her next check-in venue.

Once the meta-paths are retrieved from the network schema, for each user-venue pair in the representation model G , we use the Degree-Weighted Path Count metric [5] to quantify each meta-path as a topological feature in the training step. For the given meta-path, Degree-Weighted Path Count penalizes paths, which pass through high-degree nodes. Then, given all user-venue pairs in the representation graph G and the extracted topological features for them, a logistic regression classifier is trained as the learning model to recommend a ranked list of points-of-interest for a given user.

4 EXPERIMENTS

In this section, we describe our experiments in terms of the dataset, setup and the details of the baselines used in the paper. The performance of our approach is then compared to the state of the art baselines and our findings are discussed.

4.1 Dataset and Experimental Setup

Our experiments were conducted on a dataset collected from the popular location-based social network of Gowalla introduced in [7]. It includes check-in data (longitude, latitude, timestamp, categories, among others.) of more than 600,000 users from Austin, Chicago, Houston, Los Angeles and San Francisco. For each user, we randomly select 70% of her check-ins to construct the training data and the remaining 30% of her check-ins for testing data as suggested in [7].

We compare our approach with several state of the art point-of-interest recommendation methods that are briefly described in the following:

- (1) **BasicMF** is a classical matrix factorization techniques, which only considers users’ past venue check-ins and, hence their preferences, for Point-of-Interest recommendation.
- (2) **GeoCF** [19] is based on both user preference and geographical influence which are integrated into a collaborative filtering model.
- (3) **MGMMF** [2] is a framework based on Multi-Center Gaussian Model, which combines both the user preference and MGM based check-in probability for Point of interest recommendation.
- (4) **Markov** [4] applies Mobility Markov Chain model for predicting next venue of a user based on her mobility behavior over different time intervals and the recent venues that she has visited.
- (5) **ML** [9] considers user mobility, global mobility and temporal features to describe users’ check-in behavior and applies M5 decision tree to predict the next POIs of a user.
- (6) **CPOIR** is one of the most related work in the literature by Liu et al [7], which proposes a Category-aware Point-Of-Interest Recommendation model that exploits the transition behavior of users between venue categories. They employ a matrix factorization model to predict the transition patterns of users’ interests over categories and consequently her interests in different venues.

For evaluation purposes, we measure the performance of the methods based on Precision@K, Recall@K and F1-score as suggested in [7].

4.2 Experimental Results

In this section, inline with [7], we compare the performance of our proposed approach with other state of the art baselines when Top-6 venues are recommended by each method. The results are reported in Table 2 in terms of Recall, Precision and F1-score.

It can be observed that BasicMF model, which is solely based on user interests performs worse than others for most of the cities and in terms of all three metrics. This means that incorporating other auxiliary information such as geographical, social, and temporal features leads to improved quality of venue recommendation. Markov models that incorporate temporal features outperform BasicMF; however, they perform much less accurately than the other baselines. This is because Markov models assume that a user’s mobility data is dense, as a result they may not perform so well on users’ venue data in LBSNs which is very sparse.

As another observation, MGMMF and GeoCF that fuse geographical influence and user interest into their proposed approach and take into account the correlation between these features offer more accurate recommendations compared to the ML model, which exploits geographical influence as a single feature. As mentioned before, the CPOIR model incorporates two novel features, i.e., the transition patterns of a user's interests among venues and venue categories, for the purpose of point-of-interest recommendation. It can be seen that CPOIR offers superior results compared to both MGMMF and GeoCF in all cities and in terms of all metrics. This demonstrates the benefits of these two factors to improve the quality of venue recommendations.

Inspired from these insights, in order to be able to utilize the benefits of useful features in a unified model for point-of-interest recommendation, we formalize user LBSN information in the form of a heterogeneous graph. As highlighted in Table 2, it is evident that our proposed approach outperforms all the comparison methods in all cities in terms of Precision and F1-score. This means that our approach can successfully take advantage of different features, i.e., venue categories, geographical influence, the relationship between users, and the correlation between these features to produce more accurate recommendations, i.e., less false positive. However, it can be observed that our proposed approach results in lower Recall values, i.e., more false negatives compared to others. In other words, our method is not able to identify those venues through the current limited set of defined meta-paths in this paper. To cover more meta-paths, as our future work, we intend to increase the length constraint of meta-paths, which is currently set to 3, and take into account more features in our representation model such as transition of user's interests and sentiments of user-venue related comments.

5 CONCLUDING REMARKS

In this paper, we have proposed that venue recommendation in location-based social networks can be viewed as an instance of the link prediction problem on heterogeneous graphs. As such, we have systematically shown how various types of information can be incorporated into a heterogeneous graph based on which distance metrics between nodes can be employed as features to learn ranking classifiers. We find that even a logistic regression method can effectively show competitive performance compared to the state of the art despite its simplicity and light-weight computational requirements. We further found that while our proposed approach shows improved performance over the baselines in terms of precision and f-measure, it does not show competitive performance in recall. This can be attributed to the fact that we have only employed three meta-paths and a depth of three in the BFS search.

Our future work will explore two synergistic directions: 1) We will explore whether a more extensive set of meta-paths defined over the network schema can lead to improved recall or not. We will also study whether a higher search depth is able to identify more relevant information that can be included in the link prediction process. 2) Some users provide written textual feedback about their experience at venues they visit. These include textual reviews or recommendations. We are interested in the possibility of incorporating such unstructured user feedback into the network schema to see whether textual feedback, while quite sparse, can improve the venue recommendation task.

ABSTRACT

Exploratory data analysis characterized by analytic query workloads over large databases is now commonplace on both academia and industry. In these scenarios, data production velocity and unknown and drifting access patterns make the choice of access methods a challenging task. In this context, adaptive indexing techniques propose the use of partial indexes that are incrementally built in response to the actual query sequence and as a byproduct of query processing to optimize the access only to the key ranges of interest. This work presents a further development to this principle by leveraging the recent query history to predict the next key ranges and index them in advance, so the queries arriving in the near future find data in its final representation and higher placed in the storage hierarchy, since data must be loaded into main memory in order to be indexed. Adaptive merging is used as base architecture for the data structures and merge operations are executed in parallel with query execution instead of being the same operation. An extreme learning machine is used to perform key range forecasting and undergo continuous training by the indexing thread. The experiments show up to 38% lower query response times over a 1000 queries than adaptive merging, therefore lower overall response times and the decoupling of indexing operations during scan executions.

1 INTRODUCTION

Important modern database applications do not have a known workload in terms of access patterns. Data subsets which are the focus of query attention change over time, and ad hoc queries should be expected. Examples of this kind of application are found in scientific work or in exploratory analysis, which is an increasingly common daily task in many business areas today. No assumptions can be made about the workload, and database systems must still be able to answer the queries from these dynamic workloads efficiently, searching through and updating suitable data structures to speed up query processing.

To accomplish this task, adaptive indexing [7] was introduced. By adapting the DBMS internal structures to quickly answer queries that follow the current trends, it enables the system to perform better according to the dynamic workload. The fundamental idea is that each time data is scanned to answer a user query, an incremental step is performed to provide an index structure or refine it, which will permit subsequent scans to prune the search space and perform better. Such operations must be simple in order to avoid adding a prohibitive overhead to query execution [2] while still being useful to speed up queries and save access to slow storage devices.

Changing database physical layout in response to the workload can be powerful if used properly. The advantages of optimizing access only for the records of interest is based on the fact that,

in most applications, a subset of the records is accessed more often than the rest. Partial indexes recognize this fact by focusing layout tuning in a subset of the indexed relation, but they lack the adaptive behavior and the possibility of incremental change. Instead of relying in periodic statistics observation, our approach continuously tracks the workload, since the access patterns and the set of records requested more frequently changes over time.

On the other hand, consider the situation in which, while trying to follow the query trends, the system organizes data in response to single queries which deviate from the underlying workload pattern. This wastes time and compromises performance. Additionally, the current query may not provide sufficient information to figure out the best key range to index in order to enable the next queries to take full advantage from the structure. More contextual information is needed. A workload model, instead of the advice from the current request, provides better guidance. These issues are similar to the problems of overfitting and generalization in pattern recognition tasks.

Improvements to adaptive indexing can be achieved by indexing key ranges not strictly equal to those of the query responses, possibly adding a stochastic component to the indexing process [4]. Another possibility is using periods of time when computing resources are not being exhaustively used to index key ranges not yet touched [10]. The main advantage of these approaches is the possibility of indexing a region of data that will be queried in the near future. When this happens, the response time will be optimal and the effort of indexing can be done independently of query processing, thus not incurring any extra overhead to it.

This work develops this analogy further by using an actual machine learning technique to create and continuously update a model of the query sequence. In other words, it leverages an adaptive structure and adds a predictive behavior to the index building operations based on a dynamic model of the workload, using the most recent requests as training data. By indexing data expected to be requested next, our index builder is less sensitive to anomalies, and avoids the effort of indexing uninteresting records. Such intelligent access structures fit naturally in the context the emerging self-driving systems [1], which promise to be able to handle highly dynamical and hybrid workloads while requiring even less manual operation than traditional systems.

The benefits of performing incremental indexing detached from query processing occurs when the forecasting succeeds and a key range is placed in the final index form before it is queried. In this case the access is logarithmic in the size of the indexed data, not on the total amount of data. If the forecasting predicts the wrong key range then the cost of the next query will be that of a scan in the partial index structure built in the first query, a partitioned B+ tree, as discussed in the next section. Even in this case, the scan will not be as costly as it would be in a strictly adaptive indexing scheme, because the scan algorithm will not have to move data around, but only to find the qualifying records. This scheme keeps the hypothesis that the workload is unknown, as in previous adaptive indexes, but it recognizes that application queries are not random, and an underlying pattern should exist.

2 METISIDX

MetisIDX is an indexing mechanism for relational data that targets secondary storage (HDDs, SSDs, etc) and uses the accumulated knowledge from previous queries in the workload to guide the index construction. The partitioned B+ tree, and some of the index creation and maintenance procedures are similar to those developed for adaptive merging [3]. A B-tree based structure was chosen to exploit its paged data transfer, which is naturally performed with block-addressed devices and permits meaningful data blocks to be exchanged between the levels of a memory hierarchy. However, differently from the adaptive merging approach, MetisIDX indexing routine is decoupled from data scanning and is less sensitive to workload anomalies since it leverages the information provided by multiple requests rather than the current query alone.

The learning algorithm must be lightweight enough to be executed in time frames that do not exceed the order of magnitude required to answer a single query. This constraint makes it impractical to use many state-of-art machine learning techniques such as massive deep neural networks, since using these methods would result in a training time long enough to make the resulting model already outdated, in the sense that it reflects a workload pattern that is already gone. Additionally, it must be able to update the model using new available data, new queries in this context, without discarding the previous model version altogether. A suitable technique that fulfills these requirements is the Extreme Learning Machine (ELM) [9], a class of neural networks which always has a single hidden layer, and only the weights of the connections between the hidden neurons and the output neurons must be trained.

The training data used in model updates is the sequence of key range boundaries from the last N queries processed by the system. N is a hyper parameter that has to be chosen. The trained network is the current model of the workload, used to forecast index range candidates and trigger a new merging operation. In the next training step the model is updated to keep track of possible workload trends shift. After that, the model is used to forecast the key range to be queried next, and a new merging operation is triggered. The process of training and triggering merges is carried out cyclically in a dedicated execution thread.

The first query triggers a full scan over the non-indexed data. During this first scan execution, data is read from secondary storage in chunks, called runs hereafter. Each run is then sorted using an algorithm suitable for main memory resident data. The records that belong to the query response set are then collected and returned to the user. The sorted runs are written back to disk as the leaves of a partitioned B+ tree and global ordering is achieved by introducing an artificial leading attribute whose value is the runs creation order.

The size of the runs is limited by the amount of main memory available and should be as big as possible, since longer runs provide fewer index partitions and thus faster access, because the tree must be traversed from root to leaf level for each partition. This partitioned index is already able to speed up the processing of subsequent queries, each time a search operation is executed the partitioned tree is traversed from the root to leaf level once per partition. In order to achieve optimal read access, the partitions must be merged into a single one so that the index becomes a regular B+ tree (not partitioned). In the adaptive merging [3] approach, partition merging and query processing are a single operation.

Algorithm 1: Forecast And Index Thread

Data: Predicates of last N queries
Result: Predicted query key ranges indexed continuously

```
1 while True do
2   if at least  $N$  new queries observed then
3     train neural network;
4     discard training data;
5   else
6     predict next key range;
7     if range is not locked by query thread then
8       acquire latch on key range;
9       merge key range to final index;
10      release latch;
11   end
12 end
```

In MetisIDX, two separate structures are used, one is the partitioned tree resulting from the first query, and the second, another B+ tree structure for the final index, which is composed of the results of the merging operations performed by the indexing thread. This design was chosen to minimize the efforts of structure maintenance, as a result, no merges are performed on the nodes of the partitioned tree, i. e. they are permitted to underflow and the height of the tree is fixed. In the final index, however, overflow checks happen and nodes are split as more data is moved from the partitioned tree to their final position. Adaptive merging, on the other hand, has to deal with structure maintenance for merges and splits, because the transition from the partitioned structure to the final index is accomplished by collecting the records that belong to the response set of the query and merging them into a final partition, which becomes the full index after a number of queries. All the partitions compose a single tree structure, including the final partition.

In order to answer a range query, such as the ones used in the experiment, the query processing thread traverses the partitioned tree once for each partition in the tree and collects the records of interest, then it proceeds to scan the final index to account for the case in which the required records have already been merged to that location. The predictive behavior of MetisIDX minimizes the need for the operation of scanning the partitioned tree since the merging operations are made in anticipation and eventually make entire partitions empty.

The decisions on which key ranges to merge and the actual merging operations are done independently and in parallel to query processing. Such decision process comes from the extreme learning machine that is continuously trained in background by a dedicated thread. That same thread is used to perform merges at the end of each training mini-batch. After each merging operation the indexing thread attempts to perform a new model update if enough new queries have been observed. An important difference between a predictive system and a strictly adaptive one is the fact that, by indexing a key range before it is queried, the records in the indexed range will be brought up to cache. This means that predictive indexing is also a predictive cache prefetching.

Algorithm (1) depicts this process. The whole procedure is executed in an infinite loop in the indexing thread, that continuously tries to perform merge operations if the required resources are not protected by a latch, and performs a training step if a number of queries have been observed. This number must be chosen by the user, for our setup we used 10.

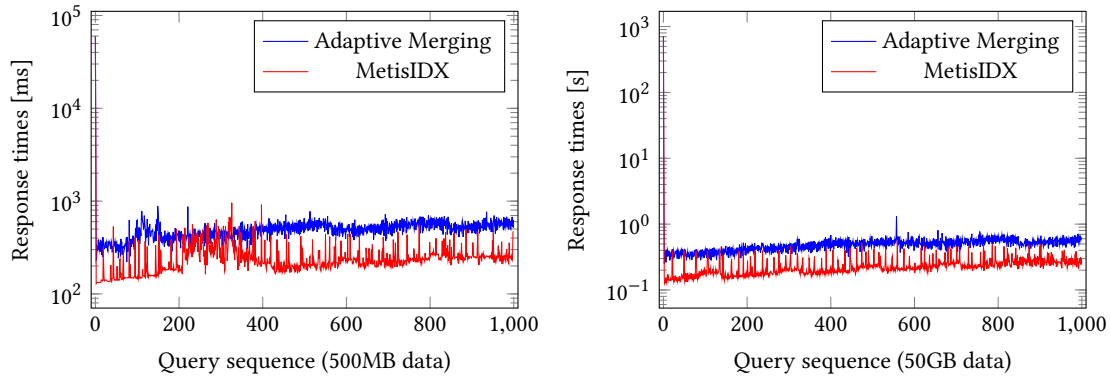

Figure 1: Response times

3 EXPERIMENTAL EVALUATION AND SETUP

MetisIDX and Adaptive Merging were both implemented for comparison in a custom storage engine named MetisDB, which implements the usual B+ tree access operations including persistence. The inclusion of adaptive merging and MetisIDX implementations in well known and complete database management systems would be a valuable way to fully evaluate and compare the performances and the implications for transaction processing by making the use of standard benchmarks possible. However, as pointed out by the authors of adaptive merging, conventional database architectures make a clear distinction between scans and index updates, treating the first as read-only, and the modifications needed to integrate the query-and-index strategies use in adaptive approaches call for whole new system architectures built with adaptive components in mind. This is the primary motivation for the MetisDB.

Since MetisIDX is not a strictly adaptive technique, and it adds indexing steps which are not part of query processing, it would make sense to compare it with Holistic Indexing, which has similar attributes. However, that technique is designed to work in the context of main memory column stores, while our approach targets tuple-based systems in secondary storage. For this reason Adaptive Merging is used as a baseline, as its application domain and data structures used are the same. The machine in which the experiments were carried out consists of a 3.1GHz Intel i5 processor, a 500GB, 7200RPM Seagate hard disk drive, and a 2x4GB DDR3 memory. The software stack is composed of a Debian GNU/Linux version 9 operating system and MetisDB was compiled using the GNU C++ compiler version 6.3.

The MetisDB storage engine contains a buffer manager that uses an LRU cache replacement policy on 8KB pages, LRU was chosen to favor recently loaded pages to remain in memory, as this is the case for recently indexed key ranges. Response times are used as a performance metric for the purpose of comparison. We use this metric instead of the usual I/O operations count used in disk-based access method evaluation because this quantity is not as directly linked to response times in MetisIDX as it is in other access methods. The reason is that, as we index data before query processing occurs and the indexing process must bring data up to the main memory cache, the select operator is expected to find its response set in the buffer pool. In other words, it does not matter how many disk accesses were performed if the data is in cache by the time one needs it.

The synthetic data used in the experiments consists of tuples with a 64bit integer used as the index key, and a 48B random string added to increase volume. Two tables were created, one containing 500MB and 7,106,208 tuples with the format described above, hereafter called $T1$, and another containing 50GB and 727,483,873 tuples, called $T2$. Two different data sizes were used to assess the effects of the domain size for the neural network predictions and cache invalidation, since the 500MB data can be entirely accommodated on cache while the larger one can not.

The query workload consists of 1000 range queries of the form `SELECT COUNT(*) ... WHERE A => QLOW AND A <= QHI`; where the key range limits, Q_{LOW} and Q_{HI} , are generated from a function Q that maps each query to a point in the search key space. Let the domain of the key be $[0, M)$ and j be the order of a query, then the Q used is

$$Q(j) = M \cdot (j/C)^2 \quad (1)$$

where M is the maximum value of the search key and C is the order of the last query, 1000 in the given setup. In this form Q will distribute the queries over the entire key range. From this function (1) Q_{LOW} and Q_{HI} are derived by

$$\begin{aligned} Q_{LOW}(j) &= Q(j) - R_1 \\ Q_{HI}(j) &= Q(j) + R_2 \end{aligned} \quad (2)$$

where R_1 and R_2 in (2) are random positive values generated by a normal distribution with standard deviation equal to 1% of the key range. This parameter determines the selectivity of the queries and additional executions with different values were performed with similar results. These are the functions the neural networks learn. A quadratic function was chosen to define the access pattern as it is a simple non-linear function, and the goal is not to test the ELM forecasting capabilities for complex functions as it is done elsewhere [5]. This quadratic function, even though non-linear, is a sequential access, the worst case for adaptive indexes since, as a key range is never queried more than once, each one faces the non-indexed part of the data.

Two ELMs were used, one learns Q_{LOW} and the other learns Q_{HI} , both as functions of j . Each network has one neuron in the input and output layers, since the target function is one-dimensional, and four neurons in the hidden layer. A test with 4 neurons was carried out and yielded the same results, since 4 is enough for such simple function. In a real application where the access pattern may be more complicated, the use of more neurons in the hidden layer is advisable.

Figure 2: Accumulated response times

Figure (1) shows the response times of MetisIDX and adaptive merging for the two data sizes. For both experiments the fact that the first query has a cost much higher than the ones that follow is visible, this result is compatible with the related work in adaptive indexing in general. The queries over the 500MB data have a noisy behavior likely due to the CPU usage of the training thread and other processes running in parallel, since the data is small enough to be all in memory after the first query. On the other hand, the queries over 50GB data have a more consistent behaviour and the advantage of decoupling indexing from query processing becomes clear. The soft increase seen along the query sequence is due to the growing number of cached pages, which increases the addressing costs.

Figure 2 Shows the accumulated query processing time, that is, the time spent to perform the first N queries as a function of N . The behavior of the curves show that as more queries are processed the gain in overall performance increases so that long running applications benefit the most from the technique. This also points a common trait of adaptive indexes, that is, as more queries are processed, the system gains knowledge of the data stored and of the workload.

In a few queries, the response times of MetisIDX jumps to the level of adaptive indexing. This happens when a key range starts being indexed and then is requested by a query before the indexing action finishes. It is the only situation in which the query processing thread waits. Since the observation window used is 10 queries and the indexing action for the next immediate query happens after each observation window, this is expected to be the periodicity of these peaks.

4 CONCLUSIONS AND FUTURE WORK

MetisIDX is able to speed up access by range queries by decoupling index building efforts from query processing while maintaining the workload oriented behavior of adaptive indexes. In this technique not only the current query is treated as a hint on how to physically organize the data but the entire query sequence is taken to be a sample of the underlying workload patterns. The workload is still assumed to be unknown, only the existence of an underlying pattern is required.

It shares the concurrency concerns of other adaptive techniques in terms of application access. Additionally, indexing occurs in parallel to query processing when the key ranges do not overlap. These considerations call for a latch free alternative to data structure access in order to alleviate latch contention, or

even make the two actions race free, and increase throughput. An option to address these challenges is the adaptation of the approach presented here to the context a latch-free B-tree based structure, such as the Bw-tree [8] and a multiversion strategy to distinguish the data accessed by the current query and that being indexed may also be an option.

An in-depth analysis of the overall concurrency issues would be valuable not only for this particular technique but for any machine learning and pattern recognition based access methods. These are interesting issues for big data exploration as building full indexes upfront is an increasingly less attractive option [6] as data volumes grow. Learning from the data not only about the information it carries but also about the best ways to access it is a reasonable and, as far as we know, open research problem.

Efficient SIMD Vectorization for Hashing in OpenCL

Tobias Behrens¹ Viktor Rosenfeld¹ Jonas Traub² Sebastian Breß^{1,2} Volker Markl^{1,2}
¹DFKI GmbH ²Technische Universität Berlin

ABSTRACT

Hashing is at the core of many efficient database operators such as hash-based joins and aggregations. Vectorization is a technique that uses *Single Instruction Multiple Data* (SIMD) instructions to process multiple data elements at once. Applying vectorization to hash tables results in promising speedups for build and probe operations. However, vectorization typically requires intrinsics – low-level APIs in which functions map to processor-specific SIMD instructions. Intrinsics are specific to a processor architecture and result in complex and difficult to maintain code.

OpenCL is a parallel programming framework which provides a higher abstraction level than intrinsics and is portable to different processors. Thus, OpenCL avoids processor dependencies, which results in improved code maintainability. In this paper, we add efficient, vectorized hashing primitives to OpenCL. Our results show that OpenCL-based vectorization is competitive to intrinsics on CPUs but not on Xeon Phi coprocessors.

1 INTRODUCTION

Modern processors support *Single Instruction Multiple Data* (SIMD) extensions. These *vectorized instructions* process multiple data values in a single instruction to increase the computational efficiency of a program. Database operators that use SIMD instructions are several times faster than scalar operators, because they process multiple tuples at once [8, 10, 11, 13].

Compilers expose SIMD instructions through function-like primitives called *intrinsics* [5]. Since intrinsics correspond directly to SIMD instructions of a processor, they are processor-dependent. Different processor architectures use specific instruction sets and each processor generation typically adds new instructions. Consequently, supporting vectorized database operators on different processors requires continuous maintenance of a growing code base and increases development costs.

Parallel computing frameworks such as OpenCL abstract from low level intrinsics and enable programmers to write code in a restricted dialect of C. The major advantage of OpenCL is its portability. Processor-specific compilers translate OpenCL programs to efficient machine code. OpenCL natively supports vectorized data types, which are directly compiled to the native SIMD instructions of a particular processor. However, OpenCL’s vectorized instruction set is limited to arithmetic, logical, and permutation operations. Therefore, we need to emulate more complex SIMD instructions such as *Gather* and *Scatter* [8].

In this paper, we leverage OpenCL to provide vectorized implementations of database operators which are portable to different instruction set architectures and processors (e.g., Intel CPUs and Xeon Phi coprocessors). OpenCL programs are implemented in special functions called *kernels*. We provide vectorized kernels for the data movement primitives *selective load*, *selective store*, *gather*, and *scatter* [8]. These primitives are essential building blocks of hash-based operators. We use vectorized hashing operations for

Figure 1: Vectorized data movement primitives. Grey boxes indicate values that are neither read nor written.

our case study because they are at the core of many database operators. Our results show that portable OpenCL-based hashing is competitive to processor-specific vectorized implementations.

Specifically, we make the following contributions:

- (1) We adapt vectorized data movement primitives to the OpenCL computation model. Using these primitives, we formulate explicitly vectorized algorithms of different data processing operations (Section 3).¹
- (2) We compare our OpenCL-based approach with intrinsics-based SIMD instruction sets – namely, AVX2 on a Haswell CPU and AVX512 on a Xeon Phi coprocessor (Section 4).

2 BACKGROUND

2.1 Vectorized Data Movement Primitives

Vectorized data movement primitives move data between *SIMD lanes* (i.e., the components of SIMD registers) and memory locations [8]. *Selective Load*, *Selective Store*, *Gather*, and *Scatter* are such data movement primitives. *Selective Load* (Figure 1a) selects data from *contiguous* memory (starting at an offset) and copies it into SIMD lanes specified by a bitmask. *Selective Store* is the inverse operation of *Selective Load*, which copies data from SIMD lanes into *contiguous* memory. *Gather* (Figure 1b) selects data from *discontiguous* memory and copies it into SIMD lanes. A separate SIMD register provides the pointers to data elements. *Scatter* is the inverse operations of *Gather* which copies data from SIMD lanes to *discontiguous* memory. Modern processors support these operations natively to a certain extent: The Intel Xeon Phi coprocessor, which uses the AVX512 SIMD instruction set, supports all four primitives. Intel Haswell CPUs, which use the AVX2 SIMD instruction set, support *Gather* operations only. However, Polychroniou et al. emulate these primitives using basic SIMD permutation instructions at a small performance penalty [8].

2.2 Vectorized Linear Probing in Hash Tables

A probe operation iterates over many keys. Vectorized hash tables use a SIMD register (k) to probe multiple keys (k_i) at once. We show the initial iteration step of vectorized hashing in Figure 2a:

- ① We load probe keys (k_i) into a SIMD register (k) with *Selective Load*. In the first iteration, we load all SIMD lanes as indicated by the green bitmask.
- ② For each probe key k_i in the SIMD register, we compute the hash h_i and store it in a SIMD register h . We keep separate SIMD registers for probe keys (k) and their hashes (h).
- ③ We use the hash values as position pointers in a *Gather* operation to load buckets from the hash table. We store the found keys in a new SIMD register k' .

¹Source Code: <https://github.com/TU-Berlin-DIMA/OpenCL-SIMD-hashing>

Figure 2: Vectorized operations on a linear probing hash table.

- ④ We compare the original probe keys (k) with the keys we retrieved from the hash table (k'). This comparison results in a collision mask (c). Light green boxes in the mask indicate matches and dark red boxes indicate collisions.

In our example, we find three expected keys: k_1 , k_3 , and k_4 . However, the hash table contains the key k_5 at position h_2 instead of k_2 , which indicates a collision (i.e., k_2 and k_5 have the same hash). In general, there are three possible cases per probe key: (1) The bucket contains the key. (2) The hash bucket is empty. (3) The key in the hash bucket and the probe key are different.

In cases one and two, we replace the matched probe key in k with a new probe key. In case three, we keep the probe key k_i , but increment its hash value h_i in h to probe the next bucket (Figure 2b, step ⑤). We now continue with the next iteration.

- ⑥ We use the collision mask to load new keys into the SIMD lanes for which there was no collision in the previous iteration, leaving key k_2 unchanged as described above.
- ⑦ We compute hashes for the new keys in k , leaving the value h_2+1 unchanged. Steps ③ to ⑦ repeat until all probe keys are processed.

Note that we need to write the payload (matched keys) into an output buffer with *Selective Store* between steps ④ and ⑤, e.g., to perform a hash join. For simplicity, we ignore empty hash buckets in the illustration in Figure 2. To handle empty hash buckets, we need to compute three bitmasks. The first bitmap (c') indicates found keys, the second bitmap (c'') indicates empty buckets, and the third bitmap (c) indicates collisions ($c = \neg c' \wedge \neg c''$).

If we are building a hash table, instead of using a *Gather* operation to load payloads, we use a *Scatter* operation to store keys. Since multiple SIMD lanes can point to the same hash bucket, we need to verify afterwards if the hash table contains the expected keys using steps ③ and ④. For successfully stored keys, we store the payload in the hash table using a scatter operation. For conflicting keys we need to probe the next bucket using step ⑤.

Note that the hash table is unaware of being accessed with vectorized operations. We can use the described scheme to access hash tables built with scalar operations and vice versa.

2.3 Related Work

Heimel et al. showed that OpenCL is a viable way to run database systems on heterogeneous processors [4]. Our work complements this research by porting vectorization optimizations to OpenCL. Pirk et al. introduced Voodoo – a vector algebra that abstracts from the underlying processor and generates OpenCL code [7]. Breß et al. introduced Hawk – a hardware-tailored code generator which produces custom code for heterogeneous processors [3]. Our work complements Voodoo and Hawk with templates for efficient vectorized hash tables in OpenCL.

Richter et al. showed a seven-dimensional analysis of hash tables [9]. Balkesen et al. [1] and Blanas et al. [2] studied efficient hash joins focusing on radix joins. Jha et al. optimized hash joins for Xeon Phi, but with limited use of SIMD instructions [6].

Zhou and Ross introduced vectorizations for major database operators (selections, joins, aggregations, etc.) [13]. They pointed out opportunities of SIMD in databases but did not apply SIMD to hash tables. Complementary to our work, Ye et al. evaluated different strategies for efficient aggregations on multi core CPUs [12].

3 PORTABLE VECTORIZED HASHING

In this section, we review vectorization support in OpenCL and present the internals of our OpenCL-based primitives *Selective Load*, *Selective Store*, *Gather*, and *Scatter*.

3.1 Vectorization Support in OpenCL

To implement data movement primitives, we use several built-in functions. OpenCL natively supports vector data types which represent SIMD registers. OpenCL also provides arithmetic and logical operations on vector types. For example, we compare two vectors containing four values in Listing 1. We can also access individual vector components by their indices which increase from left to right. For example, `probeKeys.s0` selects the left-most component containing the value k_1 .

```

1 uint4 probeKeys = {k1, k2, k3, k4};
2 uint4 foundKeys = {k1, k5, k3, k4};
3 uint4 mask = probeKeys == foundKeys; // {-1, 0, -1, -1}

```

Listing 1: Vectorized data types and operations in OpenCL.

The function `shuffle(input, mask)` returns a vector in which each component s_i contains the value of `input.sj` that is specified by the corresponding component s_i in `mask`, i.e., $j = \text{mask}.s_i$. The function `select(a, b, mask)` returns a vector in which each component s_i contains the value of `a.si` if `mask.si ≥ 0` and `b.si` otherwise.

3.2 Implementation of Primitives

Selective Load. Listing 2 shows the internals of the *Selective Load* primitive which we introduce with the other primitives in Section 2.1 (Figure 2a). The algorithm has four parameters: (1) `input`: source memory buffer, (2) `offset`: read offset on `input`. (3) `vector`: target vector, and (4) `mask`: indicates the components in `vector` which will be overwritten. The algorithm uses the parameters as follows: (1) It moves components which will be overwritten to the left of the target vector and adjusts the mask accordingly (Lines 3–6). (2) The algorithm loads the input data into a temporary vector (Line 7). (3) It copies the left-most values from the temporary vector into the target vector according to the mask (Line 8). (4) The algorithm moves the components of the target vector back to their original positions (Lines 11–12).

The shuffle functions used in steps 1 and 4 of the algorithm require permutation masks (left and back) to reorder the target vector. To speed up execution, we precompute these masks and store them in two lookup tables (one per step).

```

1 // Inputs: input, offset, vector, mask
2 // Outputs: offset, vector
3 ushort index =  $\sum_{i=0}^n -2^{n-i} \times \text{mask}.s_i$ ;
4 uchar8 left = convert_uint8(move_left_masks[index]);
5 vector = shuffle(vector, left);
6 int8 mask2 = shuffle(mask, left);
7 uint8 tmp = vload8(0, &input[offset]);
8 vector = select(vector, tmp, mask == -1);
9 offset += popcount(index);
10 // lines below can be omitted for optimization
11 uchar8 back = convert_uint8(move_back_masks[index]);
12 vector = shuffle(vector, back);

```

Listing 2: OpenCL implementation of *Selective Load*.

```

1 // Inputs: output, offset, vector, mask
2 // Outputs: offset
3 uchar index =  $\sum_{i=0}^n -2^{n-i} \times \text{mask}.s_i$ ;
4 uchar8 left = convert_uint8(move_left_masks[index]);
5 uint8 tmp = shuffle(vector, left);
6 vstore8(tmp, 0, &output[offset]);
7 offset += popcount(index);

```

Listing 3: OpenCL implementation of *Selective Store*.

```

1 // Inputs: input, vector, mask
2 // Output: vector
3 vector.s0 = input[mask.s0];
4 vector.s1 = input[mask.s1];
5 // ... up to vector.s7 = input[mask.s7];

```

Listing 4: OpenCL implementation of *Gather*.

We select the required permutation mask depending on the mask parameter (Line 3). The lookup tables together consume 4 KB and fit comfortably in the L1 cache.

Step 4 of the algorithm is only required if the calling code expects the components of target vector to remain in the original order. In many cases the calling code does not have this expectation. For example, the hashing scheme in Section 2.2 does not require the original order as long as reordering is mirrored between probe keys and the collision mask. Therefore, we optimize the general implementation shown above by omitting step 4 of the algorithm (Lines 11 and 12). This optimization discards one lookup table and saves the respective space in the L1 cache.

Selective store. The implementation of Selective Store is provided in Listing 3. It is similar to Selective Load and has the same parameters. Again, we move the components of vector that will be stored according to mask to the left (line 5). The values are then written to output (Line 6). Since the original vector is unchanged, we do not have to shuffle it back.

Gather and Scatter. We provide the implementations for the Gather and Scatter primitives in Listings 4 and 5. We access the components of vector and mask by their indices (see Section 3.1). Overall, we replace a complex and non-portable implementation based on intrinsics (Listing 6) with a fairly simple and portable implementation in OpenCL. Our implementation offers the same functionality, while improving maintainability and portability.

4 EVALUATION

4.1 Experimental Setup

Execution Environment. We evaluate our implementation on two processors, an Intel Core i7-6700K CPU² and a Xeon Phi 7120P coprocessor³ based on Intel’s MIC architecture. As of writing, the newer Xeon Phi Knights Landing (KNL) product line does not yet support OpenCL. On the Xeon Phi, we utilize 60 threads for our measurements to emphasize call overheads. On the CPU,

²4 GHz, 4 physical cores, 2 threads/core, 8 MB L3 shared, 32 GB RAM

³1.24 GHz, 61 physical cores, 4 threads/core, 512 kB L2 per-core, 16 GB RAM

```

1 // Inputs: input, vector, mask
2 output[mask.s0] = vector.s0;
3 output[mask.s1] = vector.s1;
4 // ... output[mask.s7] = vector.s7

```

Listing 5: OpenCL implementation of *Scatter*.

```

1 // Inputs: uint64_t* table, __m128i index
2 __m128i index_R = _mm_shuffle_epi32(index, _MM_SHUFFLE
3     ↪ (1, 0, 3, 2));
4 __m128i i12 = _mm_cvtepi32_epi64(index);
5 __m128i i34 = _mm_cvtepi32_epi64(index_R);
6 size_t i1 = _mm_cvtsi128_si64(i12);
7 size_t i3 = _mm_cvtsi128_si64(i34);
8 __m128i d1 = _mm_loadl_epi64((__m128i *)&table[i1]);
9 __m128i d3 = _mm_loadl_epi64((__m128i *)&table[i3]);
10 i12 = _mm_srli_si128(i12, 8);
11 i34 = _mm_srli_si128(i34, 8);
12 size_t i2 = _mm_cvtsi128_si64(i12);
13 size_t i4 = _mm_cvtsi128_si64(i34);
14 __m128i d2 = _mm_loadl_epi64((__m128i *)&table[i2]);
15 __m128i d4 = _mm_loadl_epi64((__m128i *)&table[i4]);
16 __m256i d12 = _mm256_castsi128_si256(_mm_unpacklo_epi64
17     ↪ (d1, d2));
18 __m256i d34 = _mm256_castsi128_si256(_mm_unpacklo_epi64
19     ↪ (d3, d4));
20 __m256i res = _mm256_permute2x128_si256(d12, d34,
21     ↪ _MM_SHUFFLE(0, 2, 0, 0));

```

Listing 6: SIMD implementation of *Gather* [8].

we utilize eight threads to emphasize attainable throughput. We use native implementations based on intrinsics [8] as a baseline. First, we perform microbenchmarks to measure the performance of our vectorized data movement primitives in isolation. We then evaluate the complete hash table implementation by executing a hash join. We separately measure building the hash table on the inner join table, and probing it with keys from the outer table.

Every experiment is executed 20 times. We prevent autovectorization of the scalar and intrinsics implementation. For each experiment we generate new test data to obtain unbiased results.

Load and Store. To evaluate both primitives, we stream 100 million keys (10^8 , 32-bit int) from memory into a SIMD register (or vice versa) and measure the throughput. For each invocation, we change the mask indicating which SIMD lanes are accessed, accessing four out of eight lanes on average. The large number of keys simulates a large outer table of a hash join.

Gather and Scatter. To evaluate Gather and Scatter, we read 100 million keys from discontinuous memory locations into a SIMD register. We use memory regions of different sizes, from 4 kB to 64 MB, to simulate hash tables built on inner tables used in a hash join. The stride size between the memory locations depends on the size of the memory region. Especially for large memory regions, we chose the indices so that the accessed data does not fit into the processor cache.

Hash Join Build and Probe. In general, we adopt the experimental setup of Polychroniou et al. [8] in order to obtain comparable results. We build a hash table on the inner table with a load factor of 50% and evaluate hash tables of different sizes, from 4 kB to 64 MB. On the Xeon Phi, we cannot build 60 hash tables of 64 MB in OpenCL due to OpenCL memory allocation restrictions. As the reference [8] does not provide an intrinsics implementation for the build on CPUs, we omit the curve.

To simplify partitioning the workload to different threads, the number of keys in the outer table depends on the processor. On the CPU, the outer table contains 100 million keys. On the Xeon Phi, it contains 245.76 million keys. We chose the keys in the outer table so that on average every tenth key is found in the hash table. Note, that our hash join implementation includes writing the matched probe keys to an output buffer.

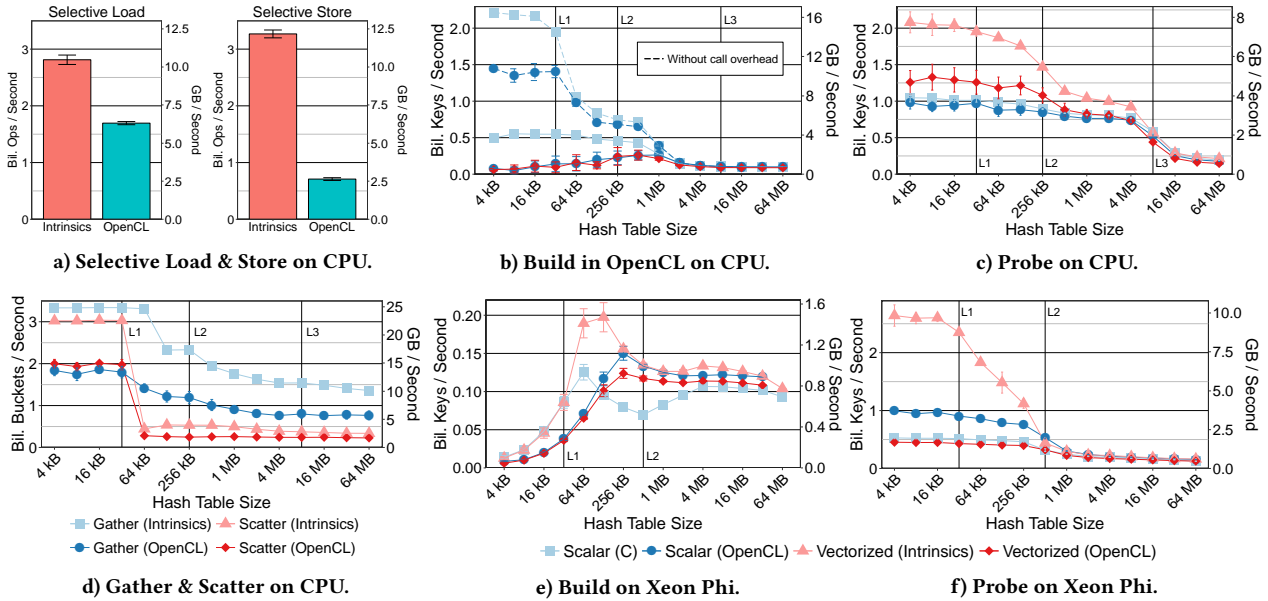

Figure 3: Evaluation results on the Intel Core i7-6700K CPU and Xeon Phi 7120 coprocessor.

4.2 Results

Selective Load and Store. Figure 3a shows the results of the Selective Load and Store microbenchmarks. The intrinsic-based version of Selective Load outperforms the portable OpenCL implementation by a factor of 1.75. The native Selective Store implementation is 4.6 times faster than the OpenCL version.

Gather and Scatter. Figure 3d shows the results of the Gather and Scatter microbenchmark. If the hash table fits into the L1 cache, the intrinsic implementation of Scatter is 1.5 times faster than the OpenCL version. However, if the hash table size exceeds the L1 cache, the performance of both implementations drops. The native implementations of Gather is between 1.75 and 1.9 times faster than the OpenCL-based implementation.

Hash Join Build. We present the results of the hash build experiment for the CPU in Figure 3b and for the Xeon Phi in Figure 3e. On the CPU, the OpenCL-based vectorized implementation is marginally slower than the OpenCL-based scalar implementation. Both are significantly slower than the C-based build and exhibit a curious rising trend up to a hash table size of 1 MB. This trend is due to overheads of OpenCL kernel invocations. To illustrate this, we also show scalar implementations which build 10000 hash tables inside a single function to minimize call overhead (dashed lines). These curves follow the expected shape. On the Xeon Phi, all implementations show a rising trend due to function call overhead. These overheads cause the bowl-shaped form of the curves which is most visible for the C-based scalar implementation. However, we cannot fully explain why the curves of the C-based and OpenCL-based scalar implementations cross between the hash table sizes of 64 kB and 128 kB.

Hash Join Probe. Figures 3c and 3f show the result of the hash probe experiment on the CPU and the Xeon Phi. We compare the vectorized OpenCL-based implementation with an intrinsic-based implementation [8] and a scalar implementation. On the CPU, both vectorized implementations outperform the scalar version as long as the hash table fits into L2 cache. For 4 kB hash tables, the intrinsic-based implementation is twice as fast as the scalar implementation, whereas the OpenCL-based implementation is 1.3 times faster. For small hash tables on the Xeon Phi, the intrinsic-based implementation greatly outperforms the scalar version whereas the OpenCL-based vectorized implementation

is slower. On this processor, the data movement primitives are implemented directly as SIMD instructions which perform much faster than implementations that rely on an emulation.

5 CONCLUSION

Vectorized database operators improve performance but require processor-specific APIs. In this paper, we vectorize the essential primitives *Gather*, *Scatter*, *Selective Load* and *Selective Store* in OpenCL to reduce code complexity and to ensure portability.

We conduct an evaluation on CPUs and Xeon Phi coprocessors. In general, vectorized hashing based on intrinsic outperforms OpenCL-based hashing. Hash tables usually exceed processor caches. In this case, both variants are memory-bound and perform similarly. However, on CPUs, OpenCL-based vectorized hashing outperforms scalar hashing for moderately sized hash tables that fit into the L2 cache. In this case, our OpenCL-based hashing scheme is competitive to intrinsic-based hashing.

ABSTRACT

We aim to improve the accuracy of path selectivity estimation in graph databases by intelligently ordering the domain of a histogram used for estimation. This problem has not, to our knowledge, received adequate attention in the research community. We present a novel framework for the systematic study of path ordering strategies in histogram construction and use. In this framework, we introduce new ordering strategies which we experimentally demonstrate lead to significant improvement of the accuracy of path selectivity estimation over current strategies. These positive results highlight the fundamental role that domain ordering plays in the design of effective histograms for efficient and scalable graph query processing.

1 INTRODUCTION

Analytics on graph-structured data is increasingly important in a variety of domains, e.g., role discovery in social networks, impact analysis in citation networks, functional analysis of biological networks, and querying knowledge graphs. Querying in graph query languages such as openCypher and PGQL is at the heart of these analytics tasks [1, 3, 11]. However, current graph database systems have difficulty in scaling query processing as the size and complexity of graph data collections continue to grow [4, 9].

Towards addressing this challenge, a crucial step in scalability of graph databases is the generation of effective query execution plans. Query optimizers rely on accurate data statistics for cardinality estimation during plan generation. Histograms are among the most widely used data structure for maintaining statistics for cardinality estimation, in particular for relational database systems [5]. However, there has been relatively little work on histograms for graph queries, even for the most basic graph query building block, namely, path queries [6–8, 10].

Our contributions. In this paper, we give an overview of findings in our ongoing investigations into histograms for path selectivity estimation [12]. We focus in particular on ordering strategies for path queries, i.e., how to order the domain over which histograms are built, with the goal of minimizing the variance within histogram buckets (and thereby improving estimation accuracy). We present a novel framework for systematically introducing ordering strategies, showing experimentally that the choice of domain ordering is a fundamental aspect of effective histograms. We introduce new ordering strategies which we demonstrate lead to significant improvement on the accuracy of obtained estimates, over current ordering approaches.

State of the art. The study and efficacy of histogram-based cardinality estimation are well-established [5], e.g., for path and twig query optimization in XML databases [2, 13]. Several studies have also considered path selectivity estimation on graph data

Figure 1: Visualization of a data distribution (black) and an equi-width histogram (red) of Moreno Health dataset with $k = 3$.

with cycles (i.e., beyond trees and DAGs) [6–8, 10]. These works, however, have not investigated histograms or the impact of path ordering on estimation quality. To the best of our knowledge, we present here the first systematic study of this basic aspect of histogram construction and use in graph data management.

2 HISTOGRAMS ON LABEL-PATHS

We investigate selectivity estimation of path queries on graphs. A graph G is composed of a finite set of vertices V , a set of edge labels L , and a set of directed labeled edges $E \subseteq V \times L \times V$. A k -label path is a sequence $\ell = l_1 / \dots / l_k$, where $l_i \in L$, for all $1 \leq i \leq k$. We say $k = |\ell|$ is the length of ℓ . Viewing ℓ as a path query, the evaluation of ℓ on G returns the set $\ell(G)$ consisting of all pairs of vertices (v_s, v_t) in G such that there exist vertices $v_0, v_1, \dots, v_k \in V$ where $v_s = v_0$, $v_t = v_k$, and for $0 < i \leq k$, $(v_{i-1}, l_i, v_i) \in E$. The total number of such pairs, i.e., the cardinality of $\ell(G)$, is called the selectivity of ℓ on G , which we denote by $f(\ell)$.

Let \mathcal{L}^k be the set of all label paths over L with length up to k .¹ An ordering of \mathcal{L}^k is a bijection from \mathcal{L}^k to integer set $[0, |\mathcal{L}^k|)$. Once we establish an ordering on a label path set, a label path can be represented by its positional index in the ordering. For each label path ℓ , let $index(\ell)$ denote the index of ℓ in the ordering.

A histogram is a mechanism used to provide the approximation of frequency for a given value (point query) or value range (range query) without storing or accessing the complete original data distribution. More precisely, given an attribute X , a histogram on this attribute is constructed by partitioning the data distribution of X into $\beta \geq 1$ mutually disjoint subsets called buckets and storing the statistics information and bucket boundaries for each bucket. In this work, attribute X , also called the domain of the

¹We will let \mathcal{L} denote a label path set regardless of k when this does not cause ambiguity.

histogram, is an ordered label path sequence produced by an ordering of \mathcal{L}^k . Then, given label path ℓ and its index $index(\ell)$, such a *label-path histogram* is used to compute an estimate $e(\ell)$ of the selectivity $f(\ell)$. An example of a label-path histogram is shown in Figure 1.

3 ORDERING FRAMEWORK

The purpose of histogram domain reordering is to ensure that label paths with similar cardinality are located close to each other, such that they can be allocated in the same bucket. This leads to lower variance, lower error rates, and overall better quality.

An intuitive and ideal way is to arrange the data distribution such that when $index(\ell)$ increases, $f(\ell)$ monotonically increases or decreases. The most straightforward, yet not feasible, approach is to sort the label paths by their selectivity and assign the *index* of each label path as its position in this sequence. This idea is not practical, however, as it requires extra memory to store $|\mathcal{L}|$ *index* values. The exact amount of memory can also be used to store the cardinality for each label path, such that instead of returning an estimation of selectivity, we can obtain the precise selectivity. We call such ordering an *ideal ordering*. Despite an ideal ordering being prohibitive, we can still construct an approximately monotonic sequence based on the awareness of precise cardinalities of a subset of \mathcal{L} .

For example, by looking at Figure 1, one can observe that the label 1 has the highest cardinality among all length-1 label paths while label 5 has the lowest. Similar trend repeats in the other 6-member groups with the same prefix $\{1/1, 1/2, \dots, 1/6\}$, $\{2/1, 2/2, \dots, 2/6\}$, and so on. Hence, we can assume that the label path that is composed of label paths with high cardinalities should also have high cardinality.

3.1 Concepts

We define a *base label set* as a $B \subseteq \mathcal{L}$ such that every label path in \mathcal{L} can be decomposed into pieces which are all in B .² Then, a *splitting rule* defines how to decompose a label path. For example, \mathcal{L}^6 on Moreno Health dataset is $\{1, 2, 3, 4, 5, 6, 1/1, \dots, 6/6/6/6/6/6\}$, if we choose B to be \mathcal{L}^2 , with a *greedy splitting rule* which at each split step always cuts a piece in B as long as possible. For example, label path “4/4/3/3/6” is decomposed into “4/4”, “3/3” and “6”.

An ordering method can be described by the following three components. First, we need a base label set B . Second, we define (*un*)*ranking function* over the base label set that gives a rank for each base label and vice-versa. It is a bijection which maps between edge label set B and integer set $[1, |B|]$. Finally, we construct an *ordering rule* which is combined with a ranking rule to eventually determine the index of a label path (sequence of base labels) in \mathcal{L}^k . It is a bijection that maps between label path set \mathcal{L} and integer set $[0, |\mathcal{L}^k|]$. A complete ordering method, therefore, is seen as the combination of a ranking rule and an ordering rule on a given dataset. We refer to an ordering method that is composed of ranking rule A and ordering rule B as B - A ordering.

We define two ranking rules in our study. *Alphabetical ranking* assigns ranks based on the alphabetical order of base labels. *Cardinality ranking* is ranking based on the cardinality of base labels, which places a base label with lower cardinality in front of the label with higher cardinality, i.e., $l_1 <^{card} l_2 \iff f(l_1) < f(l_2)$

²Naturally, $L \subseteq B$, otherwise there might exist label paths which cannot be decomposed into label paths in B .

In this work, we focus on the approach that takes the edge label set as the base label set, i.e., $B = L$. We define two bijections: *alph* and *card*. Let $alph(l)$ and $card(l)$ denote the index of edge label l , which will be referred to as the *rank* of l , in the set L totally ordered by alphabetical order and cardinality, respectively.

3.2 Numerical and Lexicographical Orderings

In numerical ordering, each rank is an integer, and a composition of ranks produces a number in $|B|$ -based numeral system. For example, to compare two label paths $\ell_1 = l_1^1/l_2^1/\dots/l_m^1$ and $\ell_2 = l_1^2/l_2^2/\dots/l_n^2$, if one is shorter than the other then it has a lower ranking (rule (1) below), otherwise the two paths’ labels are compared pairwise until a pair of different values is found at position i (rule (2) below):

$$\ell_1 < \ell_2 \iff \begin{cases} |\ell_1| < |\ell_2| & |\ell_1| \neq |\ell_2| \quad (1) \\ \bigwedge_{j=1}^{i-1} (l_j^1 = l_j^2) \wedge (l_i^1 < l_i^2) & |\ell_1| = |\ell_2| \quad (2) \end{cases}$$

Lexicographical ordering is the same as the ordering rule used in dictionaries; it is similar to numerical ordering with the following difference. Instead of comparing lengths of two label paths first, we append $k - |\ell|$ *blank* symbols (i.e., special symbols for which $\forall l \in L, rank(blank) > rank(l)$) to every ℓ to form a length- k sequence. We can then apply Formula 2 to compare the resulting label paths. The time complexity of both ranking and unranking functions for numerical and lexicographical orderings is $O(k)$.

3.3 Sum-based Ordering

Given label path ℓ , the idea of *sum-based* ordering is to use the sum of ranks of all base labels in ℓ to approximate the cardinality of ℓ . While being conceptually simple, the implementation of this ordering method is not trivial. First, given a path label ℓ of length k , ℓ is split into base labels and an integer rank is computed for each of the base labels to obtain a k -length integer *permutation*. Then, the integer permutation of ℓ is mapped to $index(\ell)$ by performing a *three-stage partitioning* of a histogram domain as follows.

The first stage partitions the histogram domain according to the length of the integer permutations, with shorter lengths being assigned partitions with lower indexes in the domain. Then, the size of each of the stage-one partitions can be computed by the following formula (where n is the length of the permutation):

$$sum_n = |L|^n$$

The second stage performs further division of stage-one partitions by grouping all m -length permutations by their *summed ranks*. Those permutations with lower summed rank will have a lower index within a stage-one partition:

$$sr_m = \sum_{i=0}^{m-1} rank(l_i)$$

To compute the boundaries of each of the stage-two partitions, we need to determine how many label paths are in the group with a certain m and sr_m . This question is the same as how many ways there are to distribute sr_m indistinguishable balls over m distinguishable bins of finite capacity $|L|$ with at least one ball in each bin. From combinatorics’ *inclusion-exclusion principle* we have:

$$dist(sr_m, m, L) = \sum_{j \geq 0} (-1)^j \binom{m}{j} \binom{sr_m - j \cdot |L| - 1}{m-1} \quad (3)$$

The third stage explores combinations inside each of the stage-two partitions marked by length m and summed rank sr_m . These combinations are all *integer partitions* of sr_m into exactly m parts, where each part is less than $|L|$. Let integers v, b represent sr_m and $|L|$ respectively. A general formula for integer partition $ip(v, b, m)$ is as follows:

$$ip(v, m, b) = \bigcup_{i=0}^{\lfloor v/b \rfloor} ip(v - i \cdot b, m - 1, b - 1, \underbrace{b, \dots, b}_{i \text{ bs}}) \quad (4)$$

Based on Formula 4, we present a partitioning algorithm which outputs all combinations in the desired cardinality-based order and has time complexity is $O(\log(|L|)^k)$ [12].

Finally, to compute the boundaries of each of the stage-three partitions, we need to determine how many permutations we skip when we skip a stage-three partition. This is equivalent to identifying how many permutations can be generated by a certain combination in which there might be duplicates. Let C denote the combination, d_i denote the number of times an integer i occurs in C , then the number of permutations is given by the following formula:

$$nop(C) = \frac{|C|!}{\prod_{i \in \{0, \dots, |L|-1\}} d_i!} \quad (5)$$

Algorithm 1 finds the combination to which the target permutation belongs and has time complexity of $O(k^2)$.

Algorithm 1 Unranking permutation of combination

```

1: procedure UNRANKING_PERMUTATION(index, C)
2:   if  $i < 0 \vee i \geq nop(C)$  then
3:     return null
4:   end if
5:   if  $|C| = 1$  then
6:     return  $[C[0]]$ 
7:   end if
8:    $i \leftarrow 0$ 
9:   while  $i < |C|$  do
10:     $S \leftarrow C \setminus [C[i]]$  ▷ subset of  $C$ 
11:    if  $index \geq nop(S)$  then
12:       $index \leftarrow index - nop(S)$ 
13:       $i \leftarrow i + count(C, C[i])$ 
14:    continue
15:    else
16:       $sub \leftarrow unranking\_permutation(index, S)$ 
17:       $sub.add(0, C[i])$ 
18:      return sub
19:    end if
20:  end while
21: end procedure

```

Algorithm 2 illustrates the complete version of unranking permutation in sum-based order and has time complexity of $O(\log(|L|)^k)$.

3.4 Ordering Example

We illustrate the proposed ordering methods with examples on an artificial dataset which has 3 unique edge labels and its label paths set with k up to 2. Consider the cardinalities 20, 100, and 80 for edge labels “1”, “2”, and “3”, respectively. Then, for the summed ranks shown in Table 1, label paths arranged in the corresponding

Algorithm 2 Unranking in sum-based order

```

1: procedure UNRANKING_IN_SUMBASED(index, L, k) ▷ index,
   edge label set, k
2:   if  $index < 0 \vee index > |\mathcal{L}^k|$  then
3:     return null
4:   end if
5:   for  $len \in 1, \dots, k$  do
6:     if  $index \geq |L|^{len}$  then
7:        $index \leftarrow index - |L|^{len}$ 
8:     continue
9:   end if
10:  for  $sum \in len, \dots, len * |L|$  do
11:    if  $index \geq dist(sum, len, |L|)$  then
12:       $index \leftarrow index - dist(sum, len, |L|)$ 
13:    continue
14:  end if
15:   $P \leftarrow ip(sum, len, |L|)$ 
16:  for  $p \in P$  do
17:    if  $index \geq nop(p)$  then
18:       $index \leftarrow index - nop(p)$ 
19:    continue
20:  end if
21:   $p' \leftarrow \{i - 1 | i \in p\}$ 
22:   $sort(p')$ 
23:  return  $unranking\_permutation(index, p')$ 
24: end for
25: end for
26: end procedure

```

orderings are shown in Table 2. Respectively, numerical ordering associated with alphabetical ranking, numerical ordering with cardinality ranking, lexicographical ordering with alphabetical ranking, lexicographical ordering with cardinality ranking, sum-based ordering with cardinality ranking are referred to as *num-alpha*, *num-card*, *lex-alpha*, *lex-card* and *sum-based*.

4 EXPERIMENTAL STUDY

We implemented a k -path histogram construction and path selectivity estimation in Java. All experiments are conducted on an Ubuntu 16.04 machine equipped with an Intel i5 CPU with 4GB of RAM. We use the datasets shown in Table 3. The goal of our experiments is two-fold. First, we verify the impact of different domain ordering techniques on the estimation time. Second, we showcase the gains in estimation accuracy which can be obtained by using sum-based histogram domain ordering.

Figure 2: Mean error rate of estimation for different domain ordering techniques on V-Optimal k -path histogram

Dataset	#Edge Labels	#Vertices	#Edges	Real world data

437	5.19	4.58	4.52	4.29	6.13

Table 4: Average estimation execution time in V-optimal histogram with different ordering methods (in ms)

Performance. We study the execution time of estimation associated with different ordering methods as follows. For $k = 6$, five V-optimal histograms are built, each of which is associated with an ordering method: *num-alpha*, *num-card*, *lex-alpha*, *lex-card*, and *sum-based*. The total number of label paths is 55996. We run 7 experiments by varying the number of buckets (β) in each histogram. All experiments are executed 100 times and the average estimation time is taken. The results (Table 4) demonstrate that sum-based ordering is approximately 20% slower in estimation than native ordering methods. This is explained by the higher complexity of the sum-based (un)ranking function.

Accuracy. We measure the average estimation accuracy by constructing a V-optimal histogram for each ordering method for varying k and β (Figure 2). We use the following $err(\ell)$ metric to measure the error of an estimation:

$$err(\ell) = \begin{cases} 0 & \text{if } e(\ell) = f(\ell) \\ \frac{e(\ell) - f(\ell)}{\max(e(\ell), f(\ell))} & \text{else} \end{cases} \quad (6)$$

³http://konect.uni-koblenz.de/networks/moreno_health

⁴<http://wiki.dbpedia.org>

⁵<https://snap.stanford.edu/snappy/>

We observe that, for the synthetic datasets, sum-based ordering provides accuracy which is far superior to other ordering methods, especially, for histograms with a low number of buckets. For the real-life datasets, the performance difference is not as significant, but still observable. This can be explained by the presence of edge-label cardinality correlations in real-life data.

5 CONCLUDING REMARKS

We have reported on initial findings in our ongoing study of domain ordering for improving histogram-based path selectivity estimation. Experimental study has demonstrated the promise of our framework, which facilitates the further systematic study of effective histogram design for graph databases. A primary future research direction is to expand the framework with additional ordering strategies, e.g., those built over richer base sets such as \mathcal{L}^2 , towards capturing correlations between label paths.

ABSTRACT

The continuing growth and success of many edge technologies such as the Internet of Things (IoT), wearables and Virtual and Augmented Reality (VR/AR) relies on providing a high-performance and low-latency computing infrastructure. In this paper, we envision extending edge computing with mobile, moving, and possibly flying edge datacenters, that we call *nomadic datacenters* to improve the performance and capacity of the edge infrastructure. In particular, we study how the introduction of nomadic datacenters will affect data management systems and find that novel challenges and opportunities need to be addressed. We present some of these challenges and opportunities in addition to an outline of how they can be tackled by future data management systems.

1 INTRODUCTION

Emerging classes of computing technologies are promising to transform our lives, change how we interact with each other and with the world. These include Internet of Things (IoT), wearables, and Virtual and Augmented Reality (VR/AR). IoT enables harnessing the multitude of sensor data via applications ranging from smart farming to autonomous cars. Wearable technology enables personalized applications such as activity tracking and health monitoring. With VR/AR, we will be immersed in designed experiences that will touch every facet of our lives. Common among these transformative technologies are the utilization of sophisticated edge devices and the demand for high-throughput and/or low-latency. We will use the term *edge technologies* to denote IoT, wearable, and VR/AR technologies in light of their common characteristics.

To realize the potential of edge technologies, it is necessary to provide the hardware and software infrastructures that support the high-throughput and low-latency demands for application processing. To this end, many efforts have advocated for the use of edge computing technology to provide more compute and storage power [4, 13]. Edge computing enhances cloud computing by introducing *edge datacenters* that are closer to users and that consist of a few to hundreds of machines. With edge computing, data can be processed at the edge, saving the communication latency to the datacenter that can take up to 100s of milliseconds [13]. Additionally, processing at edge datacenters saves the monetary bandwidth costs of cloud-edge communication.

Realizing the benefits of edge datacenters has been limited by the static nature of edge datacenter deployment. Typically, edge datacenters are rigidly stuck in fixed locations. This introduces two limitations:

- *A static deployment cannot follow the hot spots:* It is difficult for a static deployment to adapt to a dynamic, mobile environment, where the current location of the highest data traffic is continuously, and often unpredictably changing. For example, consider building an edge infrastructure to support a taxi transportation organization. Taxi cabs connect to edge datacenters that are placed in various locations around the city. However, the location of taxi cabs depends on many volatile aspects such as traffic and passengers. This makes it very difficult to decide where to place the edge datacenters and how to provision resources around the city.
- *A static deployment cannot be recovered swiftly:* In the event of a natural disaster and power outages, a large area may be affected. The edge datacenters across these large areas may be inaccessible or even permanently damaged. To recover from such catastrophic failures that damage infrastructure, replacing the infrastructure is necessary. However, it may take days to replace and deploy the new infrastructure. This is especially devastating when the edge infrastructure is needed to aid in responding to natural disasters.

In this paper, we propose extending edge computing technology with dynamic, mobile edge datacenters, and call them **nomadic datacenters**. Nomadic datacenters denote small, portable edge datacenters, that can be relocated swiftly by large vehicles (e.g., trucks) and air crafts (e.g., helicopters). Nomadic datacenters can overcome the two limitations of static edge datacenters that we outlined in the previous paragraph. A nomadic datacenter *can* follow the hot spot. In the taxi organisation example, nomadic datacenters can be continuously moving to maximize the utility of resources. Also, nomadic datacenters can replace a damaged infrastructure swiftly in cases of natural disasters and power outages. In fact, nomadic datacenters can be thought of as an aid to first responders that may need the edge computing resources to collect and process data in addition to providing connectivity during relief and rescue operations.

The potential feasibility of the concept of nomadic datacenters is due to recent advances in datacenter and communication technology. Edge datacenter technology has been continuously improving during the past decade, resulting in small, containerized datacenters, also called *micro datacenters*. A micro datacenter may contain as little as a few servers on a single rack with built-in cooling, power supply/backup, and fire suppression systems.

Already, these micro datacenters are being leveraged for their portable nature that allows deploying them in remote areas such as shallow- and deep-water oil rigs [1]. Our proposal is to leverage this portability to react to dynamic, mobile edge applications and actively follow hotspots in addition to replacing damaged edge infrastructure.

The other technology that is enabling nomadic datacenters is 5th generation mobile networks (5G). 5G is 4G's successor telecommunication standard. It aims to provide lower latency, higher communication throughput, and low power transmission. More importantly, 5G is geared towards supporting emerging edge applications, such as ones based on IoT and wearables. This is envisioned by providing support of device-to-device and mobile broadband communication. This is significant for the realization of nomadic datacenters that will rely on wireless communication to connect to edge users/devices and the cloud. 5G will allow larger-scale communication between a nomadic datacenter and edge users and devices through device-to-device and mobile broadband communication. Also, nomadic datacenters would need a large capacity wireless link to connect to the backbone in the cloud. 5G's larger capacity will ameliorate the capacity limits of wireless telecommunication technology compared to wired and optical fiber communication. Also, nomadic datacenters would typically be powered for long (or all) durations on batteries. Thus, low power consumption based on 5G is an important feature.

The concept of a nomadic datacenter is not new, as many have suggested the idea for its practical uses in many applications [12]. However, it was not realized because the relevant communication and datacenter technologies were not ready. With the advances of micro datacenters and 5G telecommunication, nomadic datacenters are positioned to be a reality now more than ever.

In this paper, we envision the last piece in the puzzle of making nomadic datacenters a feasible technology—we propose the study of data management systems for nomadic datacenters. In addition to the hardware and communication infrastructures (i.e., micro datacenters and 5G) to realize nomadic datacenters, data management technology must be revisited to tackle the unique challenges and exploit the opportunities of the new edge architecture. We present a system model that encompasses several scenarios of how nomadic datacenters will be realized. Then, our study of the system model reveals a set of novel data management challenges and opportunities. We present these challenges, opportunities and a roadmap to tackle them.

2 A SYSTEM MODEL FOR NOMADIC DATACENTERS

In this section, we present our vision of emerging system models of nomadic datacenters. The development of these system models is important to guide the design decisions and identification of the salient properties of the new technology. We begin by describing the base architecture of nomadic datacenters and its interaction with the cloud, users, and other edge datacenters. Then, we discuss how the model can be adapted to various properties of nomadic datacenter deployments that have varying sizes and mobility characteristics.

The base system model consists of three tiers (shown in Figure 1):

- (1) *Cloud tier*: This denotes the cloud resources at traditional, large datacenters.

Figure 1: The system model with nomadic datacenters.

- (2) *Edge tier*: This denotes the resources at edge and nomadic datacenters. Edge datacenters communicate with the cloud tier through high-bandwidth links, such as fiber optics, and nomadic datacenters communicate with the cloud tier via wireless telecommunication (e.g., 5G). However, nomadic datacenters are also capable of communicating with other edge datacenters through wireless links. This will enable coordination between nodes in the edge tier and also enables relaying communication between nomadic datacenters and the cloud tier through intermediate edge datacenters.
- (3) *User tier*: This denotes the users and devices generating data and making requests. Nodes in the user tier, that we will call user nodes, communicate with the application through the edge tier, if an edge or nomadic datacenter is nearby. Typically, this communication would be through wireless links, using Wi-Fi technology. If no edge or nomadic datacenter is nearby, then the user nodes communicate directly with the cloud tier.

Nomadic datacenters will vary in size to adapt to various application and environment requirements. We abstract the different sizes of nomadic datacenters to fall in one of three sizes: (1) Light: This represents nomadic datacenters that contain a single machine and minimal datacenter capabilities for cooling and security. This is ideal in cases where the nomadic datacenter should be carried by small vehicles, such as drones. (2) Medium: This represents nomadic datacenters that contain a few machines and is ideal to be carried by small vehicles such as taxi cabs. (3) Heavy: This represents nomadic datacenters that resemble current micro datacenters that contain 4 or more machines with various datacenter capabilities. This is ideal for cases where a truck or an aircraft carries the datacenter. The size of the nomadic datacenter influences its mobility characteristics. For example, light nomadic datacenters can be deployed for high mobility scenarios with constant movement and relatively smaller vehicles (e.g., drones). Medium ones can be deployed on medium-sized vehicles, and thus can be used for mobility cases in urban settings. Heavy nomadic datacenters has relatively restricted mobility and are ideal in cases where mobility is in reaction to a non-frequent event.

Given this view of the system model of nomadic datacenters, we discuss some data management issues in the context of nomadic datacenters.

	Centralized Infrastructure	Extended Infrastructure
Static Resources	Client-Server (Cloud Computing)	Edge Computing
Mobile Resources	MDMS	Nomadic Datacenters

Table 1: The high-level differences in the system model of Nomadic datacenter in comparison to other system models.

3 DATA MANAGEMENT FOR NOMADIC DATA CENTERS

In the nomadic datacenter architecture, is there a need for innovation in data management systems to support the new environment or do existing systems suffice? This section answers this question by discussing how the nomadic datacenter architecture is positioned in relation to early work on mobile databases (Section 3.1). Then, we show how the unique properties of nomadic datacenters require innovation in data management systems in Section 3.2.

3.1 Nomadic Datacenters in the Space of Mobile Data Management

Building data management systems for mobile environments has been studied extensively for a number of decades [3, 6, 8, 9]. In these early works, that we will denote as *mobile data management systems* (MDMS), users and data copies are mobile and may use wireless communication. These properties are similar to the properties brought forth in the nomadic datacenters system model (Section 2).

So, can we just use MDMS [3, 6, 8, 9] to build solutions for nomadic datacenters? Our study of MDMS systems have revealed that they are an excellent starting point and basis for data management solutions for nomadic datacenters. MDMS outlines many solutions to tackle challenges that also arise in nomadic datacenters such as resources asymmetry, mobility, caching, and energy efficiency. Many of these techniques can—and should—be adopted by data management systems for nomadic datacenters.

However, there is a key difference in the nomadic datacenters architecture compared to early MDMS architectures. In MDMS, there is a “core” database and mobile users. This makes MDMS consider a centralized infrastructure with mobile resources. For nomadic datacenters, the users are mobile like MDMS, but the infrastructure is different. The infrastructure in nomadic datacenters is extended beyond a centralized location to mobile edge nodes (*i.e.*, nomadic and edge datacenters).

Table 1 summarizes the high-level position of nomadic datacenters compared to relevant architectures. An interesting relation that can be observed from the table is that *a nomadic datacenters architecture to MDMS is what edge computing is to cloud computing*. Therefore, the data management challenges of edge computing in comparison to cloud computing will likely exist for nomadic datacenters in comparison to MDMS. The nature of these challenges stems from the fact that edge resources are more powerful than client machines, and thus there is an opportunity to leverage them more aggressively for data management tasks like caching [5], and offloading [11, 14]. This makes the caching and offloading results for edge computing [5, 11, 14] different from ones for MDMS [3, 6, 8, 9].

Although transforming edge solutions to adapt to the nomadic datacenter architecture is important and may entail interesting designs, we are interested more in the novel challenges and opportunities that are unique to nomadic datacenter architecture. The next section introduces such challenges and opportunities.

3.2 New Challenges and Opportunities

We postulate that the nomadic datacenter architecture has fundamental differences compared to previous architectures and combinations of previous architectures (*e.g.*, MDMS with edge computing). These differences require innovative solutions to tackle the challenges and benefit from the opportunities of nomadic datacenters. In this section, we present the imminent challenges and opportunities in this space.

3.2.1 The wireless link: a bottleneck and an opportunity. Nomadic datacenters communication with users, other edge and nomadic datacenters, and the cloud tier through wireless links. Although emerging technology such as 5G will ameliorate this bandwidth limitation of wireless links, they are still limited compared to wired infrastructures. In addition, communication between nomadic datacenters and users and other edge datacenters will likely still rely on Wi-Fi or similar technologies. Therefore, *communication bandwidth will be an extremely costly resource for nomadic datacenters*. This is not the case for other architectures. (Unlike MDMS, a nomadic datacenter manages the data of a large number of users and thus require a significantly larger bandwidth than a single MDMS client.) The bandwidth cost significantly affects the design trade-offs space for data management tasks as we outline in the next example.

A case study on coordination. An example of a data management task that will be affected by the high bandwidth cost is coordination. Coordination is necessary to maintain consistency across different copies of data via protocols such as Two-Phase Commit [7], Paxos [10], and others. Coordination is communication-intensive, where each request is typically coordinated among nodes that hold copies of the accessed data. Take for example a scenario of two nomadic datacenters, *A* and *B*, that are located to be close to a large event that is anticipated to generate a lot of traffic. Both nomadic datacenters, *A* and *B*, are providing access to the same data but half the users are connected to *A* and the other half is connected to *B*. Now, in applications where requests would require coordination (such as OLTP transactions), *A* and *B* must coordinate every request they receive. For example, a request that is received at *A* would create a coordination request from *A* to *B*. This means that, potentially, double the wireless link bandwidth is consumed than necessary. This is exacerbated for cases with more nomadic datacenters and represents a major source of wasted resources and stress to the most limited nomadic datacenter resource—communication bandwidth.

Optimizing the bandwidth of coordination is an open challenge for nomadic datacenters and can be tackled based on familiar approaches in batching and compression. However, there are also opportunities for innovative solutions to this problem that are allowed by the unique architecture of nomadic datacenters. Specifically, since all communication is through the wireless medium, *nodes can eavesdrop on other nodes’ communication*. Consider our earlier coordination scenario where *A* receives a request and then coordinate with *B*. Since *B* can eavesdrop on the communication from the user to *A*, then it already knows about the request, even before *A* initiates coordination for it. This allows efficient alternatives to coordination. For example, *B* can signal

that it has heard about the request and decides a certain action regarding it. This is more efficient in two ways: (1) *A* does not have to communicate with *B*, and (2) the communication from *B* is a control message only and does not need to contain the payload of the request that is likely much bigger than control messages. Another example to reduce coordination overhead is partitioning. However, unlike traditional partitioning where the system controls partitioning the data only, in our scenario, the nomadic datacenters can also partition the users between them. This means that *A* and *B* can judiciously decide which users connect to which nomadic datacenter, and in jointly with a data partitioning strategy between *A* and *B*, the need for coordination between *A* and *B* would be reduced.

To summarize, we foresee innovations in coordination and other data management tasks that tackle the main bottleneck of nomadic datacenters (communication bandwidth) via innovative solutions specific to the nomadic datacenter environment such as eavesdropping and users-data partitioning.

3.2.2 Challenges of a Dynamic Mesh Environment. In many of the scenarios we envision, there is a large number of nomadic datacenters that roam around continuously. For example, consider a deployment on taxi cabs, where each taxi cab contains a nomadic datacenter. This may serve an application for the taxi cabs, but may also be serving urban applications. In this scenario, there are potentially thousands of nomadic datacenters that get connected to each other sporadically. We call this a *dynamic mesh model*, akin to Wireless Mesh Networks (WMNs) [2]. However, unlike WMNs, mobility and relocation are rapid and each node is a nomadic datacenter that performs extensive computation and performs data management tasks on behalf of users, rather than just being a communication hub.

The dynamic mesh model introduces serious challenges to distributed protocols that are necessary to manage replicated or partitioned data across nodes. Such distributed protocols, such as Paxos [10], Two-Phase Commit [7], and others, were designed for a static infrastructure, where the participants in a protocol are known. However, in a dynamic mesh model, the participants and topology configuration changes continuously, *requiring the invocation of expensive membership and leader election protocols continuously*. This motivates the study of data management system designs that assume that membership and leader election is invoked frequently.

A case study on Paxos. For example, consider the Paxos protocol [10]. Paxos performs two tasks: leader election and replication. Replication is performed by a leader to make sure data is persistent. Leader election is only invoked during a suspected failure of the current leader. Therefore, many Paxos designs and variants optimize for the case where leader election is rare. Furthermore, Paxos reconfiguration is invoked in cases where a machine is to be replaced or to migrate the infrastructure. Paxos reconfiguration [10] is very expensive and in traditional deployment this is not problematic because it is extremely rare. Because nomadic datacenters move rapidly and the configuration changes continuously, leader election and reconfiguration are invoked frequently. This invites a redesign of the Paxos protocol to make leader election and reconfiguration more efficient. Such redesigns might be enhanced by exploiting the opportunities enabled by the special characteristics of nomadic datacenters. An example is that leader election and reconfiguration are triggered by mobility in nomadic datacenters, rather than failures as the traditional cases. This can be exploited because the current leader is aware

of the anticipated leader election and/or reconfiguration and can participate in it. Therefore, rather than elaborate complex mechanisms to ensure the correct election of a new leader, a live, mobile leader can simply relinquish leadership to another node unilaterally.

Although we discussed a single case study on Paxos, the challenges of membership and reconfiguration in an extremely mobile environment are applicable to a wide-range of distributed protocols. We believe that opportunities to optimize membership and reconfiguration mechanisms for nomadic datacenters exist akin to the high-level optimization that we discussed for the Paxos case study.

4 CONCLUSION

Nomadic datacenters have the potential of enabling a wide-range of edge applications that rely on emerging edge technologies such as IoT, wearables, and Virtual and Augmented Reality. Nomadic datacenters introduces a dynamic, mobile infrastructure that allocate resources on demand in reaction to changes in workload and failures. This makes it suitable for emerging mobile edge applications. In this paper, we outline our vision of nomadic datacenters, how they are becoming more feasible, how they will be realized, and what are the imminent data management problems that arise with their introduction. We find that the areas that require attention in designing data management systems for nomadic datacenters are: the mobility of the extended infrastructure hierarchy, the wireless nature of communication, and the dynamic, mesh nature of the topology. We outline pathways to solutions to these problems and envision that they will provide a building block towards realizing nomadic datacenters.

ABSTRACT

Searching the nearest available resource is an important query with many applications in spatial database systems. Examples are searching free parking spots or charging stations in a road network. Information about the availability is usually approximated as long-term statistics. Recently, online systems and sensor networks become more and more common providing access to real-time information about resource availability. In this paper, we consider searching the next available resource in a road network considering real-time information about all resources in a target area. To make the best use of this information, it is not enough to predict a static result route. Instead we propose to model the problem as a Markov decision process (MDP) and compute a routing policy which allows flexible reaction to newly observed developments. In our experiments, we demonstrate that our new approach is capable to exploit the additional information and outperforms previous approaches built on long-term distributions on a real-world parking data set.

1 INTRODUCTION

In modern location based services, queries often aim at finding a spatial resource of a specific type. In contrast to a point of interest (POI), a spatial resource is not generally available but might be occupied at a certain point in time. Correspondingly, an occupied resource might become available during search time. Examples for spatial resources are parking spots, charging stations, rental vehicles or drop-off locations for rental vehicles. To handle the availability of spatial resources, online systems can provide real-time information about currently available resources. However, there is no guarantee that a currently available resource will be available at the arrival time of our user. One might argue that a reservation service might solve any such problem, but reservation services often add additional complexity which often makes them impractical. Reserved resources might be used without authorization and generally available resources might remain unused due to just-in-case reservations. For example, a parking spot might be occupied even if it was reserved before because the previously parked vehicle was not removed in time. Correspondingly, inner-city parking spots might remain unused due to rich people having a permanent reservation just in case they want to go into town. To conclude, for many applications reservation systems might be unreliable and expensive to enforce. Thus, we focus on the case that a resource is claimed by the first user to arrive.

We investigate the task of finding an available resource spending minimal travel time or any other type of cost. Furthermore, we assume real-time information on all available and occupied resources in a specified target area. To properly exploit the available real-time information, a simple route is not enough. Since

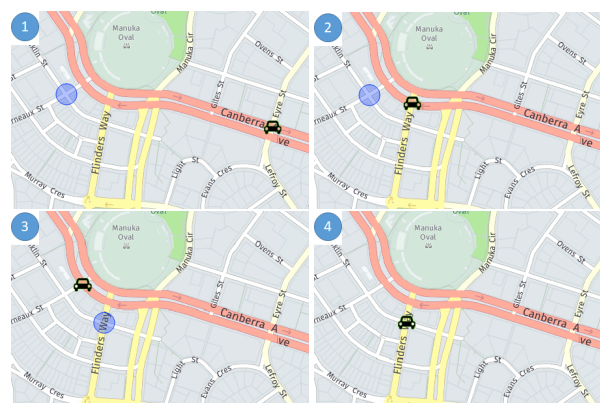

Figure 1: Example for a parking search using our new algorithm. The car symbol denotes the car whose driver is looking for a parking spot. The blue circles denote at least one free available parking slot at the corresponding location.

the availability of resources might be constantly changing, a fixed route cannot include reactions to developments during the search. Thus, we need to compute a policy which indicates the most promising action for each situation during the search. For example, when looking for a parking spot a natural behavior is to take any parking spot getting available along the way. A resource route as proposed in [5] would follow its fixed search order which is based on the information provided at search time. Thus, a resource route would only consider the vacant spot if it is scheduled in the route. In contrast, a policy driven system would recognize the improved situation and propose to take the available parking spot if it is a suitable location.

In this paper, we propose to employ the statistical model of Markov decision processes (MDP) to learn such a policy. A policy is a mapping of any possible situation to the most promising action which an agent should perform to maximize the probability of success. Thus, our proposed solution allows that resources might get occupied or available during the search. The availability of each resource is modeled as a time-continuous Markov chain. Based on these probabilities, we define an MDP to model resource search with real-time information. A drawback of this model is that the state space grows exponentially with the number of acceptable resources. Since in many cases resources are stacked at particular areas, we propose resource aggregation to limit the number of considered states. Additionally, we propose to precompute policies for relevant target areas and store them in a data structure for efficient retrieval of the proposed action. To conclude, the contributions of this paper are as follows:

- A model to compute a search policy for resource search considering real-time information.
- A method for precomputing policies and apply the learned policy for guiding a user.

- Experiments on real-world parking data demonstrating the advantage of using real-time information.

The rest of the paper is organized as follows: Section 2 surveys previous works on resource search and MDPs. In Section 3, we give a brief introduction to MDPs and introduce our model for resource search. Section 4 outlines the use of policies for routing services. In our experimental evaluation in Section 5, we demonstrate the advantages of our new approach. Section 6 concludes the paper with a short summary and directions for future work.

2 RELATED WORK

The methods being closest to our approach are [5] and [3]. [5] describes a method for computing a route minimizing the expected search time in a setting where resources can get occupied and available during the search. However, real-time information is only considered to be available at query time. Thus, the resulting resource route cannot react to updates during the search. In [3], the authors compute a policy for resource search. The solution is basically an MDP and the proposed method resembles the basic value iteration algorithm for computation. The major difference to our work is that the method does not consider the availability of real-time information during the search. However, there are already several prototypes and testbeds providing this type of information for urban areas such as the city of Melbourne in our evaluation. Our method employs Markov decision processes (MDP) as described in [7]. Though there is a plethora of more sophisticated solution methods for computing MDPs like [1, 2, 4, 6, 8, 9], we employ the basic value iteration algorithm since the approach in this paper precomputes policies and afterwards queries these policies to guide a user.

3 PROBLEM SETTING

3.1 Markov Decision Processes

A Markov Decision Process consists of a set of states S , sets of actions $\forall s \in S : A(s)$, the probability distribution for each state action pair $P(s'|s, a)$ and a cost (or reward) function $c(s, a)$. It is important to note that $P(s'|s, a)$ indicates that the result of the action (s, a) is uncertain and that any state transition $s \rightarrow s'$ with $P(s'|s, a) > 0$ for any $a \in A(s)$ is potentially possible.

A policy π is a set of state action pairs (s, a) that determines for any state $s \in S$ exactly one action $a \in A(s)$. In our usage of MDPs, we assume terminal states S^* which indicate the targets of the search. Thus, the goal of a policy π is to reach any terminal state $s^* \in S^*$ and a proper policy guarantees that we will reach a terminal state s^* at some point in time. To compare policies, we now define the expected cost $U(s)$ which is also referred to as utility or value function in literature.

In general, $U^\pi(s)$ of policy π represents the expected cost which is aggregated over all possible state sequences starting with state s . We define the optimal policy π^* for any state s as:

$$\pi^*(s) = \operatorname{argmin}_{a \in A(s)} \sum_{s'} P(s'|s, a) \cdot U^*(s')$$

Whereas $U(s)$ can be computed by the following equation also known as Bellman equation:

$$U(s) = \min_{a \in A(s)} c(s, a) + \gamma * \sum_{s'} P(s'|s, a) \cdot U(s')$$

In other words, the minimal expected cost for state s are achieved by taking the action a where the sum of direct costs $c(s, a)$ and the expected future cost are minimal. The parameter γ is used to

weight direct costs against future costs which is often beneficial for the convergence of computation.

3.2 Modelling Resource Search

After giving a brief general introduction to MDPs, we will now turn to modelling resource queries as an MDP problem. In our setting an agent, e.g., a driver or a person moves in a road network. A road network $G = (N, E)$ consists of a set of nodes N and a set of edges $E \subseteq N \times N$. Each edge $e \in E$ yields traversing costs c_e , e.g., travel time or distance. Additionally, we model resource locations as nodes $P \in N$. For each resource $p \in P$, the boolean function $a(p)$ denotes 0 if p is occupied and 1 if p is available.

The state space of our MDP is a concatenation of the agent position $l \in N$ and the value of $a(p)$ for each $p \in P$. Thus, the number of all possible states is $|N| \cdot 2^{|P|}$. All states where $l \in P$ and $a(l) = 1$ are considered as terminal states because the agent arrives at the location of a currently available resource. The actions in our model consists of the possible routing directions at each crossing, e.g., turn left, turn right, go straight or turn.

After defining states and actions, we now have to provide the likelihoods $P(s'|s, a)$. In our setting, the next location of the agent l' is determined by the selected action a . However, the change of the available resources depends on the status changes of the resources P . Thus, we need to compute the likelihood that a resource p changes its current status from occupied to available or vice versa. Given that we assume exact information at the current point of time, we only need to estimate the distribution of a state change for the required time to travel from l to l' . To do so, we rely on the continuous time Markov model being proposed in [5]. The model predicts the likelihood $P(p(t) = 0)$ that resource p is available at time t based on two parameters, the average occupation time and the average vacancy time. Both parameters can be easily derived from empirical data.

Finally, the cost of each action (s, a) is considered as the travel cost $c_{(l, l')}$ for the edge (l, l') where l is the agent location in state s and l' is the node after taking action a . Obviously, the given model allows to compute proper policies as long as any resource does not converge to a state of being constantly occupied. In this case, returning infinitely often to the resource will result in finding the resource available at some point in time.

After defining all components to model resource search as an MDP, we now want to briefly describe the employed value iteration algorithm for computing the minimal expected cost $U^*(s)$ for each state $s \in S$. The idea of value iteration is to employ the Bellman equation to each state in each iteration until the utility for any state does not improve significantly anymore. The pseudocode of value iteration is presented in algorithm 1. After computing $U^*(s)$ processing the optimal policy is straight forward by applying the *argmin* function instead of the *min* function in the Bellman equation. Note that we employed value iteration due to its simplicity and for comparability with previous approaches. For a more detailed introduction to value iteration please refer to [7].

4 USING MDPS FOR RESOURCE SEARCH

A general problem of the method proposed above is the exponential increase of the state space with the considered resources P . Obviously, computing the basic value iteration method for large numbers on resources is not feasible. Thus, in order to make the approach applicable for real systems, we need to make sure that

Algorithm 1 Value iteration algorithm for computing the expected cost U of an optimal policy.

11:  return  $U$ 

```

the number of potential resources is as small as possible. Fortunately, in many cases the region where resources are acceptable is usually limited to a certain spatial region being specified by a user. For example, parking spots should be in walking distance to the actual target of the user. Similarly, charging stations should be close to planned route and in the region where the battery is already empty to make charging feasible. Similar statements hold for rental vehicles such as bikes and drop off stations. Thus, a first approach to limit the considered resources would be to compute isochrones around the actual target of the user and only consider resources within the tolerable walking distance. However, this approach would not work if the user would not specify an exact target location but only a rough area where he needs the resource. Additionally, in many cases the amount of acceptable resources would still push the computational effort beyond interactive query times. Thus, we propose another approach where MDPs are precomputed for typical target regions. For example, parking MDPs might be precomputed for typical shopping areas and MDPs for bike sharing make sense around universities. Let us note that precomputation can be done even for overlapping areas. Finally, the selection of the most suitable area can be easily performed by the user based on map interface displaying the available areas.

However, limiting the spatial area might not yield a successful reduction of available resources because many types of resources are spatially stacked on close-by locations. Examples are parking spots and rental bikes. For these type of resources, we propose to aggregate close-by resources and model them as a single aggregate resource in the MDP. For example, instead of modeling a road segment with ten parking spots as ten nodes having one resource, we aggregate all spots on the segment into a single aggregate resource. Of course, we have to adapt the probabilities for computing the likelihood $P(p(t) = 0)$ to mirror the fact that it is enough that any of the underlying resources is available. Thus, the probability $P(\hat{p}(t) = 0)$ of the aggregate resource \hat{p} for being available corresponds to the likelihood that not all of the underlying resources are occupied at time t . Formally, given a set of close-by resources $\hat{P} = \{p_1, \dots, p_k\}$ which are aggregated to the aggregate resource \hat{p} then $P(\hat{p}(t) = 0) = 1 - \prod_{p_i \in \hat{P}} P(p_i(t) = 1)$. However, $P(\hat{p}(t) = 1) = \prod_{p_i \in \hat{P}} P(p_i(t) = 1)$ because \hat{p} can only be considered as occupied if none of the underlying resources is available. A drawback of resource aggregation is that it removes the time for traveling between the aggregated resources. Thus, the learned policy might not be able to handle searches within the combined resources. However, we argue that with a proper

selection of resources, the user should be able to solve the problem by himself, e.g. finding a free resource among the combined resources. A heuristic, we employed to find sets of resources that can be aggregated is to make sure that all heuristic can be reached by making the same routing decision. In other words, all resources are placed on the same edge of the underlying road network.

A final aspect of our proposed method is the use of the learned policy in systems for guiding users to an available resource. As mentioned before, we precompute policies and let the user decide on the best suitable precomputed query region in order to find a suitable policy. Afterwards the system can combine the current user location and the online information about available resources to determine the current state and propose the direction aka action being stored in the policy. If the user wants to have an outlook on the following actions, the system could compute the most likely states for the current situation. However, in a volatile environment it is likely that these directions will change during travel to the next waypoint. A remaining task in this solution is to efficiently retrieve the optimal action for the current state for a given policy. Though we can identify the current state by combining location and resource information, we still have to find the state in the precomputed policy. Given the exponential size of the state space finding the entry for a particular state has to be done in an efficient way. Thus, we propose to store policies in a two dimensional array. We index the set of locations N by enumeration which indicates the first dimension. For the index of the second dimension, we encode the status information of the considered resources. This is done by mapping each resource to a particular bit in a bit vector of length $|P|$ and set the bit according to the availability of the resource. The resulting bit vector is then interpreted as an integer which indicates the second index in the array. Thus, the proposed action is retrieved in constant time.

5 EVALUATION

In order to evaluate our approach on a realistic scenario, we simulate the states of the parking spots for the city of Melbourne. The simulation samples for a given time-stamp and time interval the next states of any given parking spot. We have developed two different simulation models. The first model is based on the continuous-time Markov chain (similar to our MDP model) which enables us to do experiments based on the same conditions that our MDP assumes. However, continuous-time Markov chains might not provide a suitable model for real-world data. Thus, we implemented a simulator that is based on a real-world parking dataset, namely the freely available Melbourne ‘‘Parking bay arrivals and departures 2014’’ dataset¹. The dataset that contains arrival and departure times of most central business district parking bays. When we take the arrival and departure time into consideration, we can decide for every contained time-stamp, whether the parking bay is available or occupied. This simulation can be equated to a realistic real-time information system because it retrieves events that actually happened at the given time-stamp.

We compare our new approach denoted as D3RI to the UGCM algorithm that was proposed in [3] which also computes a policy but does not consider real-time information.

In figure 2, we can observe that the average time of finding a parking spot in the simulator is two to four times shorter

¹<https://data.melbourne.vic.gov.au/Transport-Movement/Parking-bay-arrivals-and-departures-2014/mq3i-cbxd>

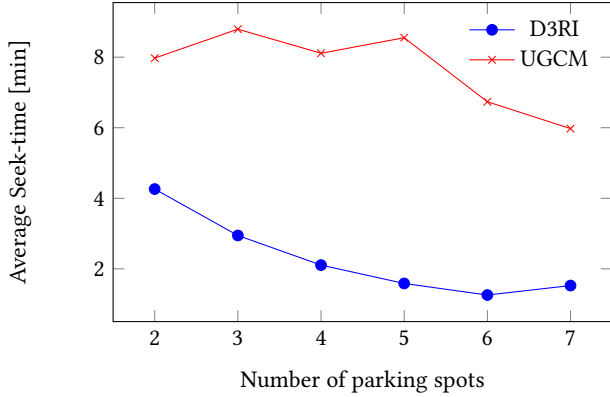

Figure 2: This figure shows the average search time of the agent in the time-continuous Markov chain simulator. Therefore we ran 1000 simulations and computed the average parking search time.

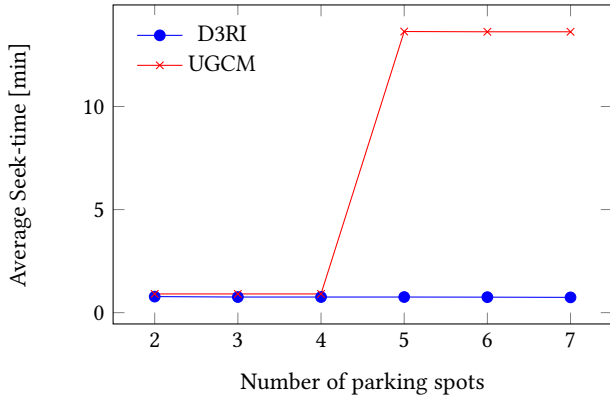

Figure 3: This figure shows the average search time of the agent in the Melbourne simulator. Therefore we ran 10 simulations on different days and computed the average parking search time.

with the approach proposed in this paper D3RI than the UGCM approach[3].

This is mainly because D3RI considers the real-time information of the parking spots while UGCM does not know if the parking spot, the agent is currently heading to, is available. This property can be observed in the real-world (Melbourne parking bays) simulation as well (c.f. figure 3). By knowing the exact states of the parking spots, D3RI can guide the driver directly to a freely available parking bay. However, if the information is not available, the driver may head to a nearby currently occupied parking spot. Because there are more possibilities for occupied parking spots, the approach of [3] becomes even worse when there are more spots available, since UGCM does not know which of the parking slots are free right now and usually with increasing amount of parking spots the amount of occupied spots increases as well. As expected, the use of real-time information yields a strong advantage which can be exploited by the D3RI model presented in this paper.

Figure 4 illustrates the runtime of our approach regarding the number of parking spots. In this experiment, we have used an error acceptance rate ϵ of 0.001 and a γ -value of 0.99. Obviously, the runtime increases exponentially with the amount of

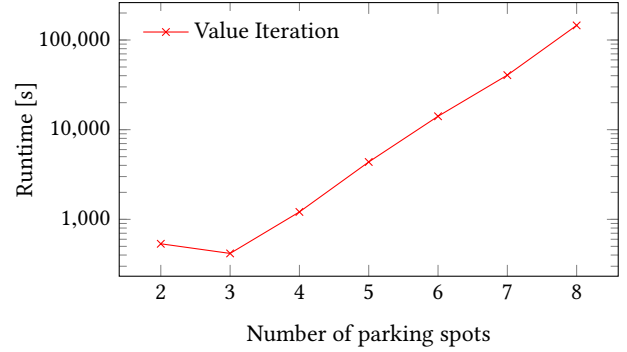

Figure 4: This figure shows the runtime of our approach depending on the number of spots. One may pay attention to the logarithmic y-axis.

considered parking spots. This suggests how essential resource aggregation is to reduce the computational overhead and the size of the policy. To conclude, without resource aggregation modeling realistic scenarios quickly get infeasible.

6 CONCLUSION

In this paper, we propose a novel approach for dynamic resource search in spatial networks considering real-time information on resource availability. To exploit valuable real-time information, solutions must react to recent developments in a flexible way. Therefore, we propose to learn a routing policy which provides the most promising action for any potentially occurring situation. To compute such a policy, we model resource search using real-time information as a Markov Decision Process (MDP). Furthermore, we discuss the design of a query system using pre-computed policies for guiding a user to an available resource. In our experiments, we compare our new approach using real-time information to a previous approach which computes policies based on historical data only. The results indicate that our new approach can exploit the real-time information to clearly outperform the comparison partner. For future work, we plan to examine techniques to mine areas for which building an MDP is most valuable. Furthermore, we will examine techniques to improve resource aggregation in order to compute MDPs for larger areas. Finally, we plan to examine database technology for storing and querying policies with very large state spaces.

ABSTRACT

Algorithmic problems of computing *influence estimation* and *influence maximization* have been extensively studied for decades. We researched several data structures for implementing the Reverse Influence Sampling method proposed by Borgs, Brautbar, Chayes, and Lucier in 2014. Our implementations solve the problems of influence estimation and influence maximization in large graphs fast and using small memory footprint. For instance, we are able to produce results 3 times faster and scale 8 times more than a state-of-the-art algorithm, all this while preserving the theoretical guarantees of Borgs *et al.* for Reverse Influence Sampling.

1 INTRODUCTION AND DEFINITIONS

The most popular definition of *influence* relies on probabilistic reachability [4, 7]. The network is modeled as a directed graph and a node influence is calculated as the (expected) number of other nodes reachable from it. Given a set of *seeds* (initial nodes), *influence estimation* is calculated as the total number of nodes reachable from all the seeds in the set. To find a set of seeds that gives the maximum influence *spread* (the number of influenced nodes) is the *influence maximization* problem.

Running time and required space are the primary considerations for the algorithms solving influence estimation and influence maximization problems; the networks of interest are usually quite massive in size. Kempe *et al.* [7] showed that the influence maximization problem is NP-hard, and Chen *et al.* [3] showed for the influence estimation problem that computing the exact influence of a single seed is #P-hard. Moreover, as Feige [5] proved in 1998, the problem is hard to approximate to anything better than $1 - (1 - 1/s)^s$ of the optimum for a seed set of size s .

To model the influence spreading, Kempe *et al.* proposed the Independent Cascade (IC) model [7]: Starting from a seed, influence spreads in rounds/steps: each node after getting influenced has one possibility to influence its neighbors. IC selects edges from the seed neighborhood with *independent* probabilities. Influenced neighbors, in their turn, have one possibility to influence their neighbors forming a *cascade* of information propagation. Kempe *et al.* proved that influence maximization on the IC model is *monotone* and *submodular*, and therefore the approximate Greedy algorithm produces near-optimal solutions with a theoretical guarantee. Approximate Greedy starts with an empty seed set S . In each iteration, it adds to S a seed - the node with maximum *marginal* gain. IC became a standard model of information diffusion, and we are using it for our algorithms.

Building on the Kempe *et al.* results, several approximate algorithms with theoretical guarantees have been developed [3, 6, 10, 11, 13, 14]. However, the problem of scalability remains.

Recently, a new approach was proposed by Borgs *et al.* [2]: the Reverse Influence Sampling (RIS) method. RIS selects (uniformly at random, with replacement) a node and finds a set of nodes that *would have influenced* it. The set of found nodes is stored in a structure called *hypergraph*. This process is repeated many times. If a node appears often in sets of “influencers”, then this node is a good candidate for the most influential node in the graph. RIS is a faster algorithm for the influence maximization problem, obtaining the near-optimal approximation factor of $(1 - 1/e - \epsilon)$, for any $\epsilon > 0$, in time $O((m * k * \epsilon^{-2} * \log(n)))$, where k is the number of seeds. RIS can be modified to allow an early termination: if it is terminated after $O(\beta * m * k * \log(n))$ steps, then it returns a solution with an approximation factor that depends on β (the greater the β , the better the approximation is, and the guarantees are made precise in [2]). However, still RIS needs to sample nodes many times and consumes vast amounts of memory. The problem of scalability remains.

We note that there are several works that propose better bounds on the number of samples that need to be taken to achieve the same theoretical approximation (cf. [6, 9, 13]). Our research is orthogonal to these works. We aim at optimizing the computation and storage of sketches in the hypergraph; the aforementioned works aim at reducing the number of sketches needed.

Algorithms in this paper. Our main goal is to scale-up computing of influence maximization and influence estimation to large graphs with tens of millions of edges. We use several data structures all aiming at reducing the required memory and speeding up the computation.

- (1) We use Webgraph, a highly efficient, and actively maintained graph compression framework [1].
- (2) We design a new way of storing the hypergraph that significantly decreases the required space, without affecting the theoretical guarantee of the approximation.
- (3) We conduct experiments on large graphs on a consumer-grade laptop comparing the data structures, and provide a detailed analysis of the results.

2 PRELIMINARIES

Notations

Let $G = (V, E, p)$ be a directed graph, where V is the node set ($|V| = n$), E is the edge set ($|E| = m$), and $p : E \rightarrow [0, 1]$ is a probability function on the edges existence. Let S be a set of seeds. The influence spread of a seed set S under the Independent Cascade (IC) model, denoted by $\sigma(S)$, is defined as the expected total number of reachable nodes for S .

IM and IE Problems

Influence Estimation Problem (IE). Given a graph $G = (V, E, p)$ and a seed set $S \subseteq V$, compute the influence spread $\sigma(S)$ of S .

Influence Maximization Problem (IM). Given a graph $G = (V, E, p)$ and an integer k , find a seed set $S \subseteq V$ of size k that maximizes $\sigma(S)$.

3 PROPOSED DATA STRUCTURES

We developed three different algorithms implementing RIS. Each algorithm uses a distinct data structure for storing the hypergraph. We compared the performance of different data structures on a consumer-grade laptop.

3.1 RIS

The original RIS method (Algorithm 1 in [2]) selects nodes uniformly at random. Let v be such a node. Then RIS determines the set of nodes that *would* have influenced v by running a search in the *inverse* graph (the graph with the directions of edges reversed). RIS stores the found set of nodes, called a *sketch*, in a data structure, called a *hypergraph*. The process continues until the hypergraph reaches a pre-defined *weight*.

The weight of the hypergraph is defined as the number of graph edges "touched" by RIS. RIS selects an edge to follow at random, with a given edge probability p . During search, each edge incident to a visited node is counted as "touched" and contributes to the weight calculation. Note, that the edge is considered "touched" regardless of it being selected by the search or not. How large the weight should be in order to guarantee an approximation to the optimal solution is defined in [2].¹

The RIS hypergraph is a two-dimensional (2D) list that contains, for each node u in the graph, the IDs of the sketches where u appeared. Further, RIS runs an approximate Greedy algorithm on the hypergraph, which returns a set of k *seeds* (nodes with approximately maximal influence in the original graph).

3.2 Two-Dimensional List (2DL)

We started with a straightforward implementation of RIS described in subsection 3.1, where we use a two-dimensional list structure (list of lists) for storing the hypergraph. Algorithm 1 shows the pseudocode of this implementation.

For a better performance, we added the following improvements: 1. The Webgraph [1] format for the input inverse graph (saves space); 2. Java 8 parallel streams and lambda expressions (speeds up performance by executing several reachability procedures in parallel); 3. BitSet structure for marking deleted sketches (speeds up the marginal influence calculation); and 4. Leskovec *et al.* technique [8] (speeds up the seed calculation).

Influence estimation is part of seeds calculation. With minor changes, the code provides the solution for IE problem, when a seed set is inputted.

We compared the runtime and space of 2DL and DIM, a state-of-the-art implementation of RIS by Ohsaka *et al.* ([12]). For both algorithms, we used the same lower bound on the hypergraph weight from [2]. Our 2DL implementation significantly outperforms DIM. Testing results are discussed in detail in subsection 4.1.

3.3 Flat Arrays (FA)

FA implementation modifies the BuildHypergraph procedure of 2DL (subsection 3.2). The pseudocode is shown in Algorithm 2.

To store the hypergraph, FA creates two flat, one-dimensional, arrays of integers: *sketches* and *nodes*. *sketches* stores the sketch

¹Theorem 4.1 in [2], version 5, updated June 22, 2016.

Algorithm 1 2DL

Input: directed graph G with n nodes and m edges, coefficient β , number of seeds k

Output: seeds set $S \subseteq V$ of size k , spread $\sigma(S)$

```

1:  $R \leftarrow \beta * m * k * \log(n)$ 
2:  $H \leftarrow \text{BuildHypergraph}(R)$ 
3: return  $\text{GetSeeds}(H)$ 
4: procedure BUILDHYPERGRAPH( $R$ )
5:   while  $H\_weight < R$  do
6:      $v \leftarrow$  random vertex of  $G^T$ 
7:      $sketch \leftarrow$  reachable nodes in  $G^T$  starting from  $v$ 
8:     for each node  $u \in sketch$  do
9:       append  $sketchID$  to  $u$ 's list of sketches
10:       $count[u] \leftarrow count[u] + 1$ 
11:   return hypergraph  $H$ 
12: procedure GETSEEDS( $H$ )
13:    $S \leftarrow \emptyset$ ,  $\sigma(S) \leftarrow 0$ 
14:   for  $i = 1, \dots, k$  do
15:     seed  $v_i \leftarrow \text{argmax}_v \{count[v]\}$ 
16:      $S.insert(v_i)$ 
17:      $\sigma(S) \leftarrow \sigma(S) + count[v_i]$ 
18:     remove the sketches containing  $v_i$ 
19:   output  $S$ ,  $\sigma(S)$ 
```

ID, *nodes* stores the node IDs reached by this sketch. Arrays *sketches* and *nodes* are synchronized, so that knowing the index of a sketch, we can easily find the corresponding nodes, and *vice versa*. In the following figure we show an example of a *sketches* array (first row) and corresponding *nodes* array (second row):

0	0	0	0	1	1	2	2	3	4	4	5
0	1	2	3	2	3	1	3	2	2	3	0

In this example, sketch IDs and their corresponding node IDs are divided by double bars from other sketches: sketch 0 contains four nodes: 0, 1, 2, and 3; sketch 1 contains two nodes: 2 and 3; and so on. Note that sketches are listed in ascending order, and the corresponding nodes for each sketch are listed in ascending order as well. We use these features for speeding up the calculation of seeds. Testing FA on real-life graphs shows its better usage of space and faster performance than 2DL (subsection 4.1).

Algorithm 2 FA

```

1: procedure BUILDHYPERGRAPH( $R$ )
2:   initialize sketches and nodes arrays to -1
3:   while  $H\_weight < R$  do
4:      $v \leftarrow$  random vertex of  $G^T$ 
5:      $sketch \leftarrow$  reachable nodes in  $G^T$  starting from  $v$ 
6:     for each node  $u \in sketch$  do
7:        $sketches[i] \leftarrow sketchID$ 
8:        $nodes[i] \leftarrow u$ 
9:        $count[u] \leftarrow count[u] + 1$ 
10:   return hypergraph  $H = (sketches, nodes)$ 
```

3.4 Compressed Flat Arrays (CS-FA)

Here we present a more efficient implementation, the CS-FA algorithm (Algorithm 3). The main difference between CS-FA and FA is the design of the *sketches* array: CS-FA stores the accumulated

Algorithm 3 CS-FA

```
1: procedure BUILDHYPERGRAPH( $R$ )
2:   initialize  $nodes$  array to -1
3:   while  $H\_weight < R$  do
4:      $v \leftarrow$  random vertex of  $G^T$ 
5:      $sketch \leftarrow$  reachable nodes in  $G^T$  starting from  $v$ 
6:     for each node  $u \in sketch$  do
7:        $node\_count \leftarrow node\_count + 1$ 
8:       add  $nodeID$  to array  $nodes$ 
9:        $count[u] \leftarrow count[u] + 1$ 
10:    add  $node\_count$  to array  $sketches$ 
11:   return hypergraph  $H = (sketches, nodes)$ 
```

count of nodes included in sketches, thus making the *sketches* array compressed. Now we do not need to store sketch id's explicitly: sketch id's are the indexes in array *sketches*. The example below shows that sketch 0 includes three nodes, sketch 1 includes $(5 - 3) = 2$ nodes, and so on. The *nodes* array lists the corresponding nodes.

sketches:

3	5	6	8	10
---	---	---	---	----

nodes:

0	1	3	0	1	0	2	3	3	4
---	---	---	---	---	---	---	---	---	---

When we want to retrieve a sketch with id, say i , we need to find where its nodes start in the nodes array. This is given by the number stored in $sketches[i - 1]$ or 0 if $i = 0$. Testing shows CS-FA's smaller footprint and better run time than 2DL's or FA's (subsection 4.1).

4 EXPERIMENTAL RESULTS

We tested our IM and IE solutions by extensive experiments on several real-world graphs. For brevity, we included in this paper only the most interesting and telling results for IM and their analysis. All the presented results are achieved on a consumer-grade laptop with 16G of main memory.

We implemented the algorithms in Java 8 taking advantage of parallel streams and lambda expressions, and used Webgraph [1] as a graph compression framework. We compared our implementations with each other and with the DIM algorithm, implemented in C++ ([12]). We used the DIM code from <https://github.com/todo314/dynamic-influence-analysis>.

Datasets. Due to space constraints, we only present results for three real world graphs. Results for other datasets were similar. The datasets are available from the Laboratory for Web Algorithmics (<http://law.di.unimi.it/datasets.php>).

Dataset	n	m
UK100K	100,000	3,050,615
CNR-2000	325,557	3,216,152
EU-2005	862,664	19,235,140

Table 1: Datasets ordered by m .

While the size of the networks we considered is in the medium range, since each node can be sampled many times (we use sampling with replacement), the count of edges touched by the algorithms is in the billions. For example, the smallest of presented datasets, UK100K, requires a hypergraph with a weight of at least 5.6 billion, in order to produce the IM solution for $\beta = 16$ and $k = 100$.

Equipment. The experiments were conducted on a laptop with processor 2.2 GHz Intel Core i7 (4-core), RAM 16GB 1600 MHz DDR3, running OS X Yosemite.

Parameters. The parameters we use in our testing are as follows. k is the number of seeds in the seed set, β is a coefficient in Borgs *et al.* formula for the hypergraph weight, and p is the probability of edge existence. The tests are conducted varying k and β for $p = 0.1$.

4.1 Comparison of arrays, 2D list, and DIM performance

Fig. 1 shows the total running time and the time used for seeds calculation by DIM vs. our implementation of 2DL vs. FA vs. CS-FA. The test shown was conducted on CNR-2000, for $k = 10$, $p = 0.1$, and $\epsilon = 0.1$, varying β in powers of 2, from 2 to 128.

Figure 1: Processing time for cnr-2000; $k=10$, varying β .

The two-dimensional list implementations, DIM and 2DL, run slower and require more memory than array implementations. The reason for comparatively poor performance of 2D list implementations is the fragmentation of the main memory, when allocating space for each second-dimension list of sketch numbers for a node. This causes the memory manager to perform a lot of work trying to rearrange memory blocks. Improvements implemented in 2DL listed in subsection 3.2 allow for a better time performance on both the hypergraph computation and seed calculation, compared to DIM. For example, for $\beta = 16$, DIM took three times longer than 2DL to produce the result. The running times of FA and CS-FA are almost identical with each other. This is good for CS-FA; the compression we perform not only does not slow down CS-FA, but it makes CS-FA slightly faster due to better memory utilization. Both FA and CS-FA are faster than 2DL and DIM.

On both charts in Fig. 1, some data points are missing, because of the required memory being higher than what is available on the machine. 2DL and FA can handle runs with a β up to 32 and 64, respectively, while CS-FA can handle β equal to 128 due to its smaller memory footprint. That is, CS-FA scales the most, about 8 times more than DIM.

Fig. 2 shows the performance of 2DL, FA, and CS-FA when parameters k and β are growing, from the first chart, where all three implementations could run to completion, till the last one, where only the most efficient data structure (CS-FA) could produce one result, for the lowest β . The larger the β and k , the longer it takes for building the hypergraph and calculating the seeds, within one graph. This can be seen in the charts, while following a column from the top chart down. The larger the graph, the longer it takes for building the hypergraph and calculating the seeds. This can be seen in the charts, while following a row from the left chart to the right.

The largest hypergraph, successfully created and processed on the laptop, touched almost 5.6 billion edges. This hypergraph was

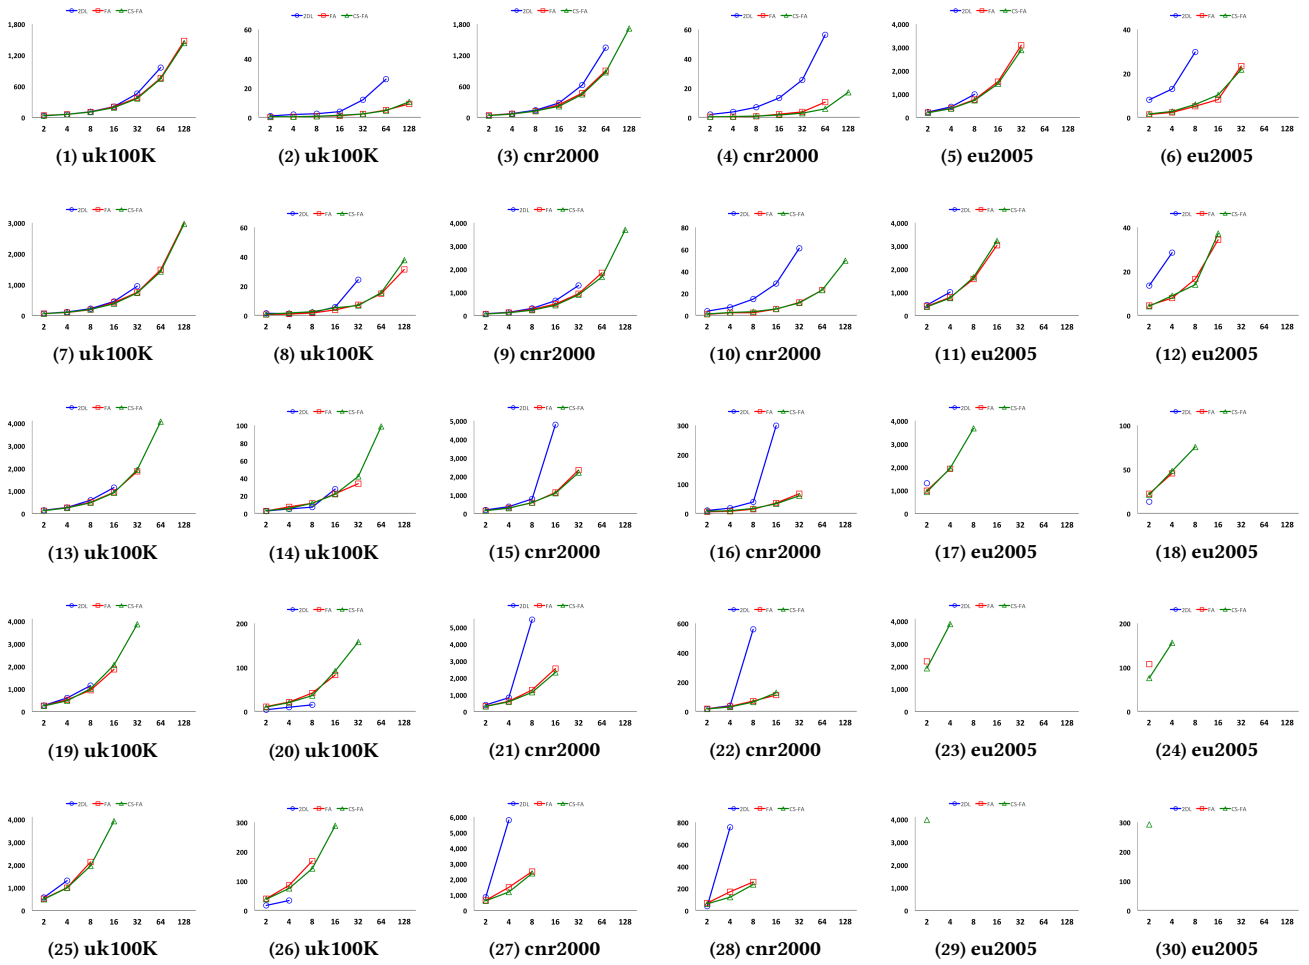

Figure 2: Total time (sec), and seeds time (sec). Per row, $k = 5, 10, 25, 50, 100$

processed by CS-FA (subsection 3.4). It took CS-FA one hour six minutes, including five minutes for calculating 100 seeds. We do not know another algorithm that can process such a hypergraph on a comparable machine.

Finally, in both Fig. 1 and 2, we observe that the time for calculating seeds is only a small part of the total time, which influenced our decision to not show separately experiments for IE (due to space constraints).

5 CONCLUSIONS AND FUTURE RESEARCH

We presented several implementations for computing influence estimation and influence maximization on graphs with multimillion edges. Our algorithms use different data structures. We tested the performance of these data structures on larger graphs, and provided a comparative analysis of test results. We substantially reduce the running time and required memory, without affecting the theoretical guarantees, to the point that multimillion-edge graphs could be processed on a consumer-grade laptop. Future research will involve further compression and parallelism aiming at scaling the computation of influence to bigger networks.

A Roadmap towards Declarative Similarity Queries

Nikolaus Augsten
 University of Salzburg

 nikolaus.augsten@sbg.ac.at

ABSTRACT

Despite many research efforts, similarity queries are still poorly supported by current systems. We analyze the main stream research in processing similarity queries and argue that a general-purpose query processor for similarity queries is required. We identify three goals for the evaluation of similarity queries (declarative, efficient, combinable) and identify the main research challenges that must be solved to achieve these goals.

1 INTRODUCTION

In a similarity query, two data objects “match” if they are similar. Similarity queries are required in scenarios where equality and exact matches are not effective, for example, when dealing with noisy data (e.g., in data analytics, ETL processes, data cleaning, and entity resolution), for detecting small differences between data objects (e.g., finding similar molecular structures in computational biology), for comparing complex objects (e.g., trees, graphs, or multimedia content), and for querying physical measurement data (e.g., time series, spatial objects, sensor data).

Similarity queries involve a *similarity function* defined on a specific data type and an *operator*. The similarity function assesses the similarity (or dissimilarity) between pairs of objects, e.g., the edit distance between strings or trees, Cosine similarity between sets, or Euclidean distance between vectors. The operator defines the input signature (e.g., lookup vs. join) and the pairs that qualify for the result set (e.g., top-*k*, range, or skyline query).

Database management systems (DBMS) for *exact queries* (i.e., predicates based on equality, less-than, or greater-than) have evolved into powerful and mature systems, which transparently and efficiently deal with data storage and querying. Unfortunately, this development has not happened for similarity queries. Applications that require advanced similarity features cannot rely on general-purpose systems that transparently handle data storage and querying. Instead, similarity queries must be dealt with in custom, ad hoc code. Writing custom code for similarity queries is expensive, requires advanced query processing skills, and often results in inflexible, hard-coded query plans. Changing the query beyond simple parameter settings requires additional programming efforts.

In this paper we argue that the integration of similarity queries into declarative DBMS (relational or non-relational) and the efficient processing in a systems context are the next challenges to be solved for similarity queries. In the past, the main research focus was on physical operators and access methods: new evaluation algorithms and index structures for specific combinations of operators, data types, and similarity functions were proposed. The evaluation of similarity queries in a larger systems context, however, has received little attention.

Developing a general-purpose query processor for similarity queries is challenging, both from a conceptual and a technical point of view. From a conceptual point of view, similarity queries pose a particular challenge. While the meaning of similarity is highly application dependent, the query interface should be general and serve a wide range of application needs. Note that application dependency is much less pronounced in equality queries: for most data types, the notion of equality is well defined and application independent.

From a technical point of view, many techniques that are effective for equality queries are not applicable to similarity queries. Techniques for equality queries often rely on exact matches or some ordering, which cannot be assumed between similar objects. An example is hashing, which leverages the fact that identical data values are hashed to the same bucket. This does not hold for similar values: they will typically be hashed to different buckets. Another example is sorting, which is not reliable for similar data items since even a small change may have a large impact on the position of the data item in the sort order. Further, little is known about the interaction of physical similarity operators with other, equality-based operators in the query context. This involves all aspects of query processing, including modeling similarity operators at the logical level (e.g., extending relational algebra), rewriting query plans, estimating the cost of similarity operators, and gracefully adapting to limited memory resources.

This paper suggests to depart from the main stream in similarity research with its narrow focus on individual physical operators and studies similarity queries from a broader systems perspective. The overall goal is to develop a deep understanding of all aspects of similarity queries that are required to build a general-purpose query processor for these queries.

2 DEC – DESIDERATA FOR SIMILARITY QUERIES

We identify three core requirements for a similarity query processing system: *declarative, efficient, combinable (DEC)*, i.e., declarative queries that combine equality and similarity predicates should be processed efficiently. We believe that all DEC requirements must be satisfied in a useful end-to-end system for similarity queries. We next discuss each of the three DEC requirements, which are orthogonal aspects of a query answering system.

Declarative. The queries should be declarative, i.e., the query describes *what* the answer to the query should look like rather than *how* the answer should be computed. A declarative approach allows flexible queries and a clearer separation between logical and physical layer. While the users express their queries at the logical level, the system must translate the query into a physical execution plan. Declarative data query languages are the predominant approach in the traditional relational model [9] with SQL (Structured Query Language) as a practical query language, but have also been applied to non-relational data models (e.g., XPath¹ for semi-structured data) and to cluster computing

¹<http://www.w3.org/TR/xpath-30/>

systems with flexible data types (e.g., HiveQL [25] for analytic queries on large data clusters). Effective techniques for translating declarative queries to physical operators are required, and the resulting query plans must be optimized.

Efficient. The queries should be executed efficiently, i.e., efficient query plans that consider appropriate techniques for similarity operators should be constructed. Similarity predicates [13, 27] often involve complex and expensive functions, and a straightforward evaluation of the similarity predicate on each tuple is not feasible. A rich set of algorithms and access methods have been proposed to allow similarity queries to be processed efficiently. Such techniques are often based on an index or a filter/verify approach to reduce the number of expensive predicate evaluations [6, 11, 23]. Filters produce a set of candidates which contains false positives; in the verification step the false positives are removed. A widespread approach avoids the evaluation of the cross product in similarity joins by rewriting the join into an equality join on tokens, e.g., q -grams in a string similarity join [13]. When the similarity function is a metric, the triangle inequality and metric index structures can be leveraged [26]. A system for similarity queries should be able to effectively apply the efficient evaluation strategies that have been developed.

Combinable. Similarity and equality predicates should be arbitrarily combinable into complex queries. In useful queries, similarity predicates are embedded into a larger query context which includes a mix of equality and similarity predicates. In order to evaluate such a complex query efficiently, the query must be considered as a whole. It is not enough to process the similarity part independently from the equality part and then intersect (or union) the results. This may lead to very poor evaluation strategies since large intermediate results are produced. An example are conjunctive queries in which each individual predicate has weak selectivity (i.e., produces a large intermediate result set), but the conjunction of all predicates is strongly selective (i.e., the final result is small). A query processor for similarity queries should not be limited to the evaluation of the similarity predicate of the query, but should be able to evaluate both similarity and exact predicates alike.

3 SIMILARITY SUPPORT IN CURRENT SYSTEMS

Database Management Systems. DBMS typically offer basic support for similarity queries on strings, e.g., Soundex, a phonetic transcription of English surnames. More advanced similarity predicates are supported in the form of user defined functions (UDF). The UDF is used to evaluate the similarity predicate on a pair of attribute values. Unfortunately, the DBMS cannot produce efficient evaluation plans for queries with UDFs since they are a black box for the optimizer. UDFs are typically applied in a naive way (e.g., on each pair of tuples in a join [13]). Since the DBMS does not understand the properties of the similarity join, efficient filter/verify techniques (which have been proposed for similarity joins) or other optimizations cannot be leveraged. Overall, DBMS offer declarative, combinable similarity queries, but fail to process them efficiently.

Custom Software. Applications that require more sophisticated algorithms rely on custom software, e.g., as part of an entity resolution tool [10], at the back-end of a search form [18], or in some scientific application [7]. Due to the narrow focus and the predictable nature of the queries, the query plan is generated by

hand and hard-coded, and appropriate algorithms and indexes are implemented. Hard-coded query plans are problematic since the quality of a query plan depends on the query parameters and the data distribution. Good query plans are particularly important for similarity queries, which often involve expensive predicates [14, 16, 27]. Extending custom software with new queries requires substantial programming efforts.

Integrating Similarity into DBMS. There have been several attempts to extend DBMS with similarity features. Barioni et al. [2] propose the SIREN system and an SQL extension to deal with similarity queries over multimedia and relational data. SIREN processes the similarity part outside the DBMS in a separate system and integrates the results in a second step. This separation substantially limits the options for efficient query plans since the similarity predicate cannot be freely moved in the query plan. Guliato et al. [15] propose an extension for PostgreSQL (an open source DBMS) for image retrieval. Similarly, the `pg_similarity` extension of PostgreSQL defines a set of similarity functions (e.g., edit and q -gram distance for strings). These approaches do not change the query processor, but are UDF-based and cannot leverage advanced algorithms, indexes, and optimization techniques. Silva et al. [21] integrate physical operators for similarity join and group-by into the core of PostgreSQL; the similarity operators are limited to numeric values. The Metric Similarity Search Implementation Framework (MESSIF) [3] is a library for object retrieval in metric space; it supports metric indexes and algorithms for range queries and top- k selection, but no declarative query interface or a query optimizer. An attempt to define an SQL-based query language for MESSIF has been reported, but query processing is not discussed.

Silva et al. [22] study the conceptual evaluation and query transformation rules for various types of similarity queries based on metric distances. In addition to the well-known ϵ -join (range distance join), the k NN-join (k nearest neighbor join), and k D-join (k -distance join) they also discuss join-around, a combination of range and nearest neighbor join. In terms of select queries, ϵ - and k NN-selection are discussed. Carey and Kossmann [5] and Bruno et al. [4] discuss the optimization of top- k queries.

The system closest to our vision is DIMA [24], which extends SQL with range queries over strings and sets. DIMA builds on Spark, supports distributed query evaluation, and uses a signature-based approach to distribute the query load and filter candidate matches. Compared to our vision discussed in the next section, the high-level similarity operators are not split into algebraic primitives, there is no metadata to select filters and transform the queries accordingly, and a high-level similarity operator is mapped one-to-one to the respective physical operator.

Other Systems. Entity resolution systems like NADEEF [10, 12] use similarity functions between individual attribute values to deal with noise in the data. Digital libraries deal with mixed objects (multimedia, text, 3D structures) with the goal of preserving digital objects, allowing users to enter new items, and accessing content. In both cases, the query patterns are hard-coded in the application, i.e., declarative queries are not supported.

Information retrieval systems like INDRI² or Lucene³ store collections of documents (e.g., plain text, HTML, PDF) in files, build indexes over these files, and deal with stemming and stop word removal. Queries are phrases, possibly with wildcards, that

²<http://www.lemurproject.org/indri>

³<http://lucene.apache.org>

can be combined with boolean operators; the search can be limited to individual fields of a document (e.g., the title field). The query result is a list of documents, which is ranked by relevance. Similarity queries are supported at a very basic level. Lucene, for instance, supports the phonetic encodings Soundex and Metaphone, and edit distance selection. The queries in these systems are limited to selection and ranking; more complex query patterns (e.g., joins) are not supported.

4 ROADMAP

Challenges. We identify three challenges that must be addressed to build similarity queries into declarative database management systems: (1) A new, *minimal set of algebraic operators* for similarity queries must be defined. (2) *Dynamic rewriting*: metadata about eligible filters, indexes, and data transformations must be made available to the query optimizer. (3) A *uniform cost model* for physical similarity operators must be developed.

Minimal algebra. The goal is to develop a new algebra for similarity queries which extends relational algebra with a *minimal set of operator primitives* that is able to express a wide range of similarity operators.

Similarity (unlike equality) is not a binary predicate, and data items can be ranked by their “degree” of similarity w.r.t. some query. This gives rise to a large variety of new matching principles, for example, k -closest neighbor selection, similarity group-by, or join-around (k closest neighbors within a maximum distance range). Previous work, e.g., Silva et al. [22], defines an algebraic operator for each of these matching principles. We believe that this approach will not scale: (a) Each new operator requires deep changes in the system. (b) Query rewriting rules for each pair of operators must be defined, leading to a quadratic number of such rules. The key to success will be to establish a minimal, non-redundant set of primitives that are composed to express high-level operators. This will provide great flexibility in reordering queries, and introducing new high-level operators will not require changes in the algebra.

The new algebra should satisfy the following requirements. (a) *Minimal*: the new operators should be small, non-redundant primitives; the new algebra should cleanly separate two orthogonal concepts, which have often been mixed in previous work: the similarity function between two objects (e.g., edit distance) and the matching principle (e.g., top- k join). (b) *Expressive*: a wide range of similarity queries should be expressible in the new algebra; complex similarity operators (e.g., top- k join with edit distance), for which efficient implementations exist at the physical level, may be expressed by composing several of the new primitives at the logical level. (c) *Extendable*: Introducing new physical operators or query flavors at the user level should not require changes in the algebra. (d) *Transformable*: The new algebra should provide equivalence rules which allow the optimizer to reorder the logical operators in a flexible way. This is particularly important for small primitives since multiple primitives may compose a single physical operator.

Dynamic Rewriting. In order to expand queries with filters, metadata about similarity functions (e.g., edit distance), their relationship and properties (e.g., upper and lower bounds, metric properties), and applicable filters (e.g., q -grams for range joins) must be available. This metadata will be leveraged to dynamically produce query transformation rules. New filters can easily be introduced by updating the filter ontology: no changes in the optimizer are required.

The metadata stores properties of (a) similarity functions, (b) matching principles, and (c) filters, and their relationships. Similarity functions may satisfy metric properties (e.g., string edit distance) or even some L_i -norm (e.g., cardinality of set intersection, geographic distances). The relationships between similarity functions are guarantees like lower and upper bounds (e.g., the q -gram distance provides a lower bound for the more expensive edit distance). The filter ontology must further relate similarity function / matching principle pairs to eligible filter techniques. Some filters require data transformations, e.g., the computation of tokens [1], which should be specified in the metadata. The filter ontology must also provide information about the selectivity of filters, which will be used to model the query cost. Given a similarity predicate, the ontology should be able to derive all eligible filters (including necessary transformations and selectivity).

Expanding queries with filters leads to very different physical plans for a single logical query. The physical plans may involve techniques that have been developed by different communities, e.g., metric and token-based techniques. A uniform cost model is required to evaluate the plans. The cost model must consider the cost of similarity functions, which may be very expensive, filter selectivity, and the effect of filters on the data distribution.

Uniform cost model. A new cost model for physical similarity operators must be developed. The cost model should quantify the cost of different physical query plans, which result among others from introducing filters into the query plan or transforming data to the appropriate representation (e.g., string data may be transformed into tokens or signatures for filtering purposes). In the past, cost models for some individual operations (e.g., M-tree lookups [8]) have been developed. For other operations (e.g., set similarity joins [19]) experimental studies provide qualitative insights, but lack a model to predict the cost. Selectivity estimates [17, 20] are an important input for cost models, but selectivities are independent of physical operators. A quantitative assessment of the costs of all physical operators in the query is required. Computing comparable cost estimations is particularly challenging for approaches that have evolved in different communities, for example, edit similarity, token-based approaches, and metric techniques. The cost estimation will need to take into account the data distribution, any query parameters, the available resources, and the filter selectivities. The cost model should further integrate well with existing cost models for non-similarity operators since the overall query cost must be assessed.

Query processing. We envision the evaluation of a query that includes similarity predicates as illustrated in Figure 1: The parser generates a query tree that involves both standard relational operators and the new algebraic similarity primitives. Thereby, a high-level similarity operator like a top- k join or a skyline query will be represented by a number of low-level algebra operators. The query planner consults the similarity metadata to learn about eligible filter techniques like lower and upper bounds for the given similarity function and operator. Thereby, the query planner is not limited to the high-level operators in the original query. For example, there may only be filter information for nearest neighbor queries in the metadata, but the query is join-around [22] (which combines nearest neighbor and range join). The planner decomposes join around into algebraic primitives and tries to rearrange and match the primitives to known combinations in the metadata.

The query plans with filters will typically include additional algebra operators (representing the filter). Some filters will require

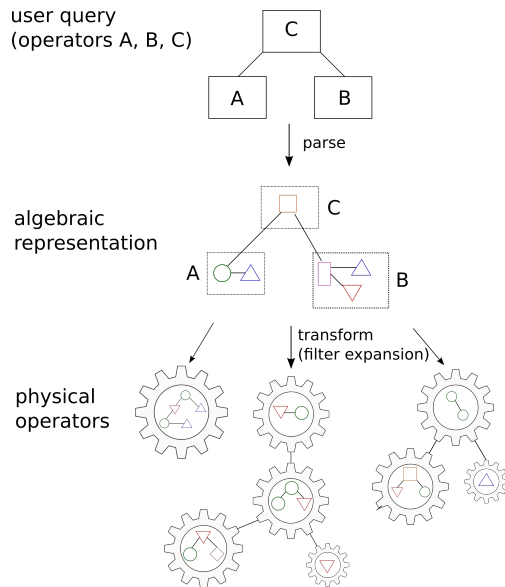

Figure 1: Interaction of system components.

on-the-fly index construction (e.g., prefix index for set similarity joins) or data transformations (e.g., tokens or signatures). The transformation rules for expanding the query plan with filters will be dynamically derived from the metadata. When new filters are registered in the metadata, they will trigger new query plans that apply these filters.

Finally, the cost of the query plans must be assessed. To this end, the algebraic operators must be arranged such that they match existing physical operators. Note that the logical query level (e.g., a query expressed in an SQL-like language) and the physical level are independent. There is no one-to-one match between the operators visible to the users and the physical operators actually implemented in the system. Rather, the operators in the user query are disassembled into algebra, and subtrees of the query plans are matched against existing physical operators.

5 CONCLUSION

This paper suggests to depart from the main stream in similarity research with its narrow focus on individual physical operators and studies similarity queries from a broader systems perspective. The overall goal is to develop a deep understanding of all aspects of similarity queries that are required to build a general-purpose query processor for these queries. The systems aspects discussed in this paper must be solved to enable wide applicability and impact of similarity queries in real systems. The main research challenges are the development of a minimal algebra for similarity queries, the design and querying of metadata regarding filter techniques for similarity queries, and the cost estimation for physical similarity operators.

A declarative interface will have a fundamental impact on the user interaction with similarity queries. Database users will no longer need to write ad-hoc code for evaluating similarity predicates. Instead, similarity predicates are expressed in a declarative way and are processed efficiently. Application developers will not need to bother about the details of similarity query processing. We expect a general-purpose query processor to trigger a wide adoption of similarity queries also in applications that so far could not afford the overhead of writing custom code.

Finally, a declarative similarity query processor will set new standards in the research community. New algorithms for physical operators must be evaluated against the query plans produced by the similarity-enabled optimizer, which can leverage a wide range of techniques, and dynamically adapts to query parameters and data distribution. Further, new algorithm proposals will not only be measured by their performance in an isolated setting, but also by their usefulness in a systems context.

ABSTRACT

Data exploration is seeing a renewed interest in our community. With the rise of big data analytics, this area is growing to encompass not only approaches and algorithms to find the next best data items to explore but also interactivity, i.e. accounting for feedback from the data scientist during the exploration. Interactivity is essential to account for evolving needs during the exploration and also customize the discovery process. In this tutorial, we focus on the interactive exploration of Composite Items (CIs).

CIs address complex information needs and are prevalent in online shopping where products are bundled together to provide discounts, in travel itinerary recommendation where points of interest in a city are combined into a single travel package, and task assignment in crowdsourcing where personalized micro-tasks are composed and recommended to workers. CI formation is usually expressed as a constrained optimization problem. For instance, in online shopping, package retrieval can retrieve the cheapest smartphones (optimization objective) with compatible accessories (constraints). Similarly, a city tour must be the most popular and conform to a total time and cost budget. A data scientist interested in exploring a variety of CIs has to repeatedly reformulate optimization problems with new constraints and objectives. In this tutorial, we investigate the applicability of interactive data exploration approaches to CI formation.

We will first review CI applications and shapes (15mn). We then discuss three big research questions (60mn): (i) algorithms for CI formation, (ii) modes of exploration for CIs, and (iii) human-in-the-loop CIs. We will conclude with research directions (15mn).

The proposed tutorial is timely. It brings together several related efforts and addresses unsolved questions in the emerging area of human-in-the-loop exploration of complex information needs. The tutorial is relevant to the general area of data science and more specifically to Scalable Analytics, Data Mining, Clustering and Knowledge Discovery, Indexing, Query Processing and Optimization, and Crowdsourcing. The technical topics covered are constrained optimization, ranking semantics, clustering, algorithms, and empirical evaluations.

1 OUTLINE AND SCOPE

1.1 Scope

The tutorial targets theoreticians and practitioners interested in the development of data science applications. It should be of particular interest to an audience who wants to learn about how different domains, such as product recommendation, scientific simulation, or team formation in the social sciences, have been developing their “siloed” definitions of CIs. Tutorial attendees are expected to have basic knowledge in algorithms and data management. Knowledge in constrained optimization is not necessary.

Figure 1: A Star CI

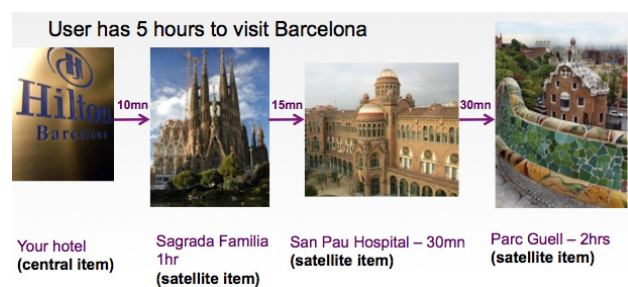

Figure 2: A Chain CI

1.2 Outline

1.2.1 CI Applications and Shapes (15mn). We will begin the tutorial by providing example applications that justify the need for Composite Items (CIs). This part will gather those examples and attempt to unify them. Figures 1, 2, 3 show the many shapes CIs can take in shopping (star shape, where satellite items must be compatible with a central item), traveling (chain shape, where an item must be geographically close to its preceding item), and dining (where items are jointly co-reviewed by the same people), respectively.

1.2.2 Research Questions: (60mn). As our tutorial topic is *building and exploring CIs interactively*, the second part of the tutorial is organized into three big research questions: (i) algorithms for CI retrieval, (ii) how data exploration is typically done for large-scale datasets and its applicability to exploring CIs, and (iii) what types of user interactivity are common and their applicability to building and exploring CIs interactively. For each question, we will review the state of the art and discuss new research challenges.

Research Question 1: CI Retrieval (20mn). Different CI shapes require the specification of different constraints and optimizations, thereby leading to a no “one-size-fits-all” CI definition. We will discuss why and how the nuances of data, such as type heterogeneity, dimensionality, distribution, or even storage, impact

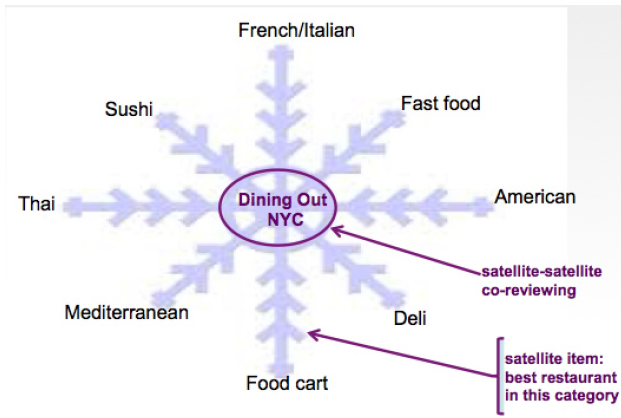

Figure 3: A Snowflake CI

the semantics and performance of building different shapes of CIs. For example, the type of aggregation that a climatologist seeks to build a CI that reflects a meaningful “climate model” is significantly different from that of a retail business manager who packages compatible items for product recommendation, or from a crowdsourcing platform that bundles diverse micro-tasks to address workers’ boredom. Using these applications, we will present scenarios where exploration of CIs and interactivity are essential. For instance, in the domain of experiment design, we will show the necessity of leveraging feedback from domain scientists to select a different set of parameters that appropriately capture a scientific simulation process, and represent it as a CI. In the travel world, we will argue that interactivity helps refine one’s partial needs and build personalized packages [20, 24]. Similarly, in crowdsourcing, a CI may represent a bundle of diverse tasks that are more exciting to workers than a ranked list of tasks [4].

Research Question 2: CI Exploration (20mn). The aim of this part is to bridge the gap between exploration in emerging data science applications and exploring structured data, and discuss how that can serve CI exploration.

We will first describe approaches that are popularly used among data scientists to explore large-scale datasets. Such data exploration techniques lack well-defined objectives and are mostly done following a trial-and-error approach. Consequently, most of the visualization-based data exploration techniques that data scientists popularly use are ad-hoc and unprincipled.

After that we will discuss data exploration techniques that are more principled and investigated in conjunction with structured databases, especially considering a user input, in the form of queries, example data, or data distributions. Some notable examples in that space relate to faceted search and query expansion techniques [8, 9, 11, 12, 14, 16, 21, 29, 30]. We will also discuss some recent work that investigates exploration and visualization techniques intended to assist users by looking for similar data distributions [5, 22, 23, 26] or in an example-driven exploration [15, 19]. We will argue why these techniques are not directly applicable to CI exploration.

Finally, we will discuss why CI exploration needs to go beyond existing techniques and rely on optimization-guided data exploration as in [18]. We will pose open problems and computational challenges in designing appropriate solutions for exploring CIs.

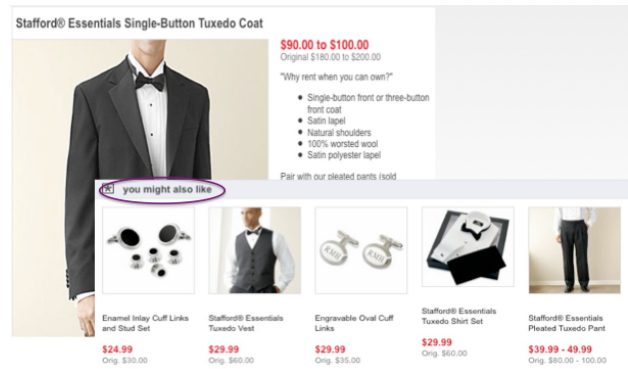

Figure 4: Recommending Satellite Items

Research Question 3: Human-in-the-Loop CIs (20mn). The third challenge is how to incorporate human-in-the-loop effectively to enable interactive data exploration.

We will first discuss different types of interactivity that a user is allowed to provide, ranging from binary responses to capturing implicit actions. We will do that in the context of different contexts such as crowdsourcing, recommender systems, experiment design, or machine learning applications that require supervised samples for training models. In conjunction, we will discuss different types of users, such as naive users or domain experts, and investigate what types of challenges, such as expressivity of interaction, bias, and real-time interactions, they incur. We will examine how these questions can be revisited in the context of building CIs and review preliminary work on satellite item recommendation [7, 20] (also see Figure 4), and on adding or deleting specific items in CIs [24] (also see Figure 5). An additional challenge when interacting with CIs is the visual layout. Unlike “flat” items, aiding users in their interactions with CIs, via recommendations or maps for instance, is necessary for a full-fledged exploration.

In a second part, we will describe other types of feedback that are rather non-traditional and only discussed in recent work, such as feedback on metadata rather than on the entire object. We will discuss how such feedback is processed for answering queries, feature selection, or feature engineering in the data science pipeline [10, 17, 32]. We will describe our vision on hybrid approaches that discuss how to leverage sophisticated yet limited human feedback in the computational loop and show their utility for CIs.

1.3 Research Challenges: (15mn)

In this last part of the tutorial, we will summarize and brainstorm our overarching framework to enable optimization-guided data exploration techniques that enable a human-in-the-loop approach. We will discuss what types of applications it will support and conclude by outlining some major challenges in combining CI exploration and interactive CIs.

1.4 Overlap with Previously Presented Tutorials

In WWW 2015, the authors presented a tutorial on composite items in the context of complex crowdsourcing [1]. This tutorial will have a very small overlap with that tutorial in the part that reviews various CI definitions. Other than that, the content of this tutorial was not presented before.

Figure 5: CIs on a Map

2 BIOGRAPHY

The authors published seminal papers on composite item retrieval and data exploration.

Sihem Amer-Yahia, *sihem.amer-yahia@cnsr.fr*, is a Research Director in Grenoble. Her interests are at the intersection of data management and social data exploration. She is the Editor-in-Chief of the VLDB Journal for Europe and Africa and PC co-chair of PVLDB 2018 and WWW Tutorials 2018.

Senjuti Basu Roy, *senjuti.basuroy@njit.edu*, is an Assistant Professor at NJIT. Her research interests lie in the area of data and content management of web and structured data with a focus on exploration, analytics, and algorithms. She is the PC Co-chair of SIGMOD 2018 mentorship track, PC co-chair of VLDB 2018 PhD workshop track.

Recent Advances in Recommender Systems: Matrices, Bandits, and Blenders

Georgia Koutrika
Athena Research Center
Athens, Greece
georgia@imis.athena-innovation.gr

ABSTRACT

Recent years have witnessed an explosion in methods applied to solve the recommendation problem. Modern recommender systems have become increasingly more complex compared to their early content-based and collaborative filtering versions. In this tutorial, we will cover recent advances in recommendation methods, focusing on matrix factorization, multi-armed bandits, and methods for blending recommendations. We will also describe evaluation techniques, and outline open issues and challenges. The ultimate goal of this tutorial is to present a toolkit of new recommendation methods in perspective to data-related problems, and highlight opportunities and new research paths for researchers and practitioners that work on problems in the intersection of recommender systems and databases.

1 INTRODUCTION

The proliferation of digital content in a plurality of forms (including e-news, movies, and online courses), along with the popularity of portable devices has created immense opportunities as well as challenges for systems to provide users with information and services that best serve the users' needs. Matching consumers with the most appropriate items is key to enhancing user satisfaction and loyalty. Recommender systems come to the rescue providing advice on movies, products, travel, leisure activities, and many other topics. Personalized recommendations can elevate the user experience. That is why e-commerce leaders like Amazon and Netflix have made recommender technology a salient part of their systems [15].

Broadly speaking, recommender systems are based on one of two strategies. *Content-based filtering* creates a profile for each user or item to characterize their features. The profiles allow the recommender system to associate users with matching items. An alternative to content-based filtering relies only on past user behavior (e.g., previous purchases or user ratings). This approach is known as *collaborative filtering*, a term coined by the developers of Tapestry, an early recommender system [10]. Collaborative filtering analyzes relationships between users and interdependencies among items to identify new user-item associations based on which to make recommendations.

Recent years have witnessed an explosion in methods applied to solve the recommendation problem and modern recommender systems have become increasingly more complex. Matrix factorization methods, popularized with the Netflix prize [15], have become a dominant methodology within collaborative filtering recommenders due to their superior performance both in terms of recommendation quality and scalability. On the other hand,

multi-armed bandits are becoming popular in interactive recommendation settings, for example for recommending songs in Pandora [29]. Ranked lists of items generated by different recommender systems are blended together into the final list of recommendations shown to the user. The blending problem is essentially a multi-objective optimization problem, with objectives such as relevancy, coverage and diversity competing with each other [6, 25]. Overall, the landscape of recommender systems has changed immensely since the first content-based and collaborative filtering systems emerged, and the state-of-the-art approaches show outstanding results and open up new opportunities and research paths.

Interestingly, we are used to thinking of recommendations in the context of systems that serve items, such as movies, products, friend connections, etc, to users. The reality is that the recommendation problem arises in many different scenarios beyond those targeting user consumption. For example, in the context of databases, such scenarios include but are not limited to data exploration, query optimization, visualization, data integration, and workflow design, where the purpose is to select tuples [7], queries [9], views [8], exploration actions [19], query plans [30], visualization graphs [26–28], work flows [12], and so forth. While there is work in these areas, it pales compared to the amount and diversity of recommendation methods developed for items such as movies and products.

Therefore, the purpose of this tutorial is two-fold. First, it aims at providing a comprehensive overview of recent advances in recommendation methods, highlighting their capabilities and their impact. The focus of the tutorial is on matrix factorization methods, multi-armed bandits, and blending methods. It will discuss major techniques, evaluation methodologies, and open issues. Since the recommendation problem appears in many different settings, it is the purpose of this tutorial to provide a solid framework for placing novel recommendation work into perspective for data-related problems, provide a toolkit of new methods, and highlight research opportunities for researchers and practitioners in database systems, data-intensive applications, and the intersection of recommender systems and databases.

The following sections describe the structure and contents of the tutorial. The tutorial does not require any prior knowledge in recommender systems since there will be detailed introductions to the relevant techniques.

2 OUTLINE

The tutorial is structured in the following parts.

2.1 Recommendation Framework

The objective of this section is to introduce the audience to the recommendation problem, define the basic concepts as well as the different instances of the problem (e.g., rating prediction and whole-page optimization), and provide an overview of the classical approaches for generating recommendations.

Recommender systems appeared back in the nineties, and two broad categories of recommendation approaches emerged: content-based and collaborative filtering. Content-based approaches analyze user past selections (e.g., web pages they visited, movies they watched) to learn user preferences and recommend items with similar content to the user’s past selections and likes.

Collaborative filtering analyzes usage data (e.g., user ratings and purchases) and recommends to the user either items with similar usage characteristics as the items selected by this user or items from users with similar usage characteristics to this user.

We will explain the basic characteristics and operations behind each family of methods as well as their advantages and their shortcomings. The objective of this section is to lay the necessary foundations for the rest of the tutorial. It also aims at preparing the ground for understanding the methods to be presented subsequently and their impact.

2.2 Matrix Factorization

Matrix Factorization has gained popularity in recommender systems in recent years due to its superior performance both in terms of recommendation quality and scalability. Part of its success is due to the Netflix Prize contest for movie recommendations, which popularized a Singular Value Decomposition (SVD) based matrix factorization algorithm [13]. The Netflix Prize competition began in October 2006 and has fueled much recent progress in the field of collaborative filtering. For the first time, the research community gained access to a large-scale, industrial strength data set of 100 million movie ratings while the nature of the competition encouraged rapid development, where innovators built on each generation of techniques to improve prediction accuracy.

Experience with datasets such as the Netflix Prize data has shown that matrix factorization methods deliver accuracy superior to classical nearest-neighbor techniques [14]. At the same time, they offer a compact memory-efficient model that systems can learn relatively easily. What makes these techniques even more convenient is that models can integrate naturally many crucial aspects of the data, such as multiple forms of user feedback, temporal dynamics, and confidence levels.

In its basic form, matrix factorization characterizes both items and users by vectors of latent factors inferred from the ratings users gave to the items. Early systems use Singular Value Decomposition (SVD) – a well-established technique for identifying latent semantic factors in information retrieval – as a matrix factorization method for collaborative filtering. In the following years, several extensions to matrix factorization have been proposed and matrix factorization becomes the foundation in most recent recommender systems.

We will start with some background on Singular Value Decomposition and describe how early works (e.g., [23]) use SVD to capture latent relationships between customers and products and to produce a low-dimensional representation of the original customer-product space in order to compute the predicted likeliness of a certain product by a customer. We will introduce Low-rank Matrix Factorization [13, 21] followed by most recent important extensions to Matrix Factorization for recommendations, such as SLIM [20].

2.3 Multi-armed Bandits

Traditional recommender systems, including collaborative filtering, content-based filtering and hybrid approaches, can provide meaningful recommendations at an individual level by leveraging

users’ interests as demonstrated by their past activity. However, in many web-based scenarios (e.g., filtering news articles or display of advertisements), the content universe undergoes frequent changes, with content popularity changing over time as well. Furthermore, a significant number of visitors are likely to be entirely new with no historical consumption record whatsoever; this is known as a cold-start situation. These issues make traditional recommender approaches difficult to apply. In such highly dynamic recommendation domains, it is essential for the recommendation method to adapt to the shifting preference patterns of the users and the evolving space of items. Exploration-exploitation methods, a.k.a. multi-armed bandits, have been shown to be an excellent solution.

In probability theory, the multi-armed bandit problem is a problem in which a gambler at a row of slot machines (sometimes known as “one-armed bandits”) has to decide which machines to play, how many times to play each machine and in which order to play them. When played, each machine provides a random reward from a probability distribution specific to that machine. The objective of the gambler is to maximize the sum of rewards earned through a sequence of lever pulls.

For example [17], in the context of article recommendation, we may view articles in the pool as arms. When a presented article is clicked, a reward of 1 is incurred; otherwise, the reward is 0. With this definition of reward, the expected reward of an article is precisely its clickthrough rate (CTR), and choosing an article with maximum CTR is equivalent to maximizing the expected number of clicks from users, which in turn is the same as maximizing the total expected reward in the bandit formulation. Furthermore, we may “summarize” users and articles by a set of informative features that describe them compactly. By doing so, a bandit algorithm can generalize CTR information from one article/user to another, and learn to choose good articles more quickly, especially for new users and articles.

We will first present context-free K-armed bandit algorithms [4, 22], such as ϵ -greedy and upper confidence-bound (UCB) algorithms [1, 3, 16], and then move to contextual bandit algorithms [17, 29]. We will focus on multi-armed bandits used in the context of recommender systems and in particular in three problems: (a) Popularity ranking, to balance exposure of new items (exploration) with old winners (exploitation), (b) Model-based collaborative filtering [11, 18], and (c) Dueling bandits, to efficiently compare multiple recommendation methods [5, 24].

2.4 Blending Models

Several domains require “blending” of recommendations from different sources. Blending allows different recommendation strategies to develop independently, and combine their outputs post-hoc into a meta-recommender. The result aims at providing recommendations of higher quality and diversity. For instance, the Pinterest Homefeed is a personalized feed of content (i.e., pins) drawn from many sources, including followed users, followed topics, and recommendations, among other sources. Each type of content is ranked by its own specialized machine learning model, and then blended with a ratio-based round-robin method to create the final Homefeed [6].

We will examine different methods to blend recommendations, including fixed ratio, greedy, calibrated ranker and multi-armed bandit-approaches [2, 6, 25]. As we examine these blending systems, new questions arise as to how to measure success. Unlike traditional search ranking problems, recommender systems face

both short- and long-term optimization challenges as there is a need to balance immediate user-engagement metrics and long term ecosystem health. We will examine new such metrics and approaches to this end.

2.5 Lessons Learnt and Open Issues

In this section, we will discuss lessons learnt, open issues and new research directions created by these novel recommendation methods. We will also discuss about recommendation problems that do not target user consumption. In particular, we will describe such scenarios including data exploration, query optimization, visualization, data integration, workflow design, and so forth, where the purpose is to sort out not movies or products but queries, views, exploration actions, query plans, visualization graphs, and so forth. We will examine these problems in the light of the recent developments in the recommendation arena and discuss new research directions and opportunities that arise.

3 PRESENTER BIO

Georgia Koutrika is Director of Research at Athena Research Center in Greece. She has worked at HP Labs in Palo Alto, at IBM Research-Almaden in San Jose, and as a postdoctoral researcher at the Computer Science Dept., Stanford University. She has worked extensively on personalization and recommender systems, large-scale information extraction, entity resolution and information integration, and querying and data exploration interfaces. Her work has been incorporated in commercial products, has been described in 7 granted patents and 19 patent applications in the US and worldwide, and has been published in more than 80 research papers in top-tier conferences and journals. An IEEE Senior member, ACM member, and ACM SIGMOD Associate Information Director, Georgia has also served as a General Co-Chair for ACM SIGMOD 2016, Industrial Track PC Chair for EDBT 2016, and Workshop and Tutorial Co-Chair for IEEE ICDE 2016. She is currently Demo PC co-chair for ACM SIGMOD 2018.

ABSTRACT

Cypher is a property graph query language that provides expressive and efficient querying of graph data. Originally designed and implemented within the Neo4j graph database, it is now being used by several industrial database products, as well as open-source and research projects. Since 2015, Cypher has been an open, evolving language, with the aim of becoming a fully-specified standard with many independent implementations.

We introduce Cypher and the property graph model, and then describe extensions – either actively being developed or under discussion – which will be incorporated into Cypher in the near future. These include (i) making Cypher into a fully compositional language by supporting multiple graphs and allowing graphs to be returned from queries; (ii) allowing for more complex patterns (based on regular path queries) to be expressed; and (iii) allowing for different pattern matching semantics – homomorphism, relationship isomorphism (the current default) or node isomorphism – to be configured at a query-by-query level.

A subset of the proposed Cypher language extensions has already been implemented on top of Apache Spark. In the tutorial, we will present our approach including an in-depth analysis of the challenges we faced. This includes mapping the property graph model to the Spark DataFrame abstraction and the translation of Cypher query operators into relational transformations. The tutorial will conclude with a demonstration based on a real-world graph analytical use case.

1 INTRODUCTION

The past few years have seen a marked increase of property graph databases [12] – such as Neo4j [20], Sparksee and JanusGraph – in both the industrial and research arenas. Property graphs have become the model of choice for next-generation graph applications¹. Their use increasingly replaces older approaches to graph data processing such as cross-linked document stores or object-oriented database management systems.

Across both research and industry, property graphs have been used in a wide variety of domains, spanning areas as diverse as fraud detection, recommendations, geospatial data, master data management, network and data centre management, authorisation and access control [23], the analysis of social networks [5], bioinformatics [1, 14, 28] and pharmaceuticals [18], software system analysis [9], and investigative journalism [3].

This trend of increased usage of property graphs is grounded in: (i) their ability to operate on multiple large and highly-connected data sets as one graph that enables novel pattern matching and

graph analytical queries; (ii) their natural ability to cleanly map onto object-oriented or document-centric data models in programming languages; (iii) their visual nature that helps communication between business, application domain, and technical experts; and (iv) their historical development based on the pragmatic needs of real world application developers.

This trend is evidenced by two major factors. The first is the emergence of Cypher as the de-facto standard declarative query language for property graphs, and the second is the growing number of both industrial and academic software products for property graphs.

Since 2015, as part of the openCypher project [22], Cypher has been an open language, and is evolving under the auspices of the openCypher Implementers Group (oCIG), with the aim of becoming a fully-specified standard that can be independently implemented. The recently released Cypher 9 reference [21] along with accompanying formal grammar definitions (EBNF and ANTLR4) and conformance test suite (TCK) – published under the Apache 2.0 license – already provide implementers with a solid basis for adopting Cypher. At the time of writing, Cypher is supported by several commercial systems including SAP HANA Graph [24], Agens Graph, Redis Graph, and Memgraph, along with research frameworks including – in varying degrees of completeness – Gradoop [11], inGraph [15], Cytosm [25], Cypher for Apache Spark [19] and Cypher over Gremlin.

Current developments that are under way include the ability to pass multiple graphs and a table as input to a Cypher query. Moreover, queries will also be able to project and save multiple graphs, and this, coupled with the ability to chain queries together, will render Cypher as the first graph compositional query language. Following on from this work, complex pattern matching and configurable pattern matching semantics will further increase the utility of Cypher in the very near future.

2 SCOPE OF THE TUTORIAL

2.1 Intended audience

This tutorial is aimed at a wide scope of audience, including researchers, students, developers, and industrial practitioners who are interested in the emerging and quickly-evolving area of graph data, databases and languages. All attendees will gain a comprehensive idea of what this field comprises, as well as the future features and challenges that lie ahead for Cypher, the most-used property graph query language.

It is our hope that owing to the many challenges that exist in this area, researchers and students will be motivated to consider this area as a future topic of research.

There are no preliminary requirements for this tutorial, as it will be self-contained and commence with the property graph data model and Cypher, thus assuming no prior knowledge of these.

¹<https://db-engines.com/en/ranking/graph+dbms>

2.2 Goals of the tutorial

The main outcomes of the tutorial comprise:

- A comprehensive understanding of the property graph data model, and how it compares against some of the other graph data models.
- A good understanding of the Cypher property graph query language and its main constructs and features.
- An in-depth treatment of how Cypher will become a fully compositional language through the introduction of multiple graph support and query chaining.
- An overview of Cypher’s version of *regular path queries* in the form of path pattern queries, which additionally include node and relationship property tests to increase the expressivity of Cypher to manage emerging industrial use-cases and requirements.
- An understanding of node and relationship isomorphism and homomorphism, the characteristics of each, the benefits and drawbacks of each (from an industrial point of view) and how these are envisioned to be incorporated into Cypher.
- A good understanding of the Cypher implementation on top of Apache Spark and how to map a schema-free graph data model to a schema-based relational abstraction.
- An understanding of real-world use-cases which can be better solved by using graphs and the proposed language extensions.

3 TUTORIAL OUTLINE

We will begin the tutorial with a brief history of Cypher and the property graph model, and provide an overview of the open-Cypher project and how this is helping to drive forward the design of the language, before proceeding onto the main topics.

3.1 The Cypher property graph query language

Property graph data model. The property graph data model will be described, along with how it originated historically from application use cases. We will compare and contrast property graphs with other graph data models. The tutorial will also contain a discussion of ongoing work on potential extensions to the property graph data model.

Cypher query language. Cypher as it stands today will be presented, focusing on its core elements: pattern matching, path functionality and how updates to the data are performed. We will also cover how Cypher queries are structured, as this will lead into the topic of query composition further on in the tutorial. To set the scene and lay the foundation for the later topics, we will walk through an example query in detail, describing the syntax and semantics at each stage of the query.

Challenge: language evolution. Evolving a language with active users is not a trivial undertaking. Every language change needs to be understood in terms of a plethora of interlocking concerns such as usability, relevant use cases, consistency, ergonomics, syntax, tractability, implementability and performance, as well as aesthetics. Every design decision may have hidden consequences in terms of constraining the design in the future. We will talk about some of these concerns, how we design language changes, and the formal openCypher process for evolving the language.

3.2 Multiple graphs and composition

Multiple graphs. Having set the scene, we will proceed with describing current developments in Cypher. The first of these is the notion of supporting multiple graphs. We will describe how graphs can be referenced, created, updated, saved as a named graph, and projected. We also define a series of set operations on graphs. Throughout, we will use a running example and describe the syntax and semantics at each stage.

Query composition. Having support for multiple graphs, and being able to return one or more graphs from a query paves the way for true graph query composition. Each query can be considered a function, taking as input a table and multiple named graphs, and returning as output a table and multiple named graphs. Thus, a Cypher query can be thought of as a chain of functions, composed of a series of constituent, elementary queries to form a *query chain* or pipeline. The addition of subqueries – a well-known construct from SQL – may be used to transform a query chain into a tree. Named queries – allowing for queries to be re-used in different contexts – will also be presented. We will illustrate these concepts with examples, and show the power and expressivity conferred through graph query composition; we note that, to our knowledge, no other declarative, widely-used query language allows for this.

Challenge: language revolution. Ideal language additions do not interfere with existing features. Sometimes languages need to be changed so substantially that it is impossible to avoid conflicting with pre-existing semantics. In the history of Cypher, various breaking changes have occurred. We will discuss our experiences with breaking changes, language versioning, and planning and executing large scale additions to the language such that the concerns of all relevant stakeholders are incorporated.

3.3 Powerful pattern matching

Path Pattern Queries (PPQs). Regular path queries were first proposed by Cruz, Mendelzon and Wood [4] in 1987, and now, thirty years later, we have turned our attention to this topic and how it may be included in Cypher in the form of *Path Pattern Queries*, or PPQs.

PPQs, inspired by recent work by Libkin, Martens and Vrgoč [13], extend RPQs with notions of node property tests, and are an extremely powerful and expressive mechanism for graph querying. PPQs have been designed to allow for the composition of paths into more complex ones, incorporating both node and relationship property tests, along with the consideration of path costing. We see this as an integral part of Cypher, particularly as the need for users to express ever more complex patterns becomes more pressing in the near future. Using a running example, we will describe the syntax and semantics in detail.

Configurable pattern-matching semantics. The default pattern-matching semantics in Cypher uses relationship (or edge) isomorphism (referred to informally as ‘Cyphermorphism’). Although it has been stated that it is a useful default in most real-world queries [26], there are some cases where a different semantics would be more appropriate. To this end, Cypher will allow the writer of a query to configure the type of pattern-matching semantics the query is to use: either homomorphism, relationship isomorphism, or node isomorphism. We will discuss how this is envisaged to function, and the benefits and drawbacks conferred by each approach.

Challenge: Tractability. Providing more powerful and flexible pattern matching is grounded in ever-growing application requirements. This needs to be balanced against what can be implemented efficiently and what is theoretically tractable. However, in certain cases, these equally valid theoretical and practical viewpoints may be at variance with each other. We will discuss this and provide a perspective on the tensions that exist between theoretical complexity analysis and industrial requirements of graph query languages.

3.4 Cypher for Apache Spark

Graph query languages are currently most prominent in graph database systems such as Neo4j [20]. However, it is our opinion that many systems can benefit from having such a language as part of their feature set. One of these systems is Apache Spark [6], which is one of the most popular open source frameworks in the context of distributed processing of large data volumes within complex analytical workloads.

Apache Spark. Apache Spark is a distributed dataflow framework supporting the declarative definition and execution of distributed dataflow programs sourced from batch data. The basic abstractions of such programs are so-called Resilient Distributed Datasets (RDDs) [29] and transformations between those. A Spark RDD is an immutable, distributed collection of arbitrarily-structured data; transformations are higher-order functions (e.g. map and reduce) that describe the construction of new RDDs either from existing ones or from data sources (e.g., HDFS or RDBMS). To describe an analytical task, a Spark program may include multiple chained transformations. During execution, Spark manages data distribution, parallel execution, load balancing and failover across a cluster of machines.

In addition to the RDD abstraction, Apache Spark includes libraries which offer a higher level of abstraction tailored to specific analytical tasks such as machine learning (SparkML), graph processing (GraphX [8, 27]) and relational operations (SparkSQL). In SparkSQL [2], the abstraction is a so-called DataFrame, which handles structured data according to a fixed schema. Available transformations are well known from relational algebra, comprising, for example, selection, projection, join and grouping. Furthermore, SparkSQL includes Catalyst [2], a rule-based query optimizer that transforms a relational query into an optimized dataflow program by undertaking well-known techniques such as predicate pushdown, column projection and code generation [7].

To incorporate the benefits of Cypher from the graph database domain into the world of distributed dataflow processing, we began developing Cypher for Apache Spark (CAPS) [19]. CAPS is an additional library built on top of SparkSQL and can be integrated into a regular Spark analytical program. CAPS is primarily focused on graph-powered data integration and graph analytical query workloads within the Spark ecosystem. In addition, CAPS is our testbed for Cypher language extensions as specified in the previous sections; for example, query composition, graph transformation and multiple graphs.

Challenge: Schema-flexible mapping. In order to benefit from the query optimization capabilities of Catalyst, we decided to implement CAPS on top of SparkSQL.² This however introduces the problem of mapping the schema-flexible property graph model to

a schema-fixed DataFrame representation. We solve this problem by defining a graph schema, which includes information about node labels, relationship types and associated properties potentially having conflicting data types. For structured data sources, such as CSV files or RDBMSs, the schema can be derived directly from meta data supplied by the data source. However, unstructured or semi-structured data sources – exemplified by native graph databases such as Neo4j or document databases such as CosmosDB [17] – will require a full scan of the source data to compute the schema, should it not exist in the first instance. Once a schema is available, it is used to split node and relationship data into multiple column entries, i.e., a row inside a structured DataFrame (“flatten out nodes and relationships”) resulting in potentially sparse tables. In the tutorial, we will discuss the process of schema computation and node / relationship flattening in detail including more information about our type system.

Challenge: Multi-phase planning. A second challenge we faced when building CAPS was the translation of a Cypher graph query to a sequence of relational operations on the Spark DataFrame API. Our implementation approach is based on our experiences from building the Neo4j query planner as well as several existing publications discussing the formal aspects of that topic [10, 11, 16]. CAPS uses multiple compilation phases to produce an executable Spark program, including: building a canonical query representation from an abstract syntax tree; translating the canonical form into graph-specific query operators (logical planning); computing the schema for intermediate results (flat planning); and translating logical operators into Spark DataFrame transformations (physical planning). A physical CAPS plan is optimized by Catalyst and translated into an executable Spark program. In the tutorial, we give an introduction into the CAPS compilation phases as well as optimization techniques like reuse of intermediate results, tree rewriting and Catalyst optimization.

3.5 Demonstration

To highlight the analytical benefits of the graph data model as well as the Cypher query language and its proposed extensions, we will end the tutorial with a live demonstration of CAPS. The demonstration will illustrate a hypothetical analytical workflow including graph data integration from multiple data sources, graph transformation and graph analytical queries. We also demonstrate the integration of CAPS within the Spark ecosystem by using Apache Zeppelin, a tool for browser-based interactive data analytics.

4 PRESENTER BIOGRAPHIES

Alastair Green is a Director of Product Management at Neo4j and is a member of the openCypher Language Group, supporting the openCypher project.

Martin Junghanns is part of the Cypher for Apache Spark Engineering team at Neo4j. Apart from that, he is finishing his PhD in Computer Science at the University of Leipzig. Martin is working on the GRADOOP project with a focus on distributed graph analytics, graph data models and analytical DSLs.

Max Kiessling is part of the Cypher for Apache Spark Engineering team at Neo4j. He recently finished his Master’s thesis at the University of Leipzig, in which he researched distributed pattern matching as part of the GRADOOP project.

Tobias Lindaaker is one of the first engineers to have worked at Neo4j. He has been and continues to be a key influencer in

²The CAPS architecture is backend-agnostic and can be ported to alternative backends / systems.

the evolution of the property graph model, as well as the Cypher query language.

Stefan Plantikow is a member of the Engineering team at Neo4j and is leading the openCypher Language Group. He has worked on the Neo4j kernel, the original implementation of Cypher and the current Neo4j query planner, as well as the BOLT protocol. Stefan has a Master's degree in Computer Science from Humboldt University, Berlin, in the area of distributed systems.

Petra Selmer is a member of Engineering team at Neo4j and is a member of the openCypher Language Group, supporting the openCypher project. For many years, she worked as a consultant and developer in a variety of different domains and roles and has a PhD in Computer Science from Birkbeck, University of London, where she researched the flexible querying of graph-structured data.

ABSTRACT

Users have come to expect reactivity from mobile and web applications, i.e. they assume that changes made by other users become visible immediately. However, developers are challenged with building reactive applications on top of traditional pull-oriented databases, because they are ill-equipped to push new information to the client. Systems for data stream management and processing, on the other hand, are natively push-oriented and thus facilitate reactive behavior, but they do not follow the same collection-based semantics as traditional databases: Instead of database collections, stream-oriented systems are based on a notion of potentially unbounded sequences of data items.

In this tutorial, we survey and categorize the system space between pull-oriented databases and push-oriented stream management systems, using their respectively facilitated means of data retrieval as a reference point. A particular emphasis lies on the novel system class of real-time databases which combine the push-based access paradigm of stream-oriented systems with the collection-based query semantics of traditional databases. We explore why real-time databases deserve distinction in a separate system class and dissect their different architectures to highlight issues, derive open challenges, and discuss avenues for addressing them.

1 INTRODUCTION

Reactive applications require the underlying data storage to publish new and updated information as soon as it is created; data access is *push-based*. In contrast, traditional **database management** systems [6] have been tailored towards *pull-based* data access where information is only made available as a direct response to a client request. While triggers and other push-oriented mechanisms have been added to their initial design, they are outperformed by several orders of magnitude when held against natively push-based systems [9]. In consequence, the inadequacy of traditional database technology for handling rapidly changing data has been widely accepted as one of the fundamental challenges in database design [8].

To warrant low-latency updates in quickly evolving domains, **data stream management** systems [5] break with the idea of

maintaining a persistent data repository. Instead of random access queries on static collections, they perform sequential, long-running queries over data streams. Data stream management systems generate new output whenever new data becomes available and are thus natively push-based. However, data is only available for processing in one single pass, because data streams are conceptually *unbounded* sequences of data items and therefore infeasible to retain indefinitely. Consequently, queries over streams are confined to data that arrives after query activation.

Database Management	Data Stream Management
pull-based	push-based
persistent collection	ephemeral stream
ad hoc, random access	continuous, sequential

Table 1: A side-by-side comparison of core characteristics of database and data stream management systems.

Database and data stream management, respectively, follow fundamentally different semantics regarding the way that data is processed and accessed as Table 1 summarizes. The concept of **persistent collections** conforms to applications that require a (consistent) view of their domain, for instance to keep track of warehouse stock or do financial accounting. The **data stream** model, on the other hand, comes natural for domains that entertain a notion of event sequences or need to reason about the relationship between events, for example to analyze stock prices or identify malicious user behavior. However, the access paradigm – pull-based or push-based – is tied to the data model: Database management systems lack support for **continuous queries** over collections, whereas data stream management systems only provide limited options for persistent data handling.

Acknowledging the gap between traditional databases on the one side and data stream management and stream processing systems on the other, a new class of information systems has emerged that combines collection-based semantics with a push-based access model. These systems are often referred to as **real-time databases** [10, 13], because they keep data at the client in-sync with current database state “in realtime” [7], i.e. as soon as possible after change. Like traditional databases, they store consistent snapshots of domain knowledge. But like stream management systems, they allow clients to subscribe to long-running queries that push incremental updates.

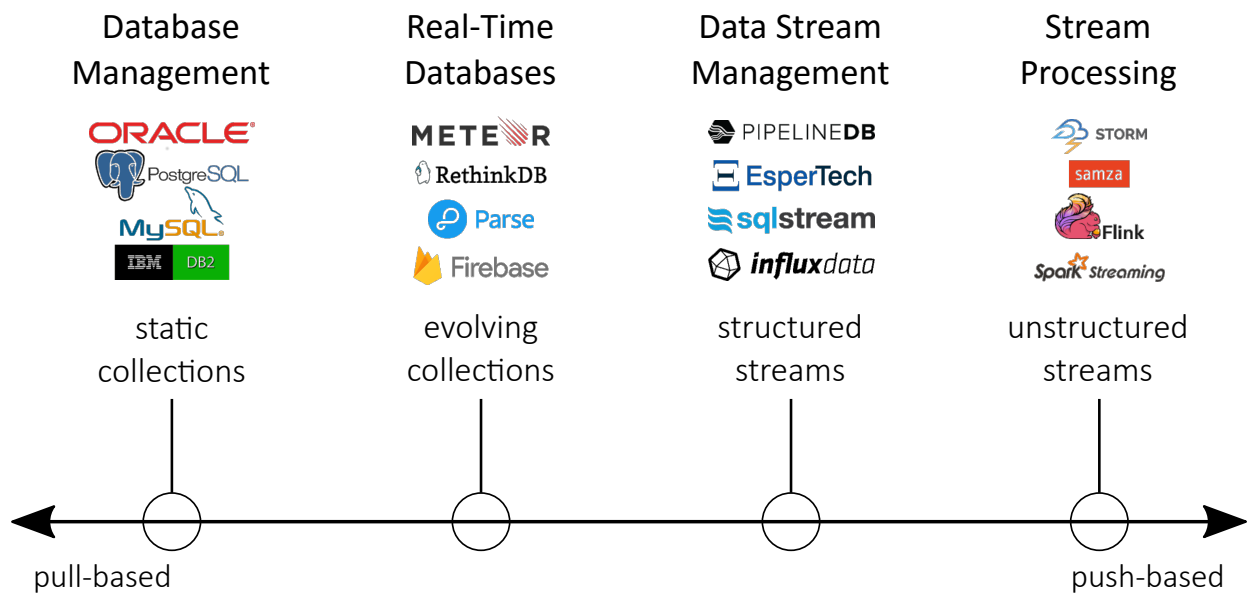

Figure 1: Different classes of data management systems and the access patterns they support.

2 SYSTEM LANDSCAPE OVERVIEW: PULL VS. PUSH

We think systems for data management can be classified by the way they facilitate access to data as illustrated in Figure 1. At the one extreme, there are **traditional databases** which represent snapshots of domain knowledge as the basis of all queries. At the other extreme, there are general-purpose **stream processing** engines which are designed to generate output from conceptually unbounded and arbitrarily structured ephemeral data streams. Real-time databases and data stream management systems both stand in the middle, but adhere to different semantics: **Real-time databases** work on evolving collections that are distinguished from their static counterparts (i.e. from database collections) through continuous integration of updates over time, enabling continuous (real-time) queries over database collections. **Data stream management** systems, as the name implies, provide APIs to query data streams, for example by filtering specific data and computing rolling aggregations and joins over to-be-specified time windows. In contrast to most general-purpose stream processors, datastream management systems usually support pull-based access to some degree, e.g. in the form of common ad hoc database queries over the set of currently retained records.

2.1 Static Queries vs. Continuous Queries

A *pull-based* (static) query assembles data from a bounded data repository and completes by returning data once, whereas a *push-based* (continuous) query processes a conceptually unbounded stream of information to generate incremental output over time. Given these fundamental differences, the design of any data management system reflects a bias towards one or the other; for example, while databases support push-based data access to a certain degree (e.g. through triggers), they are clearly geared towards efficiency for pull-based data retrieval.

2.2 Collections vs. Streams

While a database collection represents the current *state* of the application domain, a data stream rather encapsulates recent *change*.

A **stream**-based representation of an application domain provides a sequential view on events as they occur, but does not retain them indefinitely: Data items are available for a certain time window and are discarded eventually. This view on the data promotes use cases that require notifications, but queries do not reflect actions that happened long ago, since the system only operates on a suffix and not the entirety of event history. In order to serve historical data, the ephemeral events have to be applied to a persistent representation of application state.

A database **collection** reflects all data ever written and thus enables queries that take all events into account. Since collection-based ad hoc queries only generate one single output, though, traditional databases do not propagate informational updates to the client.

2.3 Real-Time Queries Over Database Collections

Given a database's limitation to mainly pull-based access, reactive user interfaces are hard to build on top of an ordinary database. One possibility is to reevaluate a given collection-based query from time to time which is inefficient and introduces staleness on the order of the refresh interval. Another approach is to merge results from collection-based and stream-based queries; thus, the application is effectively burdened with the task of view maintenance which is complex and error-prone. Real-time databases aim to close the gap between both paradigms by providing collection-based semantics for pull-based and push-based queries alike.

3 IN-DEPTH SURVEY: REAL-TIME DATABASES

Our real-time database survey will concentrate on the systems we perceive as the most popular. Due to space limitations, we do

	Meteor		RethinkDB	Parse	Firestore
	poll-and-diff	oplog tailing			
scales with write throughput	✓	✗	✗	✗	?
scales with number of queries	✗	✓	✓	✓	?
composite queries (AND/OR)	✓	✓	✓	✓	✗
sorted queries	✓	✓	✓	✗	○ <small>(single attribute)</small>
limit	✓	✓	✓	✗	✓
offset	✓	✓	✗	✗	✓
aggregations	✗	✗	✗	✗	✗
joins	✗	✗	✗	✗	✗
event stream queries	✓	✓	✓	✓	✓
self-maintaining queries	✓	✓	✗	✗	✗

Table 2: A direct comparison of the different real-time query implementations covered in the in-depth survey.

not discuss these systems in the extended tutorial abstract and refer to our written survey for reference [11]. Table 2 sums up the respective capabilities of each system detailed in our discussion: Meteor, RethinkDB and Parse provide complex real-time queries, but present scale-prohibitive bottlenecks in their respective architectures. While the technology stack behind Firestore is not disclosed, it is apparent that Firestore avoids scalability issues by simply not offering complex queries to begin with.

3.1 Open Challenges

In concept, real-time databases extend traditional databases as they follow the same semantics, but provide an additional mode of access. In practice, though, there is no established scheme how to build a practically useful real-time database system. As will be shown in the tutorial, every push-based real-time query mechanism is deficient in at least one of the following characteristics:

- (1) **scalability:** Serving real-time queries is a resource-intensive process which requires continuous monitoring of all write operations that might possibly affect query results. To sustain more demanding workloads than a single machine could handle, real-time databases typically partition the set of queries across database nodes. As each node is only responsible for a subset of all queries in this scheme, most systems can scale with the number of concurrent queries. However, we are not aware of any real-time database that supports partitioning the change stream as well. Thus, responsibility for individual queries is not shared among nodes and overall system throughput remains bottlenecked by single-machine capacity: Queries simply become intractable as soon as one node is not able to keep up with processing the entire change stream.
- (2) **expressiveness:** The majority of real-time query APIs are limited in comparison to their ad hoc counterparts. Aggregations are generally not available and sorting queries are

often unsupported or have severe restrictions; for example, there are implementations that only allow ordering by a single attribute or offer a limit, but no offset clause. The lack of such basic functionality on the database side necessitates inefficient workarounds in the application code, even for moderately sophisticated data access patterns.

- (3) **legacy support:** Today’s real-time databases have been designed from scratch or on top of NoSQL datastores [11] that do not follow standards regarding data model or query language. They implement custom protocols for pull-based and push-based data access alike and exhibit interfaces that are incompatible among different vendors. While the complete lack of support for legacy interfaces (particularly SQL) may be acceptable in development of a new application, it complicates the adoption of push-based queries in the context of existing technology stacks.
- (4) **abstract API:** Many real-time query APIs expose specificities of the underlying implementation and thus offer poor data independence. As such, these interfaces reflect bottom-up design and force developers to reason about problems that lie beyond the application domain. For example, most real-time databases do not provide interfaces that can be used without knowledge of system internals. Instead, they mostly require an understanding of internal mechanisms or the structure of change events.

During the talk, we will illustrate how the above-mentioned limitations present themselves in practice. We also identify the underlying issues in the respective system architectures and discuss possibilities to avoid them in future designs. In this context, we will discuss related technology (e.g. distributed stream processing engines [12]) and use them as a source of inspiration for resolving the apparent challenges.

4 DIFFERENTIATION FROM OTHER VERSIONS OF THE TUTORIAL

The survey of stream processing engines and the overview over real-time databases have already been presented at different occasions, e.g. at BTW 2017 [4]. Some of the use cases that will be presented have been discussed in our VLDB 2017 industry paper [2]. However, since two of the authors (Wolfram Wingerath and Felix Gessert) are just now finishing their Ph.D. theses on real-time big data management, the tutorial intended for March 2018 will incorporate significant updates and extensions. In particular, the scientific portion of the talk will be amended by recent developments in the space of real-time databases. Further, we will present our experiences in building and using a real-time database in customer-facing applications at the Backend-as-a-Service company Baqend. Thus, the tutorial will provide a unique combination of broad scientific research and real-world experiences.

5 SCOPE, LENGTH & INTENDED AUDIENCE

The tutorial in the form outlined here is intended for 90 minutes and will concentrate on push-based systems, namely real-time databases and stream processing engines. We can also extend this tutorial to 180 minutes by including our previous tutorials on NoSQL database systems [1, 3, 4] and discussing them in the light of real-time and stream processing requirements. This tutorial is intended for anybody interested in novel database technology; there are no prerequisites, even though a certain technical understanding of databases will be helpful in following the in-depth discussion.

6 PRESENTER BIOGRAPHIES

Wolfram Wingerath is a Ph.D. student under supervision of Norbert Ritter teaching and researching at the University of Hamburg. He was co-organiser of the BTW 2015 conference and has held workshop and conference talks on his published work on several occasions. Wolfram is part of the databases and information systems group and his research interests evolve around real-time databases and related technology such as scalable stream processing, NoSQL database systems, cloud computing, and Big Data analytics. His Ph.D. thesis explores a scalable design for push-based real-time queries on top of pull-based databases.

Felix Gessert is a Ph.D. student at the databases and information systems group at the University of Hamburg. His main research fields are scalable database systems, transactions, and web technologies for cloud data management. His thesis addresses caching and transaction processing for low-latency mobile and web applications. He is also founder and CEO of the startup Baqend that implements these research results in a cloud-based backend-as-a-service platform. Since their product is based on a polyglot, NoSQL-centric storage model, he is very interested in both the research and practical challenges of leveraging and improving these systems. He is frequently giving talks on different NoSQL topics.

Erik Witt is a Full Stack developer and performance engineer at Baqend where he builds and optimizes scalable web applications for the cloud. As the highlight of his master's degree at the university and in cooperation with Baqend, he developed a web-caching-based transaction concept for distributed cloud databases. Erik has talked about his work at numerous conferences and also regularly authors articles on the Baqend company blog and related media in order to present the intricacies of web performance to a broader audience.

Steffen Friedrich is a Ph.D. student working under supervision of Norbert Ritter at the University of Hamburg. He has taken part in several workshops and conferences, both as presenter and as co-organiser (BTW 2015). Being a member of the databases and information systems group, Steffen is interested in large-scale data management and data-intensive computing. Furthermore, in his Master thesis, he also dealt with data quality issues, specifically with duplicate detection in probabilistic data. His research project is primarily concerned with benchmarking of non-functional characteristics (e.g. consistency and availability) in distributed NoSQL database systems.

Norbert Ritter is a full professor of computer science at the University of Hamburg, where he heads the databases and information systems group. He received his Ph.D. from the University of Kaiserslautern in 1997. His research interests include distributed and federated database systems, transaction processing, caching, cloud data management, information integration, and autonomous database systems. He has been teaching NoSQL topics in various courses for several years. Seeing the many open challenges for NoSQL systems, he and Felix Gessert have been organizing the annual Scalable Cloud Data Management Workshop (www.scdm.cloud) to promote research in this area.

ABSTRACT

Many applications require similarity query processing. Most existing work took an algorithmic approach, developing indexing structures, algorithms, and/or various optimizations. In this work, we choose to take a different, systems-oriented approach. We describe the support for similarity queries in Apache AsterixDB, a parallel, open-source Big Data management system for NoSQL data. We describe the lifecycle of a similarity query in the system, including the support provided at the query language level, indexing, execution plans (with and without indexes), plan rewrites to optimize query execution, and so on. Our approach leverages the existing infrastructure of AsterixDB, including its operators, parallel query engine, and rule-based query optimizer. We have conducted an experimental study using several large, real data sets on a parallel computing cluster to evaluate AsterixDB's support for similarity queries, and we share the efficacy and performance results here.

1 INTRODUCTION

Similarity queries compute answers satisfying matching conditions that are not exact but approximate. The problem of supporting similarity queries has become increasingly important in many applications, including search, record linkage [1], data cleaning [27], and social media analysis [4]. For instance, during a live phone conversation with a client, a call center representative might wish to immediately identify a product purchased by the customer by typing in a serial number. The system should locate the product even in the presence of typos in the search number. A social media analyst might want to find user accounts that share common hobbies or social friends. A medical researcher may want to search for papers whose title is similar to a particular article. In each of these examples the query includes a matching condition with a similarity function that is domain specific, such as edit distance for a keyword or Jaccard for sets of hobbies.

There are two basic types of similarity queries. One is *search*, or *selection*, which finds records similar to a given record. The other is *join*, which computes pairs of records that are similar to each other. There have been many studies on these two types of queries, both with and without indexes. A plethora of data structures, partitioning schemes, and algorithms have been developed to support similarity queries efficiently on large data sets. When the computation is beyond the limit of a single computer, there are also parallel solutions that support queries across multiple nodes in a cluster. (See Section 1.1 for an overview.) The techniques developed in the last two decades have significantly improved the performance of similarity queries and have enabled applications to support such queries on millions or even billions of records.

Most existing work has taken an algorithmic approach, developing index structures and/or algorithmic optimizations. We

have taken a different, systems-oriented approach – tackling the problem of supporting similarity queries *end-to-end* in a full, declarative parallel data management system setting. Here we explain how such queries are supported in Apache AsterixDB, an open-source parallel data management system for semi-structured (NoSQL) data. By “end-to-end”, we refer to the whole lifecycle of a query, including query language support for similarity conditions, internal index structures, execution plans with or without an index, plan rewriting to optimize execution, and so on.

Achieving our goal has involved several challenges. First, as similarity in queries can be domain specific, we need to support commonly used functions as well as letting users provide their own customized functions. Second, due to the complex logic of existing algorithms, we need to consider how to support them using existing operators without “reinventing the wheel” (without introducing new, ad hoc operators). Third, we need to consider how to leverage an existing query optimizer framework to rewrite similarity queries to achieve high performance. In this paper we discuss these challenges and offer the following contributions:

(1) We show how to extend the existing query language of AsterixDB to allow users to specify a similarity query, either by using a system-provided function or specifying their own logic as a user-defined function (Section 3).

(2) We show how to implement state-of-the-art techniques using existing operators in AsterixDB, both for index-based and non-index-based plans (Section 4) and for both search and join queries. Our solution not only allows the query plans to benefit from the built-in optimizations in those operators, but also to automatically enjoy future improvements in these operators.

(3) We show how to rewrite similarity queries in an existing rule-based optimization framework (Section 5). A plan for an ad hoc similarity join can be very complex. As an example, a three-stage join plan based on the technique in [34] can involve up to 77 operators (Section 5.2). To enable the optimizer to more easily transform such complex plans, we developed a novel framework called “AQL+” that takes a two-step approach to rewriting a plan. A major advantage of the framework is that it allows AsterixDB to support queries with more than one similarity join condition, making it the first parallel data management system (to our knowledge) to support similarity queries with multiple similarity joins.

(4) We present an empirical study using several large, real data sets on a parallel cluster to evaluate the effects of these techniques. The results show the efficacy of AsterixDB's support for parallel similarity queries on large data sets. (Section 6).

1.1 Related Work

There are various kinds of similarity queries on strings and sets. For string similarity search, many algorithms use a gram-based approach (e.g., [5, 20, 29]). VGRAM [19] extends the approach by introducing variable-length grams. For string similarity join, filtering techniques are widely used. Length filtering uses the

²Contact author and part of his work was done when visiting UC Irvine. [†]Work done when affiliated with UC Irvine.

length of a string to reduce the number of candidates. For example, an algorithm called gram-count [15] utilizes the fact that for two strings to be similar based on a threshold δ , their length difference should be within δ . Prefix filtering [3, 7, 12, 22, 26, 28, 35, 37–39] utilizes the fact that two strings are similar only if they share some commonality in their prefixes. Many algorithms have been proposed based on this observation, such as All-Pair [3], PPJoin [39], PPJoin+ [39], MPJoin [28], ED-Join [38], AdaptJoin [35], QChunk [26], VChunk [37], and Pivotal prefix [12]. Other related algorithms exist such as M-Tree [9] and trie-Join [14]. There have been several evaluation studies about string-similarity [18] and set-similarity joins [24]. There is a recent survey about string similarity queries [25]. The authors of [18] found that AdaptJoin [35] and PPJoin+ [39] were best for Jaccard similarity. Meanwhile, the authors of [24] concluded that AllPair [3] was still competitive. The authors of [25] discussed prefix-filtering techniques. Many of these algorithms assume the data to be searched or joined can fit in main memory.

For parallel similarity join, a number of studies have used the MapReduce framework [11, 21, 31, 34, 36]. There is one survey that discusses parallel similarity join [13]. Vernica et al. [34] proposed a three-stage algorithm in such a setting. There are also studies on integrating similarity join into database management systems [10, 15, 16, 30, 32]. Some adopted similarity join as a UDF or express a similarity join in a SQL expression; others introduced a relational operator to support similarity joins.

Our focus is different, as it is about supporting similarity in a general-purpose parallel database system context. We needed to address various systems-oriented challenges when adopting existing techniques in this context. System-wise, a parallel similarity query processing system, Dima [33], has been proposed recently. A key difference is that Dima is an in-memory based system, unlike AsterixDB. There are some search systems and DBMSs that support similarity queries, including Elasticsearch, Oracle, and Couchbase. Unlike AsterixDB, Elasticsearch is middleware and it focuses on search, not join. Oracle supports edit distance via an extension package if a specific type of index is created. Couchbase supports edit distance searches on NoSQL data in its new full-text search service, but only via a separate full-text API (not its N1QL query language). In contrast, AsterixDB provides a general class of similarity functions for strings that work for both select and join operations, and a similarity predicate can be part of a general query along with non-similarity predicates.

2 PRELIMINARIES

2.1 Similarity Functions

A similarity measure is used to represent the degree of similarity between two objects. An object can be a string or a bag of elements. There are various types of similarity measures depending on the objects that are being compared. In this paper, we focus on two widely used classes of measures, namely string-similarity functions and set-similarity functions.

String-Similarity Functions: One widely used string similarity function is edit distance, also known as Levenshtein distance. The edit distance between two strings r and s is the minimum number of single-character operations (insertion, deletion, and substitution) required to transform r to s . For instance, the edit distance between “james” and “jamie” is 2, because the former can be transformed to the latter by inserting “i” after “m” and deleting “s”. There are other string-similarity functions such as Hamming distance and Jaro-winkler distance.

Set-Similarity Functions: These are used to represent the similarity between two sets. There are many such functions, such as Jaccard, dice, and cosine. In this paper, we focus on Jaccard similarity, which is one of the most common set-similarity measures. For two sets r and s , their Jaccard similarity is $Jaccard(r, s) = \frac{|r \cap s|}{|r \cup s|}$. For example, the Jaccard similarity between $r = \{\text{“Good”, “Product”, “Value”}\}$ and $s = \{\text{“Nice”, “Product”}\}$ is $\frac{1}{4}$. Such set-similarity functions can also be utilized to measure the similarity between two strings by tokenizing them (i.e., into n -grams or words) and measuring the set similarity of their token multisets. Dice and cosine values can be calculated similarly.

Similarity Search: Similarity search finds all objects in a collection that are similar to a given object based on a given similarity metric. Let sim be a similarity function, and δ be a similarity threshold. An object r from a collection R is similar to a query object q if $sim(r, q) \geq \delta$.

Similarity Join: Joins find similar $\langle r, s \rangle$ pairs of objects from two collections R and S , where $r \in R$, $s \in S$, and $sim(r, s) \geq \delta$.

2.2 Answering Similarity Queries

For similarity queries, using a brute-force, scan-based algorithm is computationally expensive, so there have been many studies in the literature to support similarity queries more efficiently. One widely used method is the gram-based approach, which utilizes the n -grams of a string. An n -gram of a string r is a substring of r with length n . For instance, the 2-grams of string “james” are {“ja”, “am”, “me”, “es”}.

review-id	username	review-summary
1	james	This movie touched my heart!
2	mary	The best car charger I ever
3	mario	Different than my usual but good
4	jamie	Great Product - Fantastic Gift
5	maria	Better ever than I expected

Figure 1: Example data of Amazon reviews (simplified).

String-similarity queries can be answered by utilizing an n -gram inverted index. For each gram g of the strings in a collection R , there is an inverted list l_g of the ids of the strings that include this gram g . Figure 2 shows the inverted lists for the 2-grams of the “username” field of the sample Amazon reviews in Figure 1.

gram	am	ar	es	ia	ie	io	ja	ma	me	mi	ri	ry
inverted list	1 4	2 3 5	1	5	4	3	1 4	2 3 5	1	4	3 5	2

Figure 2: Inverted lists for 2-grams of the “username” field.

We can answer a string-similarity query by computing the n -grams of the query string and retrieving the inverted lists of these grams. We then process the inverted lists to find all string ids that occur at least T times, since a string r within edit distance k of another string s must share at least $T = |G(r)| - k \times n$ grams with s [17]. This problem is called the T -occurrence problem. Solving the T -occurrence problem yields a set of candidate string ids. The false positives are removed in a final verification step by fetching the strings of the candidate string ids and computing their real similarities to the query. As an example, given a gram length $n = 2$, an edit distance threshold $k = 1$, and a query string $q = \text{“marla”}$, Figure 3 illustrates how to find the similar usernames from the data in Figure 1. We first compute the 2-grams of q as {“ma”, “ar”, “rl”, “la”} and retrieve the inverted lists of these 2-grams. We consider the records that appear at least $T = 4 - 2 \times 1 = 2$ times on these lists as candidates, which have review-ids 2, 3, and 5. Last, we compute the real similarity for these candidates, and

the review-id 5 is the final answer. Note that if the threshold $T \leq 0$, then the entire data collection needs to be scanned to compute the results, which is called a *corner case*. In the above example, if the threshold is 3, then $T = 4 - 2 \times 3 = -2$, causing a corner case.

ma	ar	rl	la	Candidate	Verification
2	2	-	-	2	x
3	3			3	x
5	5			5	✓

Figure 3: Answering an edit-distance query for “q”=marla and $T=2$.

2.3 Apache AsterixDB

Initiated in 2009, the AsterixDB project integrated ideas from three distinct areas – semi-structured data, parallel databases, and data-intensive computing – to create an open-source software platform that scales on large, shared-nothing commodity computing clusters. AsterixDB consists of several software layers. The top-most layer provides a parallel DBMS with a full, flexible data model (ADM) and query languages (AQL/SQL++) for describing, querying, and analyzing data. The next layer, a query compiler based on *Algebricks* [8], is used for parallel query processing. This algebraic layer receives a translated query plan from the upper layer and transforms it using rule-based optimization. It also generates Hyracks jobs to be executed on the *Hyracks* [6] layer. It provides storage facilities for datasets that are stored and managed by AsterixDB as partitioned LSM-based B+-trees with optional LSM-based secondary indexes [2]. AsterixDB translates a computation into a directed-acyclic graph (DAG) of operators and connectors, and sends it to Hyracks for execution.

Each record in an AsterixDB dataset is identified by a unique primary key and records are hash-partitioned across the nodes on their primary keys. Each partition is locally indexed by a primary key in an LSM B+-tree, a.k.a. the primary index, and resides on its node’s local storage. AsterixDB also supports secondary indexing, including B+-tree, R-tree, and inverted indexes, partitioned in the same way as the primary index.

3 USING SIMILARITY QUERIES

In this section, we discuss similarity measures supported in AsterixDB and how users express similarity queries. We also show how users can specify indexes to expedite query processing.

3.1 Supported Similarity Measures

AsterixDB supports two similarity measures, edit distance and Jaccard, to solve string and set similarity queries. Both measures can be processed with or without indexes. Let us focus on edit distance first. It can be calculated on two strings. As an extension in AsterixDB, edit distance can also be computed between two ordered lists. For example, the edit distance between [“Better”, “than”, “I”, “expected”] and [“Better”, “than”, “expected”] is 1. This generalization is possible since a character in a text string can be viewed as an element on an ordered list if we think of a string as a collection of ordered characters.

A Jaccard value can be computed on two lists of elements. If a field type is string, a user can use a tokenization function such as “word-tokens()” to make a list of elements from the string. For example, it is possible to calculate the Jaccard similarity between two strings by tokenizing each string into a list of words. The types of the elements on a list should be the same.

If a user wishes to use their own similarity measure, they can opt to create a user-defined function (UDF). A UDF can be expressed

in AQL or SQL++ (two query languages supported by AsterixDB) or implemented as an external Java class. If the desired UDF can be expressed in AQL or SQL++, the user can create such a function using the following syntax.

```
create function similarity-cosine(x, y) {
    .....
}
```

3.2 Expressing Similarity Queries

AsterixDB provides two ways to express a similarity query in AQL or SQL++, illustrated by the example AQL in Figure 4. These queries find the record pairs from the Amazon review dataset that have similar summaries. In Figure 4(a) before the actual query, the similarity function and threshold are defined with a “set” statement. The query then uses a similarity operator “~=", which is a syntactic sugar defined for similarity functions. The “~=" operator computes the similarity between its two operands according to the “simfunction” and “simthreshold,” and returns the records that are similar. The same query can be written without using the similarity operator by a more experienced user. In Figure 4(b), the query uses the “similarity-jaccard()” function, and this query is equivalent to that in Figure 4(a). The first syntax can be easier to use since default settings for “simfunction” and “simthreshold” exist so that a user does not need to provide the two “set” statements. In addition, the user does not need to know the exact function name. Also, if the user wants to change the similarity function, they only need to change the “set” statements without changing the query itself. During query parsing and compilation, it is easy for the optimizer to detect this syntactic sugar and generate a desired optimized plan. On the other hand, the second form gives the user more direct control. There are a few variations of similarity functions in AsterixDB, e.g., one that can do early termination during the evaluation, and a user can freely choose any of them.

```
use dataverse TextStore;
set simfunction 'jaccard';
set simthreshold '0.5';
for $t1 in dataset AmazonReview
for $t2 in dataset AmazonReview
where word-tokens($t1.summary) ~= word-tokens($t2.summary)
return { 'summary1': $t1, 'summary2': $t2 }
```

(a) ~=" Notation

```
use dataverse TextStore;
for $t1 in dataset AmazonReview
for $t2 in dataset AmazonReview
where similarity-jaccard(word-tokens($t1.summary),
word-tokens($t2.summary)) >= 0.5
return { 'summary1': $t1, 'summary2': $t2 }
```

(b) Function Notation

3.3 Using Indexes

Without an index, AsterixDB scans the whole dataset to compute the result for the given query. To expedite the execution, AsterixDB supports two kinds of inverted indexes. The first type, called “keyword index,” uses the elements of a given unordered list, and is suitable for Jaccard similarity. The two queries in Figure 4 could utilize a keyword index on the “summary” field. A keyword index can be created using the following DDL statement, where “smix” is the index name:

```
create index smix on AmazonReview(summary) type keyword;
```

The second index type is “ n -gram index,” and is suitable for edit distance. An n -gram index uses the extracted n -grams of a string as the keys, and maps those keys to their corresponding primary ids. The following is an example DDL statement to create a 2-gram index on the “reviewerName” field:

```
create index nix on AmazonReview(reviewerName) type ngram(2);
```

4 EXECUTING SIMILARITY QUERIES

In this section, we discuss how similarity queries are internally executed in AsterixDB. First, we present the execution flow for a similarity query in the presence of an index, then describe the execution flow when no index is available.

4.1 Executing Similarity Selections

We first present the execution strategy for selection queries. We use an example query to explain the execution flow for Figure 5, which computes the edit distance between a field V of a dataset and a constant C .

```
for $t1 in dataset bar
where edit-distance($t1.V, C) < 2
return {"id": $t1.id, "field": $t1.V}
```

Figure 5: A similarity-selection query.

4.1.1 Index-Based Search Execution. When running the above query on a cluster with multiple nodes, the query coordinator (*a.k.a.* cluster controller) sends a request containing the constant search key C to each participating node, since AsterixDB uses a shared-nothing architecture. Figure 6 illustrates how a similarity-selection query is executed using a secondary inverted index on a 3-node cluster. Each node contains a partitioned primary index and a local inverted index.

Figure 6: Parallel execution of a similarity-selection query.

If an index is available, AsterixDB runs an index-based selection plan at each node. It first gives the constant value C to the secondary inverted index. The secondary-inverted-index search generates $\langle \text{SecondaryKey}, \text{PrimaryKey} \rangle$ pairs that satisfy the T -occurrence condition, which may include false positives. It then looks up these primary keys in the primary index to fetch their corresponding records. The primary keys are sorted prior to this search to increase the chance of page cache hits in the buffer. After the primary-index search, a SELECT operator is applied to remove false positives and generate the final results. If the similarity condition is selective enough, such an index-based search plan can be much more efficient than a non-index-based plan that uses SCAN and SELECT operators. Once the local results are generated at each node, they are sent to the coordinator to be combined.

The compiler generates a non-index-based selection plan (the left part of Figure 7). The optimizer then transforms the initial plan to an index-based selection plan if there is an applicable index. We will discuss this rewriting process further in Section 5.1.

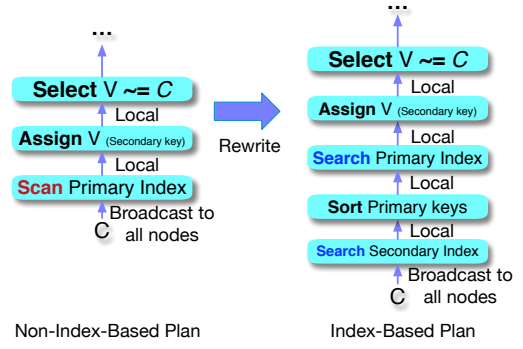

Figure 7: A similarity-selection query plan

4.1.2 Non-Index-Based Search Execution. Similar to index-based execution, when there are multiple nodes, the coordinator sends a request containing the search key C to all nodes. At each node, as there is no index on the field in the given similarity condition, AsterixDB scans the primary index, fetches all records, and verifies the similarity condition on the given field for each record. This process was depicted on the left part of Figure 7. Finally, the results will be returned to the coordinator.

4.2 Executing Similarity Joins

A join has two branches as its input. We call the first one the “outer branch” and the second one the “inner branch.” For example, in Figure 8, the AQL variable $t1$ refers to the outer branch and $t2$ refers to the inner branch.

```
for $t1 in dataset bar
for $t2 in dataset foo
where similarity-jaccard($t1.A, $t2.B) > 0.5
return {"of1": $t1.f1, "of2": $t1.f2, "A": $t1.A,
       "if1": $t2.f1, "if2": $t2.f2, "B": $t2.B}
```

Figure 8: A similarity-join query.

4.2.1 Index-Based Join Execution. Similar to the similarity-selection case, where a predicate was broadcast to all nodes, the records from the outer branch of each node are broadcast to all nodes in the similarity-join case. Figure 9 depicts how a similarity-join query is executed using a secondary inverted index on a 3-node cluster.

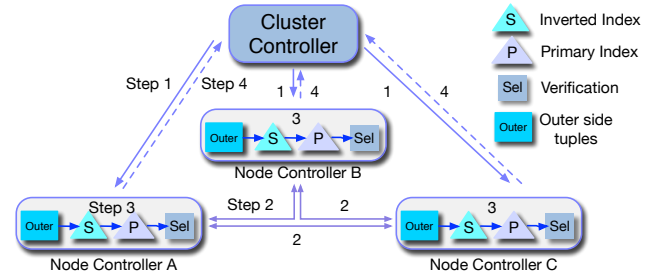

Figure 9: Parallel execution of a similarity-join query.

The coordinator sends the query request to each participating node. Each node of an outer-branch partition scans the outer-branch data and broadcasts its records to all nodes with a secondary-index partition. This broadcast replicates all records of the outer-branch on each node where the secondary-index search will be performed. Each node with an index-side partition uses the incoming outer-branch records as well as its local ones to search

its local inverted index. Once each secondary-index partition has processed all the records from the outer branch, the resulting primary keys from the search will be fed into the primary index, and a primary-index search will be executed. Again, the primary keys are sorted before the primary-index search to increase the chance of page cache hits. As before, we need to remove false positives from the index-based subplan using a SELECT operator on the original similarity condition, which is taken from the join operator. This plan is depicted on the right part in Figure 10. Finally, the results are sent to the coordinator to be combined.

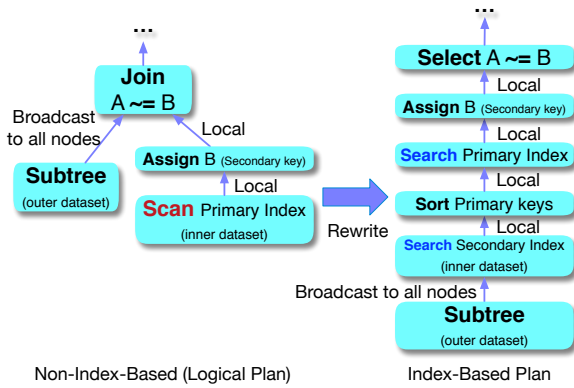

Figure 10: A similarity-join query plan.

4.2.2 Non-Index-Based Join Execution. When there is no index, a simple nested-loop join could be performed. The outer branch would feed the predicate from each record to the primary index of the inner branch. The complexity of this solution is quadratic. To avoid a costly nested-loop join, we instead adopt a three-stage algorithm [34] in AsterixDB.

Since this algorithm uses a prefix-filtering method, a global token order needs to be established to generate a prefix for each field value. This global token order can be any arbitrary order, and we choose the increasing token-frequency order, which tends to generate fewer candidate pairs [34]. The first stage computes a global token order by counting the frequency of each token in the tokenized data and sorting the tokens based on their frequencies. In the second stage, the algorithm computes a short prefix subset for each set based on the global token order produced in the first stage. Then, the record id and only the join attribute of each record are replicated and repartitioned by hashing its prefix tokens. After the repartitioning step, candidate pairs are generated by grouping the pairs by their ids, and the similarity is computed for each pair to filter out the dissimilar ones. This stage produces only similar record id pairs. Finally, the third stage rescans the inputs to fetch the rest of the record fields for these id pairs.

To apply this algorithm in AsterixDB, rather than implementing new operators and complex query plans, we chose to represent the algorithm using existing AQL constructs such as “for”, “let”, “group by”, and “order by” since this approach is more extendable in the future. In addition, if/as we improve existing operators, we do not need to modify the given AQL to utilize the improved operators. Figure 11 shows an AQL query capturing the three stages for a self-similarity join on the “summary” field of the Amazon Review dataset, using Jaccard similarity with a threshold; each step is implemented using basic AQL constructs and functions. We now discuss the details of these three stages.

Stage 1: Token Ordering is expressed in lines 11-18 of Figure 11. In this subquery we iterate over the records in the dataset. For each record, we retrieve the tokens in the “summary” field and

```

1 // -- Stage 3 --
2 for $ARevLeft in dataset('ARevs')
3 for $ARevRight in dataset('ARevs')
4 for $ridpair in
5 // -- Stage 2 --
6 for $ARevLeft in dataset('ARevs')
7 let $lenLeft := len($ARevLeft.summary)
8 let $tokensLeft :=
9   for $tokenUnranked in $ARevLeft.summary
10  for $tokenRanked at $i in
11 // -- Stage 1 --
12 for $t in dataset('ARevs')
13 let $id := $t.ARev_id
14 for $token in word-tokens($t.summary)
15 /** hash */
16 group by $tokenGrouped := $token with $id
17 order by count($id), $tokenGrouped
18 return $tokenGrouped
19 where $tokenUnranked = /** bcst */ $tokenRanked
20 order by $i
21 return $i
22 for $prefixTokenLeft in subset-collection($tokensLeft, 0,
23 prefix-len-jaccard($lenLeft, .5f) - $lenLeft + len($tokensLeft))
24
25 for $ARevRight in dataset('ARevs')
26 let $lenRight := len($ARevRight.summary)
27 let $tokensRight :=
28   for $tokenUnranked in $ARevRight.summary
29   for $tokenRanked at $i in
30 // -- Stage 1 --
31 for $t in dataset('ARevs')
32 let $id := $t.ARev_id
33 for $token in word-tokens($t.summary)
34 /** hash */
35 group by $tokenGrouped := $token with $id
36 order by count($id), $tokenGrouped
37 return $tokenGrouped
38 where $tokenUnranked = /** bcst */ $tokenRanked
39 order by $i
40 return $i
41 for $prefixTokenRight in subset-collection(
42 $tokensRight, 0, prefix-len-jaccard($lenRight, .5f))
43
44 where $prefixTokenLeft = $prefixTokenRight
45 let $sim := similarity-jaccard($tokensLeft, $tokensRight, .5f)
46 where $sim >= .5f and $ARevLeft.ARev_id < $ARevRight.ARev_id
47 group by $idLeft := $ARevLeft.ARev_id,
48 $idRight := $ARevRight.ARev_id with $sim
49 return {'idLeft': $idLeft, 'idRight': $idRight, 'sim': $sim[0]}
50
51 where $ridpair.idLeft = $ARevLeft.ARev_id and
52 $ridpair.idRight = $ARevRight.ARev_id
53 order by $ARevLeft.ARev_id, $ARevRight.ARev_id
54 return {'left': $ARevLeft, 'right': $ARevRight, 'sim': $ridpair.sim}

```

Figure 11: Three-stage set-similarity algorithm expressed in AQL for a self join on the Amazon Review (ARevs) dataset using Jaccard similarity with a threshold of 0.5.

count the number of occurrences of each token using a group-by clause. To expedite this calculation, we use a compiler hint in line 15, which suggests using hash-based aggregation instead of the default sort-based aggregation for the group-by statement, since the order of tokens at this particular step is not meaningful. Finally, we order the tokens based on their count using an order-by clause. The same subquery is repeated later, in lines 30-37, in the context of the second dataset. During the optimization, the optimizer will detect the common subquery and execute the subquery only once using a replicate operator to send the results to both outer plans. More details can be found in Section 5.4.2.

Stage 2: Record ID (RID)-Pair Generation is expressed in lines 5-50. We scan the dataset in line 6, then retrieve each token from the “summary” field. We order the tokens by the rank computed in the first stage (lines 12-23) by joining the set of tokens in one summary with the set of ranked tokens. We use a hint in line 19 that advises the compiler to use a broadcast join operator to

broadcast the ranked-tokens. Next, we order the join results by rank, stored in the variable “\$i.” We then extract the prefix tokens in line 22, and use the “prefix-len-jaccard()” built-in function to compute the length of the prefix for Jaccard similarity with a threshold of 0.5. The built-in “subset-collection()” function extracts the prefix subset of the tokens. The same process of tokenizing, ordering the tokens, and extracting the prefix tokens is done in lines 25-42 for the second stream of the dataset. We then join the two streams on their prefix tokens in line 44, and compute and verify the similarity of each joined pair. We use the built-in “similarity-jaccard()” function to compute the similarity. Since a pair of records can share more than one token in their prefixes, duplicate pairs could be produced, and they are eliminated by using a group-by clause in line 48.

Stage 3: Record Join is expressed in lines 1-4 and 51-54, which consists of two joins. The first join adds the record information for the first RID of each RID pair, while the second join adds the record information for the second.

The plan resulting from this large AQL query is shown in Figure 12. In the figure, “Hash repartition” means that a tuple is repartitioned to a corresponding node based on its hashed value. With “Hash repartition merge,” a step of merging tuples based on sort field values occurs after a “Hash repartition.” To transform a logical plan generated from a user’s similarity join query to the three-stage-similarity query plan utilizing the AQL in Figure 11, we develop a new framework called AQL+, which will be discussed in Section 5.2.

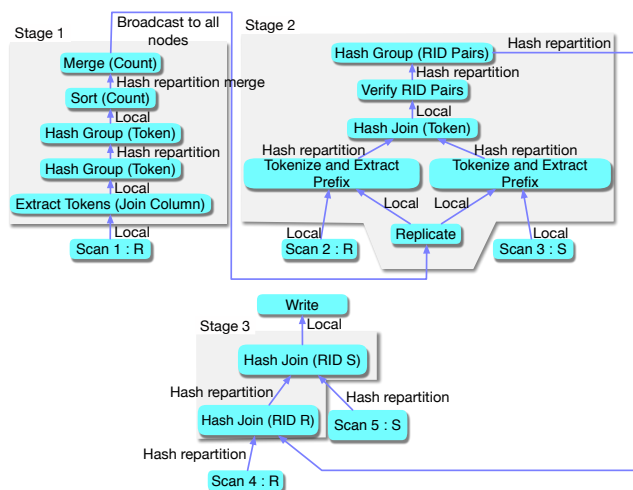

Figure 12: A logical plan of a three-stage-similarity join.

5 OPTIMIZING SIMILARITY QUERIES

In this section, we discuss how AsterixDB optimizes similarity queries and describe the AQL+ framework.

5.1 Rewriting a Similarity Query

AsterixDB uses rule-based optimization [8]. A logical plan is constructed from a given query, and each optimization rule is tried on this plan. If a rule is applicable, then the plan is transformed. A logical plan involving a dataset always starts with a primary-index scan, followed by a SELECT operator if there is one or more conditions. A non-index similarity query plan is constructed first, and an index-based transformation or a three-stage-similarity join can be introduced during the optimization.

5.1.1 Rewriting a Similarity-Selection Query. Figure 7 showed how a similarity-selection query is optimized to use an index. The left-hand side shows the original scan-based query plan, and the right-hand side shows the optimized plan. Based on a selection operator with a similarity condition (using the “~=” notation), the optimizer tries to replace the primary-index scan with a secondary-index-based search plan.

To rewrite a similarity-selection query, the optimizer first matches an operator pattern consisting of a pipeline with a SELECT operator and a PRIMARY-INDEX SCAN operator. Next, it analyzes the condition of the given SELECT operator to see if it contains a similarity condition and if one of its arguments is a constant. If so, it determines whether the non-constant argument originates from the PRIMARY-INDEX SCAN operator and whether the corresponding dataset has a secondary index on a field variable V . For each secondary index on V , it checks an index-to-function-compatibility table (Figure 13) to determine its applicability. For example, an n -gram index can be utilized for the “edit-distance()” function. The final SELECT operator filters out false positives.

Index Type	Supported Functions
n -gram	edit-distance(), contains()
keyword	similarity-jaccard()

Figure 13: Index-function compatibility table.

Corner cases: Recall that for queries using edit distance, the lower bound on the number of common q -grams (or tokens) may become zero or negative. For such a corner case, the optimizer must revert to a scan-based plan even if an index is available. For selection queries, it can foresee such cases at compile time when applying the corresponding index-rewrite rule by analyzing the constant argument in the similarity condition. When detecting a corner case, it simply stops rewriting the plan. Note that no such corner cases are possible for similarity queries based on Jaccard, because if two sets have no elements in common, then they can never reach a Jaccard similarity greater than 0. In contrast, two strings could be within a certain (large) edit distance even if the n -gram sets of the (short) strings have no common elements.

5.1.2 Rewriting a Similarity-Join Query. The basic rewriting of a similarity-join query using an index is shown in Figure 10. The optimized plan on the right-hand side uses an index-nested-loop join strategy. Similar to the rewrite for selection queries, the optimizer replaces the primary-index scan of the inner branch with a secondary-index search followed by a primary-index search. Thus, it is required that the inner branch of the join is a primary-index scan, while the outer branch could be an arbitrary operator subtree (shown as “Subtree” in the figure). In the optimized plan, the outer branch feeds into the secondary-index search operator, i.e., every record from “Subtree” will be used as a search key to the secondary index.

As in the similarity-selection case, the optimizer needs to remove false positives from the index-based subplan with a SELECT operator on the original similarity condition, which is taken from the join operator. Notice the “broadcast” connection between the outer subtree and the secondary-index search, which signifies that each partition executing the “Subtree” plan will broadcast its output stream’s records to all the secondary-index partitions. The optimizer first matches the required operator pattern consisting of a JOIN that has at least one input coming from a PRIMARY-INDEX SCAN. Next, it analyzes the join condition to make sure the similarity function has two non-constant arguments. If so, it continues

by checking if the inner argument B of the similarity condition is produced by the join input from the PRIMARY-INDEX SCAN, and whether the corresponding dataset has applicable secondary indexes. Finally, the optimizer consults the index compatibility matrix to decide whether it can rewrite the query using an index.

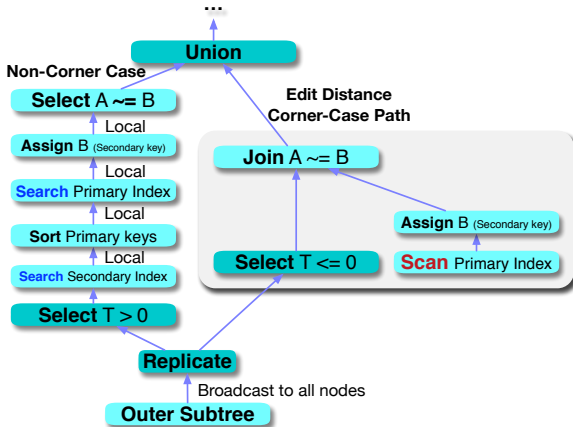

Figure 14: An optimized similarity-join query plan with the corner case.

Corner cases: For string-similarity joins using edit distance, we must modify the basic index-nested-loop join plan in Figure 10 to correctly handle corner cases. Unlike selection queries where the secondary-index search key is a constant, the secondary-index search keys for an index-nested-loop join are produced by the outer branch (“Subtree”). Join corner cases must therefore be dealt with at query runtime, as opposed to query compile time for selection queries. Figure 14 shows the modified index-nested-loop plan for correctly handling corner cases for edit distance. The main difference lies in separating the records produced by the outer subtree into two sets, one containing non-corner-case records ($T > 0$), and one containing corner-case records ($T \leq 0$). We do this by using a replicate operator above the outer subtree, followed by a selection operator on each of its two outputs to filter out the corner-case and non-corner-case records, respectively. The non-corner-case records are fed into the secondary-to-primary index plan as before, while the corner records participate in a non-index nested-loop join plan. The final query answer is the union of the results of those two joins.

5.2 AQL+ Framework

As discussed in Section 4.2.2, we need to find a way to transform a nested-loop-join plan generated from a user’s similarity-join query to a three-stage join plan. An issue is that, unlike the index-nested-loop-join optimization that adds or replaces a few operators from a nested-loop join plan, as we can see in the AQL query in Figure 11, a three-stage-similarity join query generates a large number of operators. Figure 15 shows the number of operators in a three-stage-similarity join.

Operator	Count	Operator	Count
Assign	12	Aggregate	6
Data-Scan	2	Assign	44
Join	1	Data-Scan	6
Total	15	Group	3
		Unnest	8
		Total	77

Nested-loop join plan Three-stage-similarity join plan

Figure 15: Number of operators for a nested-loop join and three-stage-similarity join plan for the same query.

Due to this complexity, it would be difficult to build an optimization rule that manually constructs these operators to transform a simple nested-loop join plan to a three-stage join plan. Instead, we develop a novel rewrite framework called “AQL+.” As shown in Figure 16, we use this framework to convert a simple logical plan generated from a user’s join query to a three-stage join plan.

Once the optimizer receives a logical plan in AQL+, it extracts the information from the logical plan and integrates it into an AQL+ query template. The generated AQL+ query can be parsed and compiled again using the AQL+ parser and translator. The result is a transformed logical plan, and the plan optimization process can then continue.

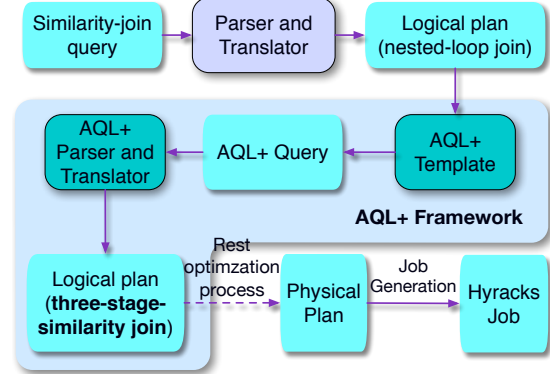

Figure 16: Execution of a similarity-join query using AQL+.

To combine the information from a logical plan and the three-stage-similarity-join AQL query template, we need to find ways to refer to the portions of the logical plan from the query template. Therefore, the AQL+ framework consists of a few AQL language extensions and the compilation of these language extensions during the optimization process. As a result, the AQL+ language is a superset of AQL. The AQL+ has three AQL extensions: Meta Variable (denoted as “\$\$”), Meta Clause (“##”), and Explicit Join (“join”). We need these extensions to refer to the logical variables and operators in the logical plan during the optimization process, since the AQL+ transformation of a given plan happens during the optimization process. This is because the optimizer only sees the logical plan and physical plan, not the original query. Since AQL itself does not have an explicit join clause, AQL+ includes one in order to express a join on two branches. For example, we use meta-variables to refer to the primary keys of the input records or variables in the similarity predicate. The usage of meta-clauses is to refer to inputs of the AQL query and to logical constructs that cannot be directly specified in AQL, such as joins. So any AQL+ template can be combined with any join input branches, where the inputs can be from any kind of subplans of other algebraic operators. In addition, to support various types of data, similarity functions, and thresholds, the similarity-join rule template uses placeholders, which are parts of the AQL+ query and are unknown until runtime. They are used for data types, similarity-specific functions, or values. For example, the “SIMILARITY” placeholder is used for built-in AQL functions, and the “THRESHOLD” placeholder is for numerical values.

Table 1: AQL+ extensions.

Extension	Symbol	Functionality
Meta Variable	\$\$	Refer to a variable in the plan
Meta Clause	##	Refer to an operator in the plan
Join Clause	join	Express an explicit join

The AsterixDB optimizer integrates the information from the given logical plan into the AQL+ query template and compiles the

resulting AQL+ query. Specifically, for a three-stage-similarity join, it needs to identify a similarity join operator that contains a Jaccard similarity join and its threshold. It also needs to get the information about the two branches of this join operator. Using the information from the join operator, the logical plan fed into this AQL+ template can be transformed to the equivalent three-stage-similarity plan. Rather than doing this transformation by introducing a number of operators by hand, we rely on the existing compilation path to generate a revised plan. This process is depicted in Figure 16; the details of this optimization will be discussed in the next subsection.

For the similarity join query in Figure 11, the optimizer will generate an equivalent AQL+ template and use it to transform a simple query during the rule-rewrite phase. In this way, the simple query of Figure 4(a) can be transformed to the query in Figure 11 during the optimization process. Figure 17 shows a part of the AQL+ template that generates a three-stage-similarity-join plan. Here, we can see that actual dataset-scans are replaced with meta-clauses and a meta-variable ($\$LEFTPK_3$) is used to refer to the primary key of an incoming record in the given logical plan. Join-clauses are used to join two meta-clauses.

```

1  //---Stage3---
2  join( (##RIGHT_1),
3        ( join( (##LEFT_1) ,
4              // --- Stage 2 ---
5                ( join( (##LEFT_2
6                  .....
7                    //--- Stage1---
8                    ##LEFT_3
9                    let $sid := $LEFTPK_3
10                   for $token in TOKENIZER($RIGHT_3)
11                   /*+ hash */
12                   group by $tokenGrouped := $token with $sid
13                   .....

```

Figure 17: A part of three-stage-similarity-join algorithm expressed in AQL+.

In addition, the AQL+ framework can be applied to transform multi-way-similarity join plans as well because of its power to handle a logical plan iteratively. Similar to non-similarity-join cases, multi-way-similarity joins can be transformed sequentially without a limitation. For instance, Figure 18 shows a similarity-join plan involving four datasets. The join between first two datasets, R and S , has already been transformed into a three-stage-similarity join plan. This branch will act as the outer branch when the optimizer processes the next join operator on the third dataset T .

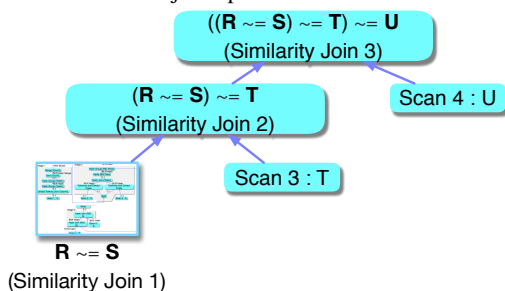

Figure 18: Rewriting a multi-way-similarity-join plan on four datasets.

It should be noted that AQL+ is a general extension framework, not only for similarity queries, and it can be used to support a transformation using AQL during the compilation process.

5.3 Optimization Rule For Similarity Queries

As discussed before, optimization in AsterixDB is rule-based [8]. Once the Algebricks layer receives a compiled plan from an AQL

query, it first optimizes the given plan logically. Then Algebricks sets up physical operators for each logical operator. After that, the physical optimization phase begins. When it is finished, a Hyracks job is created and executed. During the logical and physical optimization, there are a number of rule sets that are applied sequentially. A rule can be assigned to multiple rule sets. Based on the configuration of a rule set, each rule can be applied repeatedly until no rule in the set can transform the plan.

To apply the similarity-query optimization framework to this optimization path, we create a new rule set for the AQL+ framework and similarity queries. The rule set includes a *similarity join rule* (SJR) along with a handful of other rules that need to be applied after SJR is applied. As described earlier, the main functionality of AQL+ is a transformation using a complex AQL template to re-generate a logical plan while maintaining the current surrounding plan as part of the new plan. SJR first analyzes the conditions of each join operator. If its condition includes a similarity predicate, it applies the AQL+ template to the plan to generate an AQL+ query. Then it compiles the query into a new logical Algebricks plan. Some parts of the plan were already optimized if they belonged to the original incoming plan. However, most part of the plan is not optimized yet, since the three-phase plan was just compiled and has not gone through the optimization process before the SJR rule set. Therefore, the newly generated plan needs to go through some of the earlier optimization rules again. This re-application process is not necessary for non-similarity queries, since the plan generated from non-similarity queries is not transformed in the SJR rule set. Therefore, we need to ensure that the similarity-join rule set is only applied to similarity-join queries. The benefit of this approach is that the optimization for similarity queries can be processed without interfering with non-similarity queries. This approach also gives a chance to the newly generated similarity-query plan to reach the same level of transformation once the similarity rule set has finished its work.

5.4 Improvements

We discuss two improvements to similarity query processing, which can be applied to non-similarity query processing as well.

5.4.1 Surrogate Index-Nested-Loop-Join. A drawback of an index-nested-loop join using a local secondary index is the need to broadcast the outer side data to all secondary-index partitions as explained in Section 4. For example, during an execution of the AQL query in Figure 8, the outer side needs to broadcast join key field “A,” as well as “ $f1$ ” and “ $f2$ ” field. If there are more fields in the return clause, the broadcasting cost will be increased as well. This broadcast step is a direct consequence of the co-partitioning of each secondary index with its primary index. Also a secondary-inverted-index search can generate multiple pairs of results for the same primary key, as there can be multiple entries of the secondary keys for the same primary key; thus, we also want to reduce the sorting cost between the secondary-index search and primary index search. We can reduce the cost by only sending the secondary-key fields together with a compact surrogate for each outer-side record, so that we can later use the surrogates to obtain the surviving original records. This idea is reminiscent of semi-join optimization in distributed databases [40].

Figure 19 shows a surrogate-based index-nested-loop-similarity join plan. Notice the PROJECT operator that follows the REPLICATE operator after the outer subtree, which eliminates all non-essential fields from the outer side. The optimizer filters out the “ $f1$ ” and “ $f2$ ” fields since the search key is “A.” In addition, since

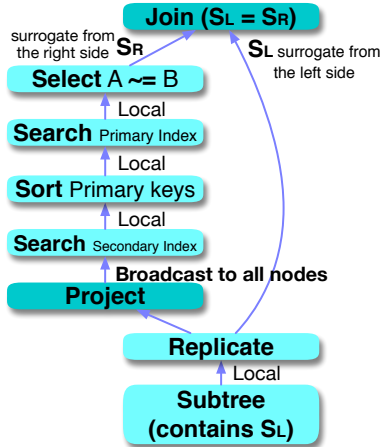

Figure 19: Surrogate index-nested-loop-join plan.

the same subtree is used twice in the plan, a REPLICATE operator is introduced to reduce the subtree calculation time. We will discuss this optimization in-depth in the next subsection. After the secondary-to-primary index search, we must use the surrogates from the outer side to obtain their complete records. As shown in the figure, we resolve the surrogates via a top-level join of the original outer subtree with the indexed nested-loop subtree (after removing false positive matches). Since the top-level join is an equi-join on the surrogates S_L and S_R , it can be executed efficiently in parallel, e.g., using a hash join.

5.4.2 Materializing/Reusing Shared Subplans. As shown in a simplified version of a three-stage-similarity join in Figure 20, in case of the three-stage-similarity self join, the dataset R may need to be scanned three to four times. For this case, we could simply execute the original data-scan operation four times. However, if the two branches of this join result from a complex computation from a subquery, it would be expensive to compute the result of the subquery many times. To minimize the cost, AsterixDB materializes the common subplan and reuses it several times.

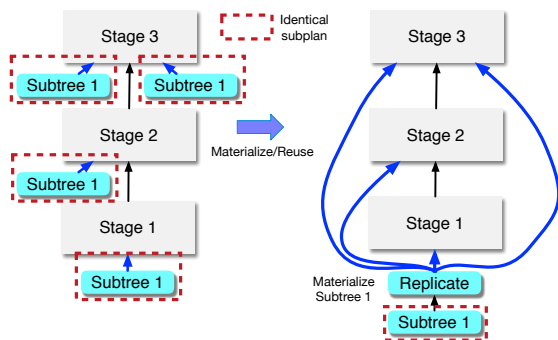

Figure 20: Materializing and reusing a subtree of a three-stage-similarity self join.

6 EXPERIMENTS

We have conducted an experimental evaluation of our approach in AsterixDB using large, real data sets. We used an 8-node cluster to host an AsterixDB (0.9.2) instance, where each node ran Ubuntu with a Quadcore AMD Opteron CPU 2212 HE (2.0GHz), 8GB RAM, 1 GB Ethernet NIC, and two 7,200 RPM SATA hard drives. Each dataset was horizontally partitioned into 16 partitions (2

per node) based on primary keys to provide full I/O parallelism. Table 2 shows the AsterixDB configuration parameters.

Table 2: AsterixDB parameters for the experiments.

Parameter	Value
Global memory budget per node	6GB
Budget for in-memory components per dataset	1.5GB
Data page size	128KB
Disk buffer cache size	2GB
Sort buffer size	128MB
Join buffer size	128MB
Group-by buffer size	128MB

6.1 Datasets

Different similarity functions were used for different types of data. Edit distance is more suitable for short string fields, while Jaccard is more suitable for long fields with many elements. To evaluate AsterixDB for different similarity functions, we used three datasets with different characteristics, as shown in Table 3. The Amazon Review dataset, discussed in earlier sections, included Amazon product reviews [23]. The Reddit Submission dataset included Reddit postings for about eight years. The Twitter dataset had 1% of US tweets for three months obtained via Twitter’s public API. When imported into AsterixDB, each data set had an additional auto-generated primary key field, as AsterixDB requires that each dataset must have a primary key. Other than this field, we did not define more fields in the schema. This gave us a lot of flexibility to import any datasets into AsterixDB. The dataset size in AsterixDB was greater than the raw data size, since each record included the information about each field. For example, for a string field, its type needs to be included in addition to its value.

Table 3: Dataset properties.

Dataset	AmazonReview	Reddit	Twitter
Content	Amazon product reviews	Reddit postings	Tweets
Number of Records	83.68M	196M	155M
Data Period	1996 - 2014	01/2006 - 08/2015	06/2016 - 08/2016
Raw Data Format	JSON	JSON	JSON
Raw Data Size	55 GB	252 GB	465 GB
Dataset Size	60.6 GB	320 GB	582 GB
Fields used	summary, reviewerName	title, author	text, user.name

Table 4 shows the characteristics of the fields of the datasets. The minimum character length and minimum word count of the fields were 0. The first three fields were used for edit distance, while the last three fields were used for Jaccard.

Table 4: The characteristics of the fields.

Field	Avg char count	Max char count	Avg word count	Max word count
AmazonReview.reviewerName	10.3	49	1.7	14
Reddit.author	24.3	275	4.1	32
Twitter.user.name	10.6	20	1.7	10
AmazonReview.summary	22.8	361	4.0	44
Reddit.title	1,056.2	400K	1,173	20K
Twitter.text	62.5	140	9.7	70

6.2 Index Size

We built a keyword index for Jaccard similarity queries and a 2-gram index for edit distance queries. To measure the execution time of basic exact match queries on the same fields as a baseline, we also built a B+ tree index on the search fields. Table 5 shows

the index sizes for the Amazon Review dataset and the time it took to create each index. An n -gram index took much more space than a B+ tree or keyword index as it had more secondary keys per record. For instance, a 2-gram index on the “reviewerName” field took 15.6GB of disk space, which was about 25% of the original dataset size. The size of a keyword index was also greater than a B+ tree index on the same field since there are many secondary keys per record. For a given type of index, the construction time was roughly proportional to the size of an index. In each case, the dataset itself was also stored in a primary B+ tree index.

Table 5: Index size and build time for Amazon reviews.

Field	Index Type	Size (GB)	Build Time (s)
Dataset itself	B+ tree	60.6	1,563
reviewerName	B+ tree	2.7	223
reviewerName	2-gram	15.6	1,441
summary	B+ tree	3.5	275
summary	keyword	5.4	573

6.3 Selection Queries

To measure the performance of similarity-selection queries, we first created a search value set that contained 10,000 random unique values extracted from the search field. For Jaccard queries, we ensured that the minimum number of words in each value in the set was 3. For edit distance queries, the minimum length of characters in each value was 3. For each similarity threshold, we randomly chose a search value from the set for each query, sent 100 such queries to the cluster, and measured the average execution time. The performance baseline for comparison purposes was an equality-condition query that used the same value for the given field. The query template in Figure 21 below was used to measure the average execution time. “Simfunction” and “simthreshold” in the queries were replaced with a specific similarity function and a threshold. “V” was the given field and “C” was the random value from the above set.

```
count ( for $o in dataset X
  where @simfunction($o.V, C) >= @simthreshold
  return {"oid":$o.id, "v":$o.V} );
```

Figure 21: Similarity-selection query template.

6.3.1 Jaccard Similarity. For each of the three datasets we ran similarity queries using Jaccard similarity on suitable fields using different thresholds: 0.2, 0.5, and 0.8. Figure 22(a) shows the results. We see that the average execution time for similarity selection queries decreased as the threshold increased in case of index-based plans. For example, it took the index-based method 67.6 seconds to conduct a Jaccard query with a threshold of 0.2, while it only took 25.5 seconds to execute a query with a threshold of 0.5. If there was no applicable index, both similarity and exact-match queries showed a high execution time as each record had to be read from the primary index and that scan time was a dominant factor in the overall execution time. We can also see the overhead of the similarity query versus the exact-match query for all the thresholds since it takes more time to calculate a Jaccard value than to get the result of an exact match. This overhead decreased as the threshold increased; this is because we applied certain optimizations such as early termination and pruning based on string lengths, which significantly reduced the cost of computing the similarity.

When the threshold was low, the times were similar for both index-based and non-index-based queries. This is because the candidate set size using T -occurrence for index-based queries was quite large when the threshold was low. This can be seen in

Figure 22: Execution time of selection queries on Amazon reviews.

Table 6. As the number of candidates increased, the search time increased due to the need for a primary-index lookup for each candidate.

Table 6: Candidate size and the final result size for the indexed-select query for Amazon reviews in Figure 22(a).

Jaccard Threshold	Actual Record Count (B)	Candidate Set Record Count (C)	Ratio (B/C)
0.2	559,167	8,298,473	6.7%
0.5	12,260	660,016	1.9%
0.8	36	12,420	0.3%

6.3.2 Edit Distance. We measured the average execution time of an edit distance selection query using different thresholds, namely 1, 2, and 3. Figure 22(b) shows the results. As the threshold increased, the execution time increased. The reason is similar to the case of Jaccard queries: the candidate set size using T -occurrence increased as the threshold increased. It took the index-based method 2 seconds to run a selection query with a threshold of 2; it took 8.9 seconds to run a query with a threshold of 3. We can also see that the execution time of non-index-based edit distance queries increased as the threshold increased for the same reason as described above.

6.4 Join Queries

To measure the performance of similarity join queries, we ran self-join queries on the three datasets. Specifically, the query template in Figure 23 was used to measure the average execution time as in the similarity-selection query case. Here, V is the field on which we applied a similarity function and id is the primary key field.

```
count ( for $o in dataset X
  for $i in dataset X
  where @simfunction($o.V, $i.V) >= @simthreshold
  and $o.f1 = C and $o.id < $i.id
  return {"oid":$o.id} );
```

Figure 23: Similarity-join query template.

6.4.1 Varying Threshold. We first extracted certain number of records from the outer branch of the join to limit its input. For each query, we chose 10 random records from the outer branch. In the query template in Figure 23, a field named $f1$ was used to specify such a limit. For Jaccard join queries, we used different thresholds, namely 0.2, 0.5, and 0.8. For edit distance queries, we used thresholds of 1, 2, and 3. When there was no applicable index, AsterixDB chose to employ the three-stage-similarity-join plan for Jaccard queries. The results are shown in Figures 24(a) and 24(b). The trends were similar to those of selection queries except for the exact-match join, which significantly outperformed both Jaccard

and edit distance joins since it used a hash join, where the join keys were broadcast to multiple nodes.

Regarding the compilation overhead of AQL+, we observed that the average overhead of generating a new logical three-stage-similarity-join plan using AQL+ for the queries in Figure 24(a) was around 50 ms, and it took around 500 ms to optimize that plan. The overall compilation time of the three-stage-similarity-join query was around 900 ms.

Figure 24: Execution time of join queries on Amazon reviews.

6.4.2 Varying Record Number. For a Jaccard join query, its execution time was smallest when the threshold was 0.8. In this experiment, we varied the number of records from the output branch and fixed the threshold at 0.8. The times for the non-index-nested-loop self-join, index-nested-loop self-join, and three-stage-similarity self-join on the Amazon Review dataset are shown in Figure 25(a). We increased the number of output records from the outer branch and measured the resulting execution time of each join. First, we see that the execution time of non-index-nested-loop self-join was already highest for 200 records and increased drastically compared to other two types of joins. Once the number of output records from the outer branch reached around 400, the three-stage-similarity join began to outperform the index-nested-loop join. This is because the time for the index-nested-loop join is proportional to the number of records fed to the secondary-index search, as it needs to deal with each record at a time. In contrast, for the three-stage-similarity join, most of the time is spent on global-token-order generation in the first stage. Once this is generated and broadcast to all the nodes, hash joins in stage 2 and 3 can deal with the incoming records efficiently, since each join key is sent to only one node. This benefit is visible in the figure. For instance, the time for the three-stage-similarity join for 800 records was 619 seconds, while it was 674 seconds for 1,000 records. This result shows only 55 seconds of increase, while the execution-time difference for the index-nested-loop joins going from 800 to 1,000 records was 384 seconds.

Figure 25: Execution time of join queries.

6.4.3 Multi-Way Join Queries. So far, we have used only one similarity condition per similarity query. Next, we used two similarity conditions in a query and varied the order of the two conditions. The query template in Figure 26 was used to measure

the average execution time. The dataset Y and the field $f1$ were used to limit the number of records from the outer branch.

```

count ( for $p in dataset Y
        for $o in dataset X
        for $i in dataset X
        where $p.f1 = $o.f1 and $p.id = C
        and @simfunction1($o.V1, $i.V1) >= @simthreshold1
        and @simfunction2($o.V2, $i.V2) <= @simthreshold2
        and $o.id < $i.id
        return {"oid":$o.id, "iid":$i.id} );

```

Figure 26: Multi-way-join query template.

Each query had an equi-join and a similarity join with two conditions, including a Jaccard condition with a threshold of 0.8 and an edit distance condition with a threshold of 1. For the equi-join, we used an index-nested-loop join to fetch output records quickly. Also, this join was used to limit the number of output records from the outer branch fed into the similarity join. Then, Jaccard similarity and edit distance conditions were applied. If we applied the Jaccard condition first, the Jaccard join will be followed by the edit distance condition in a SELECT operator. For both similarity conditions, we used an index-based method for the first condition and a non-index-based method for the second. Figure 25(b) shows that the performance was the best when the index-based-Jaccard join was conducted first, as there were no corner cases for Jaccard similarity. This order generated fewer candidates than applying the index-based edit distance predicate first. In contrast, for the edit distance case, it needed to augment the corner-case path in the logical plan, thus generated more candidates. In addition, it should be noted that other queries showed similar patterns for all the three datasets as well. That is, the average execution time of a similarity query was proportional to the size of datasets when the result cardinality was similar.

6.5 Scalability Tests

6.5.1 Scale-Out. For the scale-out experiment, we used four clusters with different sizes, namely 1, 2, 4, and 8 nodes. When we doubled the number of nodes in a cluster, we also doubled the data size to store the same amount of data per node. Thus, the 1-node cluster had 12.5% of our original data set size, the 2-node cluster had 25%, and the 4-node cluster had 50% of the data. The 8-node cluster contained the original dataset, where the data size was 100%. In other words, each node had 12.5% of the original dataset. Ideally, the response-time graph would show a flat line per query. As the number of nodes increased, the queries were handled as expected, as shown in Figure 27(a). We can see some variance in the case of the Jaccard-similarity join without an index; in the three-stage-similarity join, the global token order generated in stage 1 of the join needed to be broadcast to all the nodes. Therefore, as the number of nodes increased, the communication cost increased as well. This gap was the greatest between 1 node and 2 nodes, since that was where we first incurred the communication cost of global-token-order propagation. However, the execution time increase was not high between 2 nodes and 4 nodes. Between 4 nodes and 8 nodes, we can see the trend as well. Once the communication cost was accounted for, the execution time of three-stage-similarity joins was quite scalable.

6.5.2 Speed-Up. For the speed-up experiment, we also used four cluster sizes (1, 2, 4, and 8 nodes) with each cluster size

Figure 27: Scale-out and speed-up queries on Amazon reviews.

being given the entire (100%) data set. Figure 27(b) shows that the speed-up was proportional to the number of nodes. The speed-up for the index-based-Jaccard-selection query with a threshold 0.8 was less than that of the other Jaccard queries. This was because its execution time was already less than a few seconds on the 1-node cluster, and there was a basic overhead for each cluster such as communication cost. In particular, the execution time of that query on the 1-node cluster was 6.5 seconds, and its execution time on the 8-node cluster was 1.5 seconds. Figure 27(c) shows the execution time of the same queries on each cluster.

7 CONCLUSIONS

In this paper, we presented the support for similarity queries in Apache AsterixDB, a parallel data management system. We described the entire life cycle of a similarity query in the system, including the query language, indexing, execution plans with or without index, and plan rewriting to optimize the execution. Our solution leverages the existing infrastructure of AsterixDB, including its operators, query engine, and rule-based optimizer. We presented an experimental study based on several large, real data sets on a parallel computing cluster to evaluate the proposed techniques, and showed their efficacy and performance to support similarity queries on large data sets using parallel computing.

Acknowledgments The Apache AsterixDB project has been supported by an initial UC Discovery grant, by NSF IIS awards 0910989, 0910859, 0910820, 0844574, and by NSF CNS awards 1305430 and 1059436. ABSTRACT

To derive real-time actionable insights from the data, it is important to bridge the gap between managing the data that is being updated at a high velocity (i.e., OLTP) and analyzing a large volume of data (i.e., OLAP). However, there has been a divide where specialized solutions were often deployed to support either OLTP or OLAP workloads but not both; thus, limiting the analysis to stale and possibly irrelevant data. In this paper, we present Lineage-based Data Store (L-Store) that combines the real-time processing of transactional and analytical workloads within a single unified engine by introducing a novel update-friendly lineage-based storage architecture. By exploiting the lineage, we develop a contention-free and lazy staging of columnar data from a write-optimized form (suitable for OLTP) into a read-optimized form (suitable for OLAP) in a transactionally consistent approach that supports querying and retaining the current and historic data.

1 INTRODUCTION

We are witnessing an architectural shift and divide in database community. The first school of thought emerged from an academic conjecture that “one size does not fit all” [37] (i.e., *advocating specialized solutions*), which has led to manifolds of innovations over the last decade in creating specialized and subspecialized database engines geared toward various niche workloads and application scenarios [5, 9, 12, 22, 28, 29, 37, 38]. This school has motivated major commercial database vendors such as Microsoft to focus on building novel specialized engines offered as loosely integrated engines, namely, Hekaton in-memory engine [9] and Apollo column store engine [19], within a single umbrella of database portfolio. Notably, recent efforts are focused on a tighter real-time integration of Hekaton and Apollo engines [17]. It has inspired Oracle to push the boundary of the basic premise that “one size does not fit all” as far as data representation is concerned and has led Oracle to develop a dual-format technique [15] that maintains two tightly integrated representation of data (i.e., two copies of the data) in a transactionally consistent manner.

However, the second school of thought, supported by both academia (e.g., [2, 6, 7, 13, 16, 24]) and industry (e.g., SAP [10], IBM DB2 BLU [29], and IBM Wildfire [4]) have revisited the aforementioned fundamental premise and advocates a generalized solution. Proponents of this idea, rightly in our view, make the following arguments. First, there is a tremendous cost in building and maintaining multiple engines from both the perspective of database vendors and users of the systems (e.g., application development and deployment costs). Second, there is a compelling case to support real-time decision making on the latest version of the data [27] (likewise supported by [15, 17]), which may not be feasible across loosely integrated engines that are connected through

the extract-transform load (ETL) process. Closing this gap may be possible, but its elimination may not be feasible without solving the original problem of unifying OLTP and OLAP capabilities or without being forced to rely on ad-hoc approaches to bridge the gap in hindsight. We argue that the separation of OLTP and OLAP capabilities defers solving the actual challenge of real-time analytics. Third, combining real-time OLTP and OLAP functionalities remains as an important basic research question, which demands deeper investigation even if it is purely from the theoretical standpoint.

In this dilemma, we support the latter school of thought (i.e., *advocating a generalized solution*) with the goal of undertaking an important step to study the entire landscape of single engine architectures and to support both transactional and analytical workloads holistically (i.e., “one size fits all”). In this paper, we present Lineage-based Data Store (L-Store) with a novel update-friendly lineage-based storage architecture to address the conflicts between row- and column-major representation. This is achieved by developing a contention-free and lazy staging of columnar data from write optimized into read optimized form in a transactionally consistent manner without the need to replicate data, to maintain multiple representation of data, or to develop multiple loosely integrated engines that sacrifices real-time capabilities.

To further disambiguate our notion of “one size fits all”, in this paper, we restrict our focus to real-time relational OLTP and OLAP capabilities. We define a set of architectural characteristics for distinguishing the differences between existing techniques. First, there could be a single product consisting of multiple loosely integrated engines that can be deployed and configured to support either OLTP or OLAP. Second, there could be a single engine as opposed to having multiple specialized engines packaged in a single product. Third, even if we have a single engine, then we could have multiple instances running over a single engine, where one instance is dedicated and configured for OLTP workloads while another instance is optimized for OLAP workloads, in which these instances are assumed to be connected using an ETL process. Finally, even when using the same engine running a single instance, there could be multiple copies or representations (e.g., row vs. columnar layout) of the data, where one copy (or representation) of the data is read optimized while the second copy (or representation) is write optimized.

In short, we develop L-Store, an important first step towards supporting real-time OLTP and OLAP processing that faithfully satisfies our definition of *generalized solution*, and, in particular, we make the following contributions:

- Introducing an update-friendly lineage-based storage architecture that enables a contention-free update mechanism over a native multi-version, columnar storage model in order to lazily and independently stage stable data from a write-optimized columnar layout (i.e., OLTP) into a read-optimized columnar layout (i.e., OLAP)
- Achieving (at most) 2-hop away access to the latest version of any record (preventing read performance deterioration for point queries)

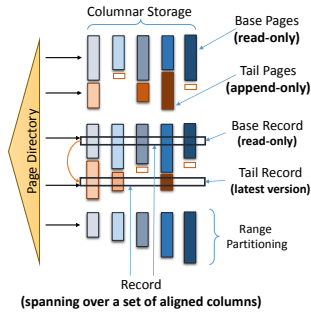

Figure 1: Overview of the lineage-based storage architecture.

- Contention-free merging of only stable data, namely, merging of the read-only base data with recently committed updates (both in columnar representation) without the need to block ongoing or new transactions by relying on the lineage
- Contention-free page de-allocation (upon the completion of the merge process) using an epoch-based approach without the need to drain the ongoing transactions
- A first of its kind comprehensive evaluation to study the leading architectural storage design for concurrently supporting short update transactions and analytical queries (e.g., an in-place update with a history table architecture and the commonly employed main and delta stores architecture)

2 UNIFIED ARCHITECTURE

The divide in the big data community is partly attributed to the storage conflict pertaining to the representation of transactional and analytical data. In particular, transactional data requires write-optimized storage, namely the row-based layout, in which all columns are co-located (and preferably uncompressed for in-place updates). This layout improves point update mechanisms, since accessing all columns of a record can be achieved by a single I/O (or few cache misses for memory-resident data). In contrast, to optimize the analytical workloads (i.e., reading many records), it is important to have read-optimized storage, i.e., columnar layout in highly compressed form. The intuition behind having columnar layout is due to the observation that most analytical queries tend to access only a small subset of all columns [1]. Thus, by storing data column-wise, we can avoid reading irrelevant columns (i.e., reducing the raw amount of data read) and avoid polluting processor’s cache with irrelevant data, which substantially improve both disk and memory bandwidth, respectively. Furthermore, storing data in columnar form improves the data homogeneity within each page, which results in an overall better compression ratio.

2.1 L-Store Storage Overview

To address the dilemma between write- and read-optimized layouts, we develop L-Store. As demonstrated in Figure 1, the high-level architecture of L-Store is based on a native multi-version, columnar layout (i.e., data across columns are aligned to allow implicit re-construction), where records are (virtually) partitioned into disjoint ranges (also referred to as update range). Records within each range span a set of read-only, compressed pages, which we refer to them as the *base pages*. More importantly, for every range of records, and for each updated column within the range, we maintain a set of append-only pages to store the latest updates, which we refer to them as the *tail pages*. Anytime a record is updated in base pages, a new record is appended to its corresponding tail pages, where there are explicit values only for the updated columns (non-updated columns are preassigned a special null value when a page is first allocated). We refer to the records in base pages as the *base records* and the records in tail pages as the *tail records*. Each record (whether falls in base

or tail pages) spans over a set of aligned columns (i.e., no join is necessary to pull together all columns of the same record).¹

A unique feature of our lineage-based architecture is that tail pages are strictly append-only and follow a write-once policy. In other words, once a value is written to tail pages, it will not be over-written even if the writing transaction aborts. The append-only design together with retaining all versions of the record substantially simplifies low-level synchronization and recovery protocol and enables efficient realization of multi-version concurrency control. Another important property of our lineage-based storage is that all data are represented in a common unified form; there are no ad-hoc corner cases. Records in both base and tail pages are assigned record-identifiers (RIDs) from the same key space. Therefore, both base and tail pages are referenced through the database page directory using RIDs and persisted identically. Therefore, at the lower-level of the database stack, there is absolutely no difference between base vs. tail pages or base vs. tail records; they are presented and maintained identically.

To speed up query processing, there is also an explicit linkage (forward and backward pointers) among records. From a base record, there is a forward pointer to the latest version of the record in tail pages. The different versions of the same records in tail pages are chained together to enable fast access to an earlier version of the record. The linkage is established by introducing a table-embedded indirection column that stores forward pointers for base records and backward pointers for tail records (i.e., RIDs).

The final aspect of our lineage-based architecture is a periodic, contention-free merging of a set of base pages with its corresponding tail pages. This is performed to consolidate base pages with the recent updates and to bring base pages forward in time (i.e., creating a set of merged pages). Each merged page independently maintains its lineage information, i.e., keeping track of all tail records that are consolidated onto the page thus far. By maintaining explicit in-page lineage information, the current state of each page can be determined independently, and the base page can be brought up to any desired snapshot. Tail pages that are already merged and fall outside the snapshot boundaries of all active queries are called historic tail-pages. These pages are re-organized, so that different versions of a record are stored contiguously in-lined. Delta-compression is applied across different versions of tail records, and tail records are ordered based on the RIDs of their corresponding base records. Below, we describe the unique design and algorithmic features of L-Store that enables efficient transactional processing without performance deterioration of analytical processing; thereby, achieving a real-time OLTP and OLAP.

2.2 Lineage-based Storage Architecture

In L-Store, the storage layout is natively columnar and applies equally to both base and tail pages. A detailed view of our lineage-based storage architecture is presented in Figure 2. In general, one can perceive tail pages as directly mirroring the structure and the schema of base pages. As we pointed out earlier, conceptually for every record, we distinguish between base vs. tail records, where each record is assigned a unique RID. But it is important to note that the RID assigned to a base record is stable and remains constant throughout the entire life-cycle of a record, and all indexes only reference base records (base RIDs); consequently, eliminating index maintenance problem associated when update operation results in creation of a new version of the record [33, 34]. When a reader performing index lookup, it always lands at a base record, and from the base record it can reach any desired version of the record by following the table-embedded indirection to access the latest (if the base record is out-of-date) or an earlier version of the record. However, when a record is updated, a new version is

¹Fundamentally, there is no difference between base vs. tail record, the distinction is made only to ease the exposition.

Figure 2: Detailed, unfolded view of lineage-based storage architecture (a multi-version, columnar storage model).

created. Thus, a new tail record is created to hold the new version, and the new tail record is assigned a new tail RID that is referenced by the base record (as demonstrated in Figure 2).

Each table in addition to having the standard data columns has several meta-data columns. These meta-data columns include the *Indirection* column, the *Schema Encoding* column, the *Start Time* column, and the *Last Updated Time* column. An example of table schema is shown in Table 1.

The *Indirection* column exists in both the base and tail records. For base records, the *Indirection* column is interpreted as a forward pointer to the latest version of a record residing in tail pages, essentially storing the RID of the latest version of a record. If a record has never been updated, then the *Indirection* column will hold a null value. In contrast, for tail records, the *Indirection* column is used to store a backward pointer to the last updated version of a record in tail pages. If no earlier version exists, then the *Indirection* column will point to the RID of the base record.

The *Schema Encoding* column stores the bitmap representation of the state of the data columns for each record, where there is one bit assigned for every column in the schema (excluding the meta-data columns), and if a column is updated, its corresponding bit in the *Schema Encoding* column is set to 1, otherwise is set to 0. The schema encoding enables to quickly determine if a column has ever been updated or not for base records. In tail records, the encoding tracks which columns have been updated and have explicit values as opposed to those columns that have not been updated and have an implicit special null values (denoted by \emptyset). An example of *Schema Encoding* column is provided in Table 1.

The *Start Time* column stores the time at which a base record was first installed in base pages (the original insertion time), and for a tail record, the *Start Time* column holds the time at which the record was updated, which is also the implicit end time of the previous version of the record. The *Start Time* column is essential for distinguishing between different version of the record. In addition, to the *Start Time* column, for base records, we maintain an optional *Last Updated Time* column, which is only populated after the merge process is taken place and reflects the *Start Time* of those tail records included in merged pages. Also note that the initial *Start Time* column for base records is always preserved even after the merge process for faster pruning of those records that are not visible to readers because they fall outside the reader’s snapshot. Lastly, we may add the *Base RID* column optionally to tail records to store the RIDs of their corresponding base records; this is utilized to improve the merge process. *Base RID* is a highly compressible column that would require at most two bytes when restricting the range partitioning of records to 2^{16} records.

3 FINE-GRAINED MANIPULATION

The transaction processing can be viewed as two major challenges: (1) how data is physically manipulated at the storage layer and how changes are propagated to indexes and (2) how multiple

RID	Indirection	Schema Encoding	Start Time	Key	A	B	C
Partitioned base records for the key range of k_1 to k_3							
b_1	t_8	0000	10:02	k_1	a_1	b_1	c_1
b_2	t_5	0101	13:04	k_2	a_2	b_2	c_2
b_3	t_7	0001	15:05	k_3	a_3	b_3	c_3
Partitioned base records for the key range of k_4 to k_6							
b_4	\perp	0000	16:20	k_4	a_4	b_4	c_4
b_5	\perp	0000	17:21	k_5	a_5	b_5	c_5
b_6	\perp	0000	18:02	k_6	a_6	b_6	c_6
Partitioned tail records for the key range of k_1 to k_3							
t_1	b_2	0100*	13:04	\emptyset	a_2	\emptyset	\emptyset
t_2	t_1	0100	19:21	\emptyset	a_{21}	\emptyset	\emptyset
t_3	t_2	0100	19:24	\emptyset	a_{22}	\emptyset	\emptyset
t_4	t_3	0001*	13:04	\emptyset	\emptyset	\emptyset	c_2
t_5	t_4	0101	19:25	\emptyset	a_{22}	\emptyset	c_{21}
t_6	b_3	0001*	15:05	\emptyset	\emptyset	\emptyset	c_3
t_7	t_6	0001	19:45	\emptyset	\emptyset	\emptyset	c_{31}
t_8	b_1	0000	20:15	\emptyset	\emptyset	\emptyset	\emptyset

Table 1: An example of the update and delete procedures (conceptual tabular representation).

transactions (where each transaction consists of many statements) can concurrently coordinate reading and writing of the shared data. The focus of this paper is on the former challenge, and we defer the latter to our discussion on the employed low-level synchronization and concurrency control in Section 5.

Without loss of generality, from the perspective of the storage layer, we focus on how to handle a single point update or delete in L-Store (but note that we support multi-statement transactions through L-Store’s transaction layer as demonstrated by our evaluation). Furthermore, in our technical report [31], we discuss how our model can easily be extended to deal with insertion as well. Each update may affect a single or multiple records. Since records are (virtually) partitioned into a set of disjoint ranges as shown in Table 1, each updated record naturally falls within only one range. Now for each range of records, upon the first update to that range, a set of tail pages are created (and persisted on disk optionally) for the updated columns and are added to the page directory, i.e., lazy tail-page allocation. Consequently, updates for each record range are appended to their corresponding tail pages of the updated columns only; thereby, retraining all versions of the record, avoiding in-place updates of modified data columns, and clustering updates for a range of records within their corresponding tail pages.

To describe the update procedure in L-Store, we rely on our running example shown in Table 1. When a transaction updates any column of a record for the first time, two new tail records (each tail record is assigned a unique RID) are created and appended to the corresponding tail pages. For example, consider updating the column A of the record with the key k_2 (referenced by the RID b_2) in Table 1. The first tail record, referenced by the RID t_1 , contains the original value of the updated column, i.e., a_2 , whereas implicit null values (\emptyset) are preassigned for remaining unchanged columns. Taking a snapshot of the original changed values becomes essential in order to ensure contention-free merging as discussed in Section 4.1. The second tail record contains the newly updated value for column A, namely, a_{21} , and again

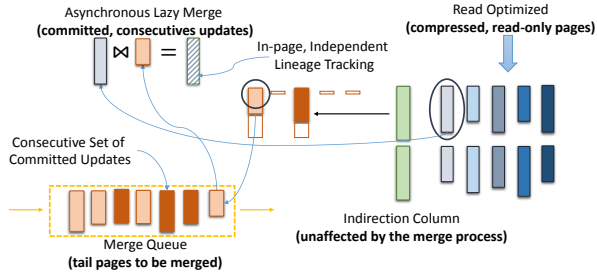

Figure 3: Lazily, independently merging of tail & base pages.

implicit special null values for the rest of the columns; a column that has never been updated does not even have to be materialized with special null values. However, for any subsequent updates, only one tail record is created, e.g., the tail record t_3 is appended as a result of updating the column A from a_{21} to a_{22} for the record b_2 .

In general, updates could either be cumulative or non-cumulative. The cumulative property implies that when creating a new tail record, the new record will contain the latest values for all of the updated columns thus far. For example, consider updating the column C for the record b_2 . Since the column C of the record b_2 is being updated for the first time, we first take a snapshot of its old value as captured by the tail record t_4 . Now for the cumulative update, a new tail record is appended that repeats the previously updated column A , as demonstrated by the tail record t_5 . If non-cumulative update approach was employed, then the tail record would consist of only the changed value for column C and not A . It is important to note that cumulation of updates can be reset at anytime. In the absence of cumulation, readers are simply forced to walk back the chain of recent versions to retrieve the latest values of all desired columns. Thus, cumulative update is an optimization that is intended to improve the read performance.

As part of the update routine, the embedded *Indirection* column (forward pointers) for base records is also updated to point to the newly created tail record. In our running example, the *Indirection* column of the record b_2 points to the tail record t_5 . Also after updating the column C of the record b_3 , the *Indirection* column points to the latest version of b_3 , which is given by t_7 . Likewise, the *Indirection* column in the tail records point to the previous version of the record. It is important to note that the *Indirection* column of base records is the only column that requires an in-place update in our architecture. However, as discussed in our low-level synchronization protocol (cf. Section 5), this is a special column that lends itself to latch-free synchronization.

Furthermore, indexes always point to base records (i.e., base RIDs), and they never directly point to any tail records (i.e., tail RIDs) in order to avoid the index maintenance cost that arise in the absence of in-place update mechanism [33]. Therefore, when a new version of a record is created (i.e., a new tail record), first, all indexes defined on unaffected columns do not have to be modified and, second, only the affected indexes are modified with the updated values, but they continue to point to base records and not the newly created tail records. Suppose there is an index defined on the column C (cf. Table 1). Now after modifying the record b_2 from c_2 to c_{21} , we add the new entry (c_{21}, b_2) to the index on the column C .² Subsequently, when a reader looks up the value c_{21} from the index, it always arrives at the base record b_2 initially, then the reader must determine the visible version of b_2 (by following the indirection if necessary) and must check if

²Optionally the old value (c_2, b_2) could be removed from the index; however, its removal may affect those queries that are using indexes to compute answers under snapshot semantics. Therefore, we advocate deferring the removal of changed values from indexes until the changed entries fall outside the snapshot of all relevant active queries.

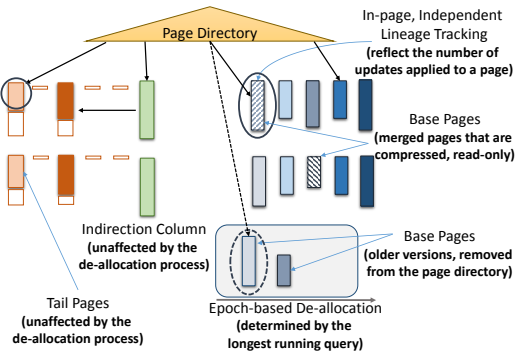

Figure 4: Epoch-based, contention-free page de-allocation.

the visible version has the value c_{21} for the column C , essentially re-evaluating the query predicates.

There are two other meta-data columns that are affected by the update procedure. The *Start Time* column for tail records simply holds the time at which the record was updated (an implicit end of the previous version). For example, the record t_7 has a start time of 19:45, which is also the implied end time of the first version of the record b_3 . The *Schema Encoding* column is a concise representation that shows which data columns have been updated thus far. For example, the *Schema Encoding* of the tail record t_7 is set to "0001", which implies that only the column C has been changed. To distinguish between whether a tail record is holding new values or it is the snapshot of old values, we add a flag to the *Schema Encoding* column, which is shown as an asterisk. For example, the tail record t_6 stores the old value of the column C , which is why its *Schema Encoding* is set to "0001*". The *Schema Encoding* can also be maintained optionally for base records as part of the update process or it could be populated only during the merge process.

Notably, when there are multiple individual updates to the same record by the same transaction, each update is written as a separate entry to tail pages. Each update results in a creation of a new tail record and only the final update becomes visible to other transactions. The prior entries are implicitly invalidated and skipped by readers. Also delete operation is simply translated into an update operation, in which all data columns are implicitly set to \emptyset , e.g., deleting the record b_1 results in creating the tail record t_8 . An alternative design for delete is to create a tail record that holds a complete snapshot of the latest version of the deleted record.

4 REAL-TIME STORAGE ADAPTION

To ensure a near optimal storage layout, outdated base pages are merged lazily with their corresponding tail pages in order to preserve the efficiency of analytical query processing. Recall that the base pages are read-only and compressed (read optimized) while the tail pages are uncompressed³ that grow using a strictly append-only technique (write optimized). Therefore, it is necessary to transform the recent committed updates accumulated in tail pages that are write optimized into read optimized form. A distinguishing feature of our lineage-based architecture is to introduce a contention-free merging process that is carried out completely in the background without interfering with foreground transactions. Furthermore, the contention-free merging procedure is applied only to the updated columns of the affected update ranges. There is even no dependency among columns during the merge; thus, the different columns of the same record can be merged completely independent of each other at different points in time. This is achieved by independently maintaining in-page lineage information for each merged page. The merge process is conceptually depicted in Figure 3, in which writer threads (i.e., update transactions) place candidate tail pages to be merged into

³Even though compression techniques such as local and global dictionaries can be employed in tail pages, but these directions are outside the scope of the current work.

the merge queue while the merge thread continuously takes pages from the queue and processes them.

4.1 Contention-free, Relaxed Merge

In L-Store, we abide to one *main design principle* for ensuring contention-free processing that is “*always operating on stable data*”. The inputs to the merge process are (1) a set of base pages (committed base records) that are read-only,⁴ thus, stable data and (2) a set of consecutive committed tail records in tail pages,⁵ thus, also stable data. The output of the merge process (that is also relaxed) is a set of newly consolidated base pages (also referred to as merged pages) with in-page lineage information that are read-only, compressed, and almost up-to-date, thus, stable data. To decouple users’ transactions (writers) from the merge process, we also ensure that the write path of the ongoing transactions does not overlap with the write path of the merge process. Writers append new uncommitted tail records to tail pages, but as stated before uncommitted records do not participate in the merge. Writers also perform in-place update of the *Indirection* column within base records to point to the latest version of the updated records in tail pages, but the *Indirection* column is not modified by the merge process. In contrast, the write path of the merge process consists of creating only a new set of read-only base pages.

Merge Algorithm The details of the merge algorithm, conceptually resembling the standard left-outer join, consists of (1) identifying a set of committed tail records in tail pages; (2) loading the corresponding outdated base pages; (3) consolidating the base and tail pages while maintaining the in-page lineage; (4) updating the page directory; and (5) de-allocating the outdated base pages. The pseudo code for the merge is shown in Algorithm 1, where each of the five mentioned steps are also highlighted.

Step 1: Identify committed tail records in tail pages: Select a set of consecutive fully committed tail records (or pages) since the last merge within each update range.

Step 2: Load the corresponding outdated base pages: For a selected set of committed tail records, load the corresponding outdated base pages for the given update range (limit the load to only outdated columns). This step can further be optimized by avoiding to load sub-ranges of records that have not yet changed since the last merge. No latching is required when loading the base pages.

Step 3: Consolidate the base and tail pages: For every updated column, the merge process will read n outdated base pages and applies a set of recent committed updates from the tail pages and writes out m new pages.⁶ First the Base RID column of the committed tail pages (from Step 1) are scanned in reverse order to find the list of the latest version of every updated record since the last merge (a temporary hashtable may be used to keep track whether the latest version of a record is seen or not). Subsequently, applying the latest tail records in a reverse order to the base records until an update to every record in the base range is seen or the list is exhausted, skipping any intermediate versions for which a newer update exists in the selected tail records. If a latest tail record indicates the deletion of the record, then the deleted record will be included in the consolidated records. The merged pages will keep track of the lineage information in-page, i.e., tracking

⁴The *Indirection* column is the only column that undergoes in-place update that also never participates in the merge process.

⁵Note that not every committed update has to be applied as the merge process is relaxed, and the merge eventually process all committed tail records.

⁶At most up to one merged page per column could be left underutilized for a range of records after the merge process. To further reduce the underutilized merged pages, one may define finer range partitioning for updates (e.g., 2^{12} records), but operate merges at coarser granularity (e.g., 2^{16} records). This will provide the benefit of locality of access for readers given smaller range size of 2^{12} , yet it provides a better space utilization and compression for newly created merge pages when larger ranges are chosen (cf. Section 4.3).

Algorithm 1: Merge Algorithm

```

Input      : Queue of unmerged committed tail pages (mergeQ)
Output    : Queue of outdated and consolidated base pages to be deallocated
              (deallocateQ)

1 while true do
2   // Step 1
3   // wait until the the concurrent merge queue is not empty
4   if mergeQ is not empty then
5     // Step 2
6     // fetch references to a set of committed tail pages
7     batchTailPage ← mergeQ.dequeue()
8     // create a copy of corresponding base pages
9     batchConsPage ← batchTailPage.getBasePageCopy()
10    decompress(batchConsPage)
11    // track if it has seen the latest update of every record
12    HashMap seenUpdatesH
13    //reading a set of tail pages in reverse order
14    // Step 3
15    for i = 0; i < batchTailPage.size; i ← i + 1 do
16      tailPage ← batchTailPages[i]
17      for j = k - 1; j ≥ tailPage.size; j ← j - 1 do
18        record[j] ← jth record in the tailPage
19        RID ← record[j].RID
20        if seenUpdatesH does not contain RID then
21          seenUpdatesH.add(RID)
22          // copy the latest version of record into consolidated pages
23          batchConsPage.update(RID, record[j])
24        end
25        if all RIDs OR all tail pages are seen then
26          compress(batchConsPage)
27          persist(batchConsPage)
28          stop examining remaining tail pages
29        end
30      end
31    end
32    // Step 4
33    // fetch references to the corresponding base pages
34    batchBasePage ← batchTailPage.getBasePageRef()
35    // update page directory to point to the consolidated base pages
36    PageDirect.swap(batchBasePage, batchConsPage)
37    // Step 5
38    // queue outdated pages for deallocation once readers prior merge are drained
39    deallocateQ.enqueue(batchBasePage)
40  end
41 end

```

how many tail records have been consolidated thus far. Any compression algorithm (e.g., dictionary encoding) can be applied on the consolidated pages (on column basis) followed by writing the compressed pages into newly created pages. Moreover, the old Start Time column is remained intact during the merge process because this column is needed to hold the original insertion time of the record.⁷ Therefore, to keep track of the time for the consolidated records, the Last Updated Time column is populated to store the Start Time of the applied tail records. The Schema Encoding column may also be populated during the merge to reflect all the columns that have been changed for each record.

Step 4: Update the page directory: The pointers in the page directory are updated to point to the newly created merged pages. Essentially this is the only foreground action taken by the merge process, which is simply to swap and update pointers in the page directory – an index structure that is updated rarely only when new pages are allocated.

Step 5: De-allocate the outdated base pages: The outdated base pages are de-allocated once the current readers are drained naturally via an epoch-based approach. The epoch is defined as a time window, in which the outdated base pages must be kept around as long as there is an active query that started before the merge process. Pointers to the outdated base pages are kept in a queue to be re-claimed at the end of the query-driven epoch-window. The pointer swapping and the page de-allocation are illustrated in Figure 4. ■

⁷The Start Time column is also highly compressible column with a negligible space overhead to maintain it.

RID	Indirection	Schema Encoding	Start Time	Last Updated Time	Key	A	B	C
Partitioned base records for the key range of k_1 to k_3 ; Tail-page Sequence Number (TPS) = 0								
b_1	t_8	0000	10:02		k_1	a_1	b_1	c_1
b_2	t_5	0101	13:04		k_2	a_2	b_2	c_2
b_3	t_7	0001	15:05		k_3	a_3	b_3	c_3
Relevant tail records (below TPS $\leq t_7$ high-watermark) for the key range of k_1 to k_3								
t_5	t_4	0101	19:25		\emptyset	a_{22}	\emptyset	c_{21}
t_7	t_6	0001	19:45		\emptyset	\emptyset	\emptyset	c_{31}
Resulting merged records for the key range of k_1 to k_3 ; TPS = t_7								
b_1	t_8	0000	10:02	10:02	k_1	a_1	b_1	c_1
b_2	t_5	0101	13:04	19:25	k_2	a_{22}	b_2	c_{21}
b_3	t_7	0001	15:05	19:45	k_3	a_3	b_3	c_{31}

Table 2: An example of the relaxed and almost up-to-date merge procedure (conceptual tabular representation).

An example of our merge process is shown in Table 2 based on our earlier update example, in which we consolidate the first seven tail records (denoted by t_1 to t_7) with their corresponding base pages. The resulting merged pages are shown, where the affected records are highlighted. Note that only the updated columns are affected by the merge process (and the *Indirection* column is not affected). Furthermore, not all updates are needed to be applied, only the latest version of every updated record needs to be consolidated while the other entries are simply discarded. In our example, only the tail records t_5 and t_7 participated in the merge, and the rest were discarded.

Merge Correctness Analysis A key distinguishing feature of our lineage-based storage architecture is to allow contention-free merging of tail and base pages without interfering with concurrent transactions. To formalize our merge process, we prove that merge operates only on stable data while maintaining in-page lineage without any information loss and that the merge does not limit users’ transactions to access and/or modify the data that is being merged.

LEMMA 4.1. *Merge operates strictly on stable data.*

PROOF. By construction, we enforced that merge “always operate on stable data”. The inputs to the merge process are (1) a set of base pages consisting of committed base records that are read-only, i.e., stable data and (2) a set of consecutive committed tail records in tail pages, thus, also stable data. The output of the merge process is a set of newly merged pages that are read-only, i.e., stable data as well. Hence, the merge process strictly takes as inputs stable data and produces stable data as well. \square

LEMMA 4.2. *Merge safely discards outdated base pages without violating any query’s snapshot.*

PROOF. In order to support snapshot isolation semantics and time travel queries, we need to ensure that earlier versions of records that participate in the merge process are retained. Since we never perform in-place updates and each update is transformed into appending a new version of the record to tail pages, then as long as tail pages are not removed, we can ensure that we have access to every updated version. But recall that outdated base pages are de-allocated using our proposed epoch-based approach after being merged. Also note that base pages contain the original values of when a record was first created. Therefore, any original values that later were updated must be stored before discarding outdated base pages after a merge is taken place. In another words, we must ensure that outdated base pages are discarded safely.

As a result, the two fundamental criteria, namely, relaxing the merge (i.e. constructing an almost up-to-date snapshot) and operating on stable data, are not sufficient to ensure the *safety property* of the merge. The last missing piece that enables safety of the merge is accomplished by taking a snapshot of the original values when a column is being updated for the first time (as described in Section 3). In other words, we have further strengthened our *data stability* criterion by ensuring even *stability in the committed history*. Hence, outdated base pages can be safely discarded without any information loss, namely, the merge process is safe. \square

RID	Indirection	Schema Encoding	Start Time	Last Updated Time	Key	A	B	C

Table 3: An example of the indirection interpretation and lineage tracking (conceptual tabular representation).

THEOREM 4.3. *The merge process and users’ transactions do not contend for base and tail pages or the resulting merged pages, namely, the merge process is contention-free.*

PROOF. As part of ensuring contention-free merge, we have already shown that merge operates on stable data (proven by Lemma 4.1) and that there is no information loss as a result of the merge process (proven by Lemma 4.2). Next we prove that the write path of the merge process does not overlap with the write path of users’ transactions (i.e., writers). Recall that writers append new uncommitted tail records to tail pages, but as stated before, uncommitted records do not participate in the merge. Writers also perform in-place update of the *Indirection* column within base records to point to the latest version of the updated records in tail pages, but the *Indirection* column is not modified by the merge process. In contrast, the write path of the merge process consists of creating only a new set of read-only merged pages and eventually discarding the outdated base pages safely.

Therefore, we must show that safely discarding base pages does not interfere with users’ transactions. In particular, as explained in Lemma 4.2, if the original values were not written to tail records at the time of the update, then during the merge process, we were forced to store them somewhere or encounter information loss. It is not even clear where would be the optimal location for storing the original values. A simple minded approach of just adding them to tail pages would have broken the linear order of changes to records such that the older values would have appeared after the newer values, and it would have interfered with the ongoing update transactions. But, more importantly, the need to store the old values at any location would have implied that during the merge process multiple coordinated actions were required to ensure consistency across modification to isolated locations; hence, breaking the contention-free property of the merge. Therefore, by storing the original updated values at the time of update, we trivially eliminate all the potential contention during the merge process in order to safely discarding outdated base pages.

As a result, users’ transactions are completely decoupled from the merge process, and users’ transactions and the merge process do not contend over base, tail, or merged pages. \square

4.2 Maintaining In-Page Lineage

The lineage of each base page and consequently merged pages is maintained within each page independently as a result of the merge process. In-page lineage information is instrumental to decouple the merge and update operations and to allow independent merging of the different columns of the same record at different points in time. In-page lineage information is captured using a rather simple and elegant concept, which we refer to as *tail-page sequence number (TPS)* in order to keep track of how many updated entries (i.e., tail records) from tail pages have been applied to their corresponding base pages after a completion of a merge.

Original base pages always start with TPS set to 0, a value that is monotonically increasing after every merge. Again to ensure this monotonicity property, as stressed earlier, always a consecutive set of committed tail records are used in the merge process.

TPS is also used to interpret the indirection pointer (also a monotonically increasing value) by readers after the merge is taken place. Consider our running example in Table 2. After the first merge process, the newly merged pages have TPS set to 7, which implies that the first seven updates (tail records t_1 to t_7) in the tail pages have been applied to the merged pages. Consider the record b_2 in the base pages that has an indirection value pointing to t_5 (cf. Table 2), there are two possible interpretations. If the transaction is reading the base pages with TPS set to 0, then the 5^{th} update has not yet reflected on the base page. Otherwise if the transaction is reading the base pages with TPS 7, then the update referenced by indirection value t_5 has already been applied to the base pages as seen in Table 2. Notably, the *Indirection* column is updated only in-place (also a monotonically increasing value) by writers, while merging tail pages does not affect the indirection value.

More importantly, we can leverage the TPS concept to ensure read consistency of users' transactions when the merge is performed lazily and independently for the different columns of the same records. Therefore, when the merge of columns is decoupled, each merge occurs independently and at different points in time. Consequently, not all base pages are brought forward in time simultaneously. Additionally, even if the merge occurs for all columns simultaneously, it is still possible that a reader reads base pages for the column A before the merge (or during the merge before the page directory is updated) while the same reader reads the column C after the merge; thus, reading a set of inconsistent base and merged pages.

LEMMA 4.4. *An inconsistent read with concurrent merge is always detectable.*

PROOF. Since each base page independently tracks its lineage, i.e., its TPS counter; therefore, TPS can be used to verify the read consistency. In particular, for a range of records, all read base pages must have an identical TPS counter; otherwise, the read will be inconsistent. Hence, an inconsistent read across different columns of the same record is always detectable. \square

THEOREM 4.5. *Constructing consistent snapshots with concurrent merge is always possible.*

PROOF. As proved in Lemma 4.4, the read inconsistency is always detectable. Furthermore, once a read inconsistency is encountered, then each page is simply brought to the desired query snapshot independently by examining its TPS and the indirection value and consulting the corresponding tail pages using the logic outlined earlier. Hence, consistent reads by constructing consistent snapshots across different columns of the same record is always possible. \square

TPS, or an alternative but similar counter conceptually, could be used as a high-water mark for resetting the cumulative updates as well. Continuing with our running scenario, in which we have the original base pages with the TPS 0 (as shown in Table 2), the merged pages with the TPS 7 (as shown in Table 3). For simplicity, we assume the cumulation was also reset after the 7^{th} tail record. For the record b_2 , we see that the indirection pointer is t_{12} , for which we know that the cumulative update has been reset after the 7^{th} update. This means that the tail record t_{12} does not carry updates that were accumulated between tail records 1 to 7. Suppose that the record was updated four times, where the update entries in the tail pages are 3^{rd} , 5^{th} , 10^{th} , and 12^{th} tail records. The tail record t_5 is a cumulative and carries the updated

values from the tail record t_3 . However, the tail record t_{10} is not cumulative (reset occurred at the 8^{th} update), whereas the tail record t_{12} is cumulative, but carries updates only from the tail record t_{10} and not from t_5 and t_3 . Suppose that a transaction is reading the base pages with the TPS 0, then to reconstruct the full version of the record b_2 , it must read both the tail records t_5 and t_{12} (while skipping 3^{rd} and 10^{th}). But if a transaction is reading from the merged pages with the TPS 7, then it is sufficient to only read the tail record t_{12} to fully reconstruct the record because the 3^{rd} and 5^{th} updates have already been applied to the merged pages.

4.3 Record Partitioning Trade-offs

When choosing the range of records for partitioning (i.e., update range) there are several dimensions that needs to be examined. An important observation is that regardless of the range size, recent updates to tail pages will be memory resident and no random disk I/O is required. This trend is supported by continued increase in the size of main memory and the fact that the entire OLTP database is expected to fit in the main memory [9, 17].

In our evaluation, we did an in-depth study of the impact of the range size, and we observed that the key deciding factor is the frequency at which the merges are processed. How frequent a merge is initiated is proportional to how many tail records are accumulated before the merge process is triggered. We further experimentally observed that the update range sizes in the order of 2^{12} to 2^{16} exhibit a superior overall performance vs. data fragmentation depending on the workload update distribution. Because for a smaller update range size, we may have many corresponding half-filled tail pages, but as the range size increases, the cost of half-filled tail pages are amortized over a much larger set of records.⁸ Furthermore, the range size affects the clustering of updates in tail pages. For larger the range size, it is more likely that cache misses occur when scanning the recent update that are not merged yet. Again, considering that recent cache sizes are in order of tens of megabytes, the choice of any range value between 2^{12} to 2^{16} is further supported. As noted before, one may choose a finer range partitioning for handling updates (i.e., update range), e.g., 2^{12} , to improve locality of access while choosing coarser virtual range sizes when performing merges, essentially forcing the merge to take-in as input a set of consecutive update ranges that have been updated, e.g., choosing 2^4 consecutive 2^{12} ranges in order to merge $2^{12} \times 2^4 = 2^{16}$ records.

For example, suppose the scan operation (even if there are concurrent scans) may access 2 columns, assume each column is 2^3 bytes long. We further assume that the merge can keep up, namely, even for 2^{16} update range size, the number of tail records yet to be merged is less than 2^{16} (as shown in Section 6, such merging rate can be achieved while executing up to 16 concurrent update transactions). The overall scan footprint (combining both base pages and tail pages) is approximately $2^{16} \times 2^3 \times 2 \times 2 = 2^{21}$ (2 MB), which certainly fits in today's processor cache (in our evaluation, we used Intel Xeon E5-2430 processor, which has 15 MB cache size). Thus, even as scanning base records, if one is forced to perform random lookup within a range of 2^{16} tail records, the number of cache misses are limited compared to when the range size was beyond the cache capacity.

Another criteria for selecting an effective update range size is the need for RID allocation. In L-Store, upon the first update to a range of records (e.g., 2^{12} to 2^{16} range), we pre-allocate 2^{12} to 2^{16} unused RIDs for referencing its corresponding tail pages. Tail RIDs are special in a sense they are not added to indexes and no unique constraint is applied on them. Once the tail RID range is

⁸To reduce space under-utilization, tail pages could be smaller than base pages, for instance, tail pages could be 4 KB while base pages are 32 KB or larger.

fully used, then either a new unused RID range is allocated or an existing underutilized tail RID range can be re-assigned (partially used RID range must satisfy TPS monotonicity requirement). Furthermore, in order to avoid overlapping the base and tail RIDs, one could assign tail RIDs in the reverse order starting from 2^{64} ; therefore, tail RIDs will be monotonically decreasing, and the TPS logic must be reversed accordingly. The benefit of reverse assignment is that while scanning page directory for base pages, there is no need to first read and later skip tail page entries (read optimization).

5 FAST TRANSACTIONAL CAPABILITIES

In order to support concurrent transactions where each transaction may consist of many statements, any database engine must provide necessary functionalities to ensure the correctness of concurrent reads and writes of the shared data. Furthermore, transaction logging is required in order to recover the system from crash and media failure. In this section, we focus on low-level synchronization protocol and logging requirements. In terms of concurrency protocol for transaction processing, any existing protocols can be leveraged because L-Store primarily focuses on the storage architecture. In particular, we relied on our recently proposed optimistic concurrency model in [32] that supports full ACID properties for multi-statement transactions, and we also employed the speculative reads proposed in [18]. The details of the concurrency protocol is presented in our technical report [31].

Low-level Synchronization Protocol In terms of low-level latching, our lineage-based storage has a set of unique benefits, namely, readers do not have to latch the read-only base pages or fully committed tail pages. Also there is no need to latch partially committed tail pages when accessing committed records. More importantly, writers never modify base pages (except the *Indirection* column) nor the fully committed tail pages, so no latching is required for stable pages. The *Indirection* column is at most 8-byte long; therefore, writers can simply rely on atomic compare-and-swap (CAS) operators to avoid latching the page.

As part of the merge process, no latching of tail and base pages are required because they are not modified. The only latching requirement for the merge is updating the page directory to point to the newly created merged pages. Therefore, every affected page in the page directory are latched one at a time to perform the pointer swap or alternatively atomic CAS operator is employed for each entry (pointer swap) in the page directory. Alternatively, the page directory can be implemented using latch-free index structures such as Bw-Tree [20].

Recovery and Logging Protocol Our lineage-based storage architecture consists of read-only base pages (that are not modified) and append-only updates to tail pages (which are not modified once written). When a record is updated, no logging is required for base pages (because they are read-only), but the modified tail pages requires redo logging. Again, since we eliminate any in-place update for tail pages, no undo log is required. Upon a crash, the redo log for tail pages are replayed, and for any uncommitted transactions (or partial rollback), the tail record is marked as invalid (e.g., tombstone), but the space is not reclaimed until the compression phase.

The one exception to above rule for logging and recovery is the *Indirection* column, which is updated in-place. There are two possible recovery options: (1) one can rely on standard undo-redo log for the *Indirection* column only or (2) one can simply rebuild the *Indirection* column upon crash. The former option can further be optimized based on the realization that tail pages undergo strictly redo policy and aborted transactions do not physically remove the aborted tail records as they are only marked as tombstones. Therefore, it is acceptable for the *Indirection* column to continue pointing to tombstones, and from the tombstones finding the latest

committed values. As a result, even for the *Indirection* column only the redo log is necessary. For the latter recovery option, as discussed earlier, to speedup the merge process, we materialize the *Base RID* column in tail records that can be used to populate the *Indirection* column after the crash. Alternatively, even without materializing an additional RID column, one can follow back-pointers in the *Indirection* column of tail records to fetch the base RID because the very first tail record always points back to the original base record.

The merge process is idempotent because it operates strictly on committed data and repeated executions of the merge always produce the exact same results given a set of base pages, their corresponding tail pages, and a merge threshold that dictates how many consecutive committed tail records to be used in the merge process. Therefore, only operational logging is required for the merge process. Also updating the entries in the page directory upon completion of the merge process simply requires standard index logging (both undo-redo logs). If crash occurs during the merge, simply the partial merge results can be ignored and the merge can be restarted.

6 EXPERIMENTAL EVALUATION

In order to study the impact of high-throughput transaction processing in the presence of long-running analytical queries, we carried out a comprehensive set of experiments. These experiments were performed using an existing micro benchmark proposed in [18, 32], i.e., a comprehensive transactional YCSB-like benchmark [8], for the sake of a fair comparison and evaluation. This benchmark allows us to study different storage architectures by narrowing down the impact of concurrency with respect to the active data set by adjusting the degree of contention between readers and writers.

6.1 Experimental Setting

We evaluate the performance of various aspects of our real-time OLTP and OLAP system. Our experiments were conducted on a two-socket Intel Xeon E5-2430 @ 2.20 GHz server that has 6 cores per socket with hyper-threading enabled (providing a total of 24 hardware threads). The system has 64 GB of memory and 15 MB of L3 cache per socket. We implemented a complete working prototype of L-Store and compared it against two different techniques, (i) In-place Update + History and (ii) Delta + Blocking Merge, which are described subsequently. The prototype was implemented in Java (using JDK 1.7). Our primary focus here is to simultaneously evaluate read and write throughputs of these systems under various transactional workloads concurrently executed with long-running analytical queries, which is the key characteristic of any real-time OLTP and OLAP system.

Our employed micro benchmark defined in [18, 32] consists of three key types of workloads: (1) low contention, where the active set is 10M records; (2) medium contention, where the active set is 100K records; and (3) high contention, where the active set is 10K records. It is important to note that the data size is not limited to the active set and can be much larger (millions or billions of records). Similar to [18, 32], we consider two classes of transactions. (1) *Read-only transactions* executed under snapshot isolation semantics that scan up to 10% of the data to model TPC-H style analytical queries. (2) *Short update transactions* executed under committed read semantics to model TPC-C and TPC-E transactions, in which each *short update transaction* consists of 8 read and 2 write statements over a table schema with 10 columns. In addition, we vary the ratio of read/writes in these update transactions to model different customer scenarios with different read/write degrees. By default, transactional throughput of these schemes are evaluated while running (at least) one scan thread and one merge thread to create the real-time OLTP

Figure 5: Scalability under varying contention level.

and OLAP scenario. Unless stated explicitly, the percentage of reads and writes in the transactional workload is fixed at 80% and 20%, respectively. On average 40% of all columns are updated by the writers. Lastly, the page size is set to 32 KB for both base and tail pages because a larger page size often results in a higher compression ratio suitable for analytical workloads [13].

Next we describe the two techniques that are compared with L-Store. We point out the primary features of these techniques and describe it with respect to L-Store. For fairness, across all techniques, we have maintained columnar storage, maintained a single primary index for fast point lookup, and employed the embedded-indirection column to efficiently access the older/newer versions of the records. Additionally, logging has been turned off for all systems as logging could easily become the main bottleneck (unless sophisticated logging mechanisms such as group commits and/or enterprise-grade SSDs are employed). In the In-place Update + History technique, we are required to write both redo-undo logs for all updates while for L-Store and Delta + Blocking Merge only redo log is needed due to their append-only scheme.

In-place Update + History (IUH): A prominent storage organization is to append old versions of records to a history table and only retain the most recent version in the main table, updating it in-place. Such table organization is motivated by commercial systems such as [26]; thus, our In-place Update + History is inspired by such table organization that avoids having multiple copies and representations of the data. However, due to the nature of the in-place update approach, each page requires standard shared and exclusive latches that are often found in major commercial big data systems. In addition to the page latching requirement, if a transaction aborts, then the update to the page in the main table is undone, and the previous record is restored. Scans are performed by constructing a consistent snapshots, namely, if records in the main table are invisible with respect to query’s read time, then the older versions of the records are fetched from the history table by following the indirection column. In our implementation of In-place Update + History, we also ignored other major costs of in-place update over the compressed data, in which the new value may not fit in-place due to compression and requires costly page splits or shifting data within the page as part of update transactions. We further optimized the history table to include only the updated columns as opposed to inserting all columns naively.

Delta + Blocking Merge (DBM): This technique is inspired by [14], where it consists of a main store and a delta store, and undergoes a periodic merging and consolidation of the main and delta stores. However, the periodic merging requires the draining of all active transactions before the merge begins and after the merge ends. Although the resulting contention of the merge appears to be limited to only the boundary of the merge for a short duration, the number of merges and the frequency at which this merge occurs has a substantial impact on the overall performance. We optimized the delta store implementation to be columnar and included only the updated columns [27]. Additionally, we applied our range partitioning scheme to the delta store by dedicating a separate delta store for each range of records to further reduce the cost of merge operation in presence of data skew. The partitioning

	L-Store	IUH	DBM
Scan Performance (in secs.)	0.24	0.28	0.38

Table 4: Scan performance for different systems.

allow us to avoid reading and writing the unchanged portion of the main store.

6.2 Experimental Results

In what follows, we present our comprehensive evaluation results in order to compare and study our proposed L-Store with respect to state-of-the-art approaches.

Scalability under contention: In this experiment, we show how transaction throughput scales as we increase the number of update transactions, in which each update transaction is assigned to one thread. For the scalability experiment, we fix the number of reads to 8 and writes to 2 for each transaction against a table with active set of $N = 10$ million rows. Figure 5(a) plots the transaction throughput (y-axis) and the number of update threads (x-axis). Under low contention, the throughput for L-Store and In-place Update + History scales almost linearly before data is spread across the two NUMA nodes. The Delta + Blocking Merge approach however does not scale beyond a small number of threads due to the draining of active transaction before/after of each merge process, which brings down the transaction throughput noticeably. With increasing number of threads, the number of merges and the draining of active transactions become more frequent, which reduces the transaction throughput significantly. The In-place Update + History approach has lower throughput compared to L-Store due to the exclusive latches held for data pages that block the readers attempting to read from the same pages. The presence of a single history table also results in reduced locality for reads and more cache misses.

In addition, we study the impact of increasing the degree of contention by varying the size of the active set. For a fixed degree of contention, we vary the number of parallel update transactions from 1 to 22. For both medium contention (Figure 5(b)) and high contention (Figure 5(c)), we observe that L-Store consistently outperforms the In-place Update + History and Delta + Blocking Merge techniques as the number of parallel transactions is increased. For medium contention, we observed a speedup of up to 5.09 \times compared to the In-place Update + History technique and up to 8.54 \times compared to the Delta + Blocking Merge technique. Similarly for high contention, we observed up to 40.56 \times and 14.51 \times speedup with respect to the In-place Update + History and Delta + Blocking Merge techniques, respectively. The greater performance gap is attributed to the fact that in In-place Update + History, latching contention on the page is increased that is altogether eliminated in L-Store. In Delta + Blocking Merge, since the active set is smaller, and all updates are concentrated to smaller regions, the merging frequency is increased, which proportionally reduces the overall throughput due to the constant draining of all active transactions. Finally, due to the smaller active set sizes in the medium- and high-contention workloads, the cache misses are also reduced as the cache-hit ratio increases. As a consequence, the transaction throughput also increases proportionately.

Scan Scalability: Scan performance is an important metric for real-time OLTP and OLAP systems because it is the basic building block for assembling complex ad-hoc queries. We measure the

Figure 6: Scan performance.

scan performance of L-Store by computing the SUM aggregation on a column that is continuously been updated by the concurrent update transactions. Thus, the goal of this experiment is to determine whether the merge can keep up with high-throughput OLTP workloads. As such, this scenario captures the worst-case scan performance because it may be necessary for the scan thread to search for the latest values in the merged page or tail pages when the merge cannot cope with the update throughput. For columns which do not get updated, the latest values are available in the base page itself, as described before. In this experiment (Figure 6), we study the single-threaded scan performance with one dedicated merge thread. We vary the number of tail records (M) that are processed per merge (x -axis) and observe the corresponding scan execution time (y -axis) while keeping the range partitioning fixed at 64K records. We repeat this experiment by fixing the number of update threads to 4 and 16, respectively. In general, we observe that as we increase M , the scan execution time decreases. The main reasoning behind this observation is that the scan thread visits tail pages for the latest values less often because the merge is able to keep up. However, for the smaller values of M , the merge is triggered more frequently and cannot be sustained. Additionally, the overall cost of the merge is increased because the cost of merge is amortized over fewer tail records while still reading the entire range of 64K base records. Notably, if we delay the merge by accumulating too many tail records, then there is slight deterioration in performance. Therefore, it is important to balance the merge frequency vs. the amortization cost of the merge for the optimal performance, which based on our evaluation, it is when M is set to around 50% of the range size.

We also compare the single-threaded scan performance (for low contention and 4K range size) of L-Store with the other two techniques in the presence of 16 concurrent update threads (as shown in Table 4). Our technique outperforms the In-place Update + History and Delta + Blocking Merge techniques by 14.28% and 36.84%, respectively. It is important to note that smaller update range sizes, namely, assigning separate tail pages for each 4K base records instead of 64K base records, increases the overall scan performance by improving the locality of access within tail pages. Therefore, as elaborated previously in Section 4.3, it is beneficial to apply (virtual) fine-grained partitioning over base records (e.g., 4K records) to handle updates in order to improve locality of access within tail pages while applying (virtual) coarser-grained partitioning (e.g., 64K records) when performing the merge in order to reduce the space fragmentation in the resulting merged pages.

Impact of varying the workload read/write ratio: Short update transactions update only a few records. A typical transactional workload comprises of 80% read statements and 20% writes [18]. However, our goal is to explore the entire spectrum from a read-intensive workload (read/write ratio 10:0) to a write-intensive workload (read/write ratio 0:10) while fixing the number of update threads to 16. Figure 7(a) shows transaction throughput (y -axis) as the ratio of read-only transactions varies in the workload (x -axis) with low contention. As expected, the performance of all the schemes increases as we increase the ratio of reads in the transactions because contention is a function of writes. As we have more writes in the workload, In-place Update + History technique suffers from increased contention as acquiring read latches

Figure 7: Impact of varying the read/write ratio of short update transactions.

conflict with the exclusive latches resulting in an extended wait time. The performance of the Delta + Blocking Merge technique also exacerbates since increasing the number of writes increases the number of merges performed. This brings down the performance further due to frequent halt of the system while draining active transactions. However, note that the gap between all of the schemes is the least when the workload consists of 100% reads. In summary, the speedup obtained with respect to In-place Update + History is up to 1.45 \times and up to 5.78 \times with respect to Delta + Blocking Merge technique. Note, even for 100% read, In-place Update + History continues to pay the cost of acquiring read latches on each page.

We repeat the same experiment but restrict the active set size to 100K rows (Figure 7(b)). L-Store significantly outperforms the other techniques across all workloads while varying the read/write ratio. But the performance gap is similar with respect to the low contention scenario when there are no update statements in the workload. The speedup obtained compared to In-place Update + History and Delta + Blocking Merge techniques is up to 4.19 \times and up to 6.34 \times respectively.

Impacts of long-read transactions: As mentioned previously, it is not uncommon to have long-running read-only transactions in real-time OLTP and OLAP systems. These analytical queries touch a substantial part of the data compared to the short update transactions, and the main goal is to reduce the interference between OLTP and OLAP workloads. In this experiment, we investigate the performance of the different schemes in the presence of these long-running read-only transactions, which on an average touch 10% of the base table. We fix the number of concurrent active transactions to 17 while increasing the number of concurrent read-only transactions from 1 to 16 (the short transactions simultaneously vary from 16 to 1). We also allocated a single merge thread for L-Store and Delta + Blocking Merge. Figures 8(a)-8(b) represent the scenario for a low contention workload, while Figures 8(c)-8(d) represent the scenario for medium contention.

We observe that for both low and medium contention, there is an increase in throughput for both long-read transactions and short update transactions when the number of threads are increased. Moreover, the performance of read-only transaction increases for the medium contention scenario for all the techniques as the updates are restricted to a small portion of the data resulting in a higher read throughput. In other words, majority of the read-only transactions touch portions of the data in which updates do not take place resulting in higher throughput. For read-only transactions, our technique outperforms Delta + Blocking Merge up to 1.97 \times and 2.37 \times for low and medium contention workloads, respectively. For short update transactions, we outperform In-place Update + History and Delta + Blocking Merge by at most 5.37 \times and 7.91 \times , respectively, for medium-contention workload. In the earlier experiments, we had demonstrated that L-Store outperforms other leading approaches for update-intensive workloads, and in this experiment, we further strengthen our claim that L-Store substantially outperforms the leading approaches in the mixed OLTP and OLAP workload as well, the latter is due to our novel contention-free merging that does not interfere with the OLTP portion of the workload.

Impacts of comparing row vs. columnar layouts We revisit the scan and point query performance while considering both row

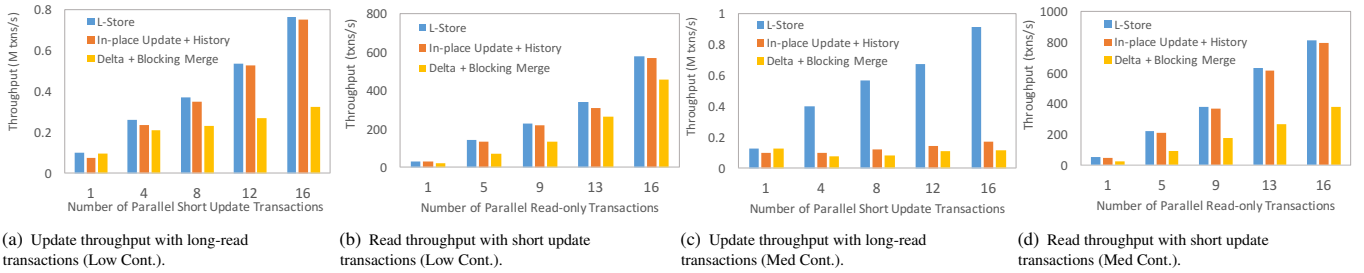

Figure 8: Impact of varying the number of short update vs. long read-only transactions.

Scan Performance without updates (in secs.)	0.043	0.196
Scan Performance with updates (in secs.)	0.24	0.66

Table 5: Scan performance based on row vs. columnar layouts.

	10% of Columns	20%	40%	80%	All Columns
L-Store (Column)	1.46	1.35	1.17	1.08	0.98
L-Store (Row)	1.45	1.45	1.45	1.45	1.45

Table 6: Point query performance vs. percentage of columns read (M txns/second).

	Lineage-based	Log-structured
Update throughput (16 threads) with 1 scan thread	0.76M txns/sec	0.15M txns/sec
Scan performance (in sec) with update txns (16 threads)	0.24	0.63

Table 7: Update/Scan performance of lineage-based vs. log-structured storage architecture.

and columnar storage layouts. To enable this comparison, we additionally developed a variation of our L-Store prototype using row-wise storage layout, which we refer to as L-Store (Row).⁹ In particular, we compared the single-threaded scan performance (for low contention and 4K range size) of L-Store using both row and columnar layouts in the presence of when there is no updates or when there are 16 concurrent update threads (as shown in Table 5). As expected, the scan performance of L-Store (Column) is substantially higher than L-Store (Row) by a factor of 2.75 \times and 4.56 \times , with and without updates, respectively. Also note that we did not enable column compression for L-Store (Column), otherwise even a higher performance gap would be observed because in column stores, an average of 10 \times compression is commonly expected [5, 36].

We further conducted an experiment with only point queries (on a table with 10 columns), where each transaction now consists of 10 read statements, and each read statement may read 10% to 100% of all columns (as shown in Table 6). As expected, the performance of any column store is deteriorated as more columns are fetched. When reading only 10-20% of columns, L-Store (Column) exhibit a comparable throughput as L-Store (Row); however, as we increase the number of fetched columns, the throughput is decreased. But, even in the worst case when all columns are fetched, the throughput only drops by 33%. However, the prevalent observation is that rarely all columns are read or updated in either OLTP or OLAP workloads [1, 5, 36]; thus, given the substantial performance benefit of columnar layout for predominant workloads, then it is justified to expect a slight throughput decrease in rare cases of when point queries are forced to access all columns.

Impacts of comparing lineage-based vs. log-structured storage architecture For completeness, in our prototype, we also implemented log-structured merge-tree (LSM) [25] storage architecture that is predominant in the distributed key-value stores. In particular, we have based our implementation on LevelDB [21]. In this experiment, we studied the single-threaded scan performance (for low contention) of L-Store (i.e., lineage-based storage architecture) and LSM while having 16 concurrent update threads (as shown in Table 7). As expected, due to the multi-layered structured of LSM, the fine-grained read/write access and scan performance

⁹Notably our proposed lineage-based storage architecture is not limited to any particular data layout; in fact, our technique can be employed even for non-relational data such as document or graph data.

of LSM are substantially lower than L-Store. As a result, L-Store outperforms LSM on update throughput and scan performance by a factor of 5 \times and 2.6 \times , respectively.

7 RELATED WORK

In recent years, we have witnessed the development of many in-memory engines optimized for OLTP workloads either as research prototypes such as HyPer [13, 24], ES2 [6], and ExpoDB [11] or for commercial use such as Microsoft Hekaton [9], Oracle In-Memory [15], VoltDB [38], and HANA [14, 27]. Most of these systems are designed to keep the data in row format and in the main memory to increase the OLTP performance. In contrast, to optimize the OLAP workloads, columnar format is preferred. The early examples of these engines are C-Store [36] and MonetDB [5]. Recently, major big data vendors also started integrating columnar storage format into their existing engines. SAP HANA [10] is designed to handle both OLTP and OLAP workloads by supporting in-memory columnar format. IBM DB2 BLU [29] introduces a novel columnar OLAP engine that is memory-optimized and substantially improves the execution of complex analytical workloads by operating directly on compressed data. In what follows, we shift our focus to the recent developments that aim to bring both OLTP and OLAP capabilities into the same platform.

HyPer, a powerful main-memory system, guarantees the ACID properties of OLTP transactions and supports running OLAP queries on consistent snapshot [13]. The design of HyPer leverages a novel OS-processor-controlled lazy copy-on-write mechanism enabling to create a consistent virtual memory snapshot. Unlike L-Store, HyPer resorts to running transactions serially when the workload is not partitionable. Notably, HyPer recently employed multi-version concurrency to close this gap [24]. IBM Wildfire is a variant of DB2 BLU [29] that is integrated into Apache Spark to support fast ingest by adopting the relaxed last-writer-wins semantics and offers an efficient snapshot isolation on recent, but stale, data by relying on periodic shipment and writing of the logs onto a distributed file system [4]. In the same spirit, BatchDB is based on primary-secondary replication design to efficiently isolate OLTP and OLAP workloads by relying on batch migration of recent updates and executing OLAP queries over recent (but possibly stale) snapshots [23]. The unified storage architecture in L-Store eliminates the need for classical log shipment design and does not restrict reads to stale snapshots. Elastic power-aware data-intensive cloud computing platform (epiC) was designed to provide scalable big data services on cloud [6]. epiC is designed to handle both OLTP and OLAP workloads [7]. However, unlike L-Store, the OLTP queries in ES2 are limited to basic get, put, and delete requests (without multi-statements transactional support). Furthermore, in ES2, it is possible that snapshot consistency is violated and the user is notified subsequently [6].

Microsoft SQL Server currently consists of three unique engines: the classical SQL Server engine designed to process disk-based tables in row format, the Apollo engine designed to maintain the data in columnar format that offers significant performance gain for OLAP workloads [19], and the completely redesigned Hekaton in-memory engine designed to excel at OLTP workloads [9, 17]. Noteworthy, Microsoft has also recently announced

moving towards supporting real-time OLTP and OLAP capabilities [17], which further reinforces our position to support real-time analytics. To support OLTP and OLAP among loosely integrated engines, an intricate foreground routine is proposed to enable a continuous data migration from Hekaton (a row-based engine) into Apollo (a columnar engine) [17]. In contrast, in L-Store, we rely on a single unified columnar engine (without the need for maintaining multiple copies of the data) and, more importantly, our consolidation is based on a novel contention-free merge process that is performed asynchronously and completely in the background, and the only foreground task is pointer swaps in the page directory for pointing to the newly created merged pages.

Oracle offers a novel dual-format option to support real-time OLTP and OLAP, where data resides in both columnar and row formats [15]. To avoid maintaining two identical copies of data in both columnar and row format, an effective “layout transparency” abstraction was introduced that maps data into a set of disjoint tiles (driven by the query workload and the age of data), where a tile could be stored in either columnar or row format [3]. The key advantage of the layout-transparent mapping is that the query execution runtime operates on the abstract representation (layout independent) without the need to create two different sets of operators for processing the column- and row-oriented data. In the same spirit, SnappyData proposed a unified runtime engine to combine streaming, transaction, and analytical processing, but from the storage perspective, it maintains recent transactional data in row format while it ages data to a columnar format for analytical processing [30]. SnappyData employed data aging strategies similar to the original version of SAP HANA [35].

Contrary to the aforementioned efforts, in L-Store, we strictly keep only one copy and one representation of data; thus, fundamentally eliminating the need to maintain layout-independent mapping abstraction and storing data in both columnar and row formats. HANA [14, 27] also strives to achieve real-time OLTP and OLAP engine. Most notably, we share the same philosophy governing HANA that aims to develop a generalized solution for unifying OLTP and OLAP as opposed to building specialized engines. But what distinguishes our architecture from HANA is that we propose a unified columnar storage without the need to distinguishing between a main store and a delta store. We further propose a contention-free merge process, whereas in [14], the merge process is forced to drain all active transactions at the beginning and end of the merge process, a contention that results in a noticeable slow down as demonstrated in our evaluation.

8 CONCLUSIONS

We develop Lineage-based Data Store (L-Store) to realize real-time OLTP and OLAP processing within a single unified engine. The key features of L-Store can succinctly be summarized as follows. Recent updates for a range of records are strictly appended and clustered in its corresponding tail pages to eliminate read/write contention, which essentially transforms costly point updates into an amortized, fast analytical-like update query. L-Store achieves (at most) 2-hop access to the latest version of any record through an effective embedded indirection layer. We introduce a novel contention-free and relaxed merging of only stable data in order to lazily and independently bring base pages (almost) up-to-date without blocking on-going and new transactions. Every base page relies on independently tracking the lineage information in order to eliminate all coordination and recovery even when merging different columns of the same record independently. Lastly, a novel contention-free page de-allocation using epoch-based approach is introduced without interfering with ongoing transactions. We demonstrate that L-Store outperforms In-place Update + History by factor of up to 5.37× for short update transactions while achieving slightly improved performance for scans. It also outperforms Delta

+ Blocking Merge by 7.91× for short update transactions and up to 2.37× for long-read analytical queries.

ABSTRACT

False alarms triggered by security sensors incur high costs for all parties involved. According to police reports, a large majority of alarms are false. Recent advances in machine learning can enable automatically classifying alarms. However, building a scalable alarm verification system is a challenge, since the system needs to: (1) process thousands of alarms in real-time, (2) classify false alarms with high accuracy and (3) perform historic data analysis to enable better insights into the results for human operators. This requires a mix of machine learning, stream and batch processing – technologies which are typically optimized independently. We combine all three into a single, real-world application.

This paper describes the implementation and evaluation of an alarm verification system we developed jointly with Sitasys, the market leader in alarm transmission in central Europe. Our system can process around 30K alarms per second with a verification accuracy of above 90%.

1 INTRODUCTION

False alarms triggered by sensors of alarm systems pose a significant challenge due to the high costs they incur for all involved parties. On the one hand, false alarms waste expensive police, medical and firefighter resources. On the other hand, Alarm Receiving Centers (ARCs) cannot efficiently prioritise important alarms, because they are overwhelmed with false ones. According to police reports, a large majority of alarms prove to be false [34]. This is often attributed to technical errors, installation errors or user errors. As a consequence, owners of alarm systems end up switching their systems off to avoid the risk of paying for intervention forces deployed as a response to a false alarm.

From a technical perspective, false alarm verification is very challenging, since it requires the combination of three traditionally separate fields, namely stream processing, batch processing and machine learning. Depending on the data sources used for verification, both structured data (originating from the physical security sensors) and unstructured (originating from external sources, such as social media or police news feeds, available in free-text format) should be integrated. Recently, stream and batch processing have been integrated into combined systems such as

Flink [7] or Apache Structured Streaming [44]. However, adding machine learning, unstructured data and a real use-case to the equation makes the problem much harder. Machine learning has proven successful in a wide range of classification and anomaly detection tasks [26]. In particular, a classification model can be trained in order to compute the likelihood that a new alarm is either true or false, based on the history of alarms previously received in the system. Such algorithms have the potential to significantly reduce costs involved by false alarms, by enabling ARCs to focus on the alarms that are most likely true, while reducing the priority and the resources allocated for alarms that are likely false.

In this paper we present our experience in building an end-to-end alarm verification system that combines stream processing, batch processing and machine learning on both structured and unstructured data in an industrial setting. We use state-of-the-art Big Data technology such as Apache Kafka [21], MongoDB [33] and Apache Spark [38]. We show that our models can classify false alarms with over 90% accuracy and can scale up to 30K alarms per second including historical analysis using real alarm data from our industrial partner. Furthermore, we show that our models can be adapted with minimal effort and achieve good performance for similar use cases. For example, we use the same algorithms to train a new model from the history of fire incidents recorded by the cities of London and San Francisco.

The main contributions of this paper are:

- We present an end-to-end application that combines stream processing, batch processing and machine learning in order to uncover false alarms in an industrial setting. Using a dataset of 350K real alarms from alarm sensors deployed in production, we evaluate 4 machine learning algorithms and show that the best 2 algorithms (random forest and deep neural networks) can classify alarms with over 90% accuracy. This is, to our knowledge, the first study to show the applicability of machine learning techniques for false alarm reduction in the field of physical security, using real data collected from alarm sensors used in production.
- We show that a simple set of generic alarm features (location, time, property type) can be used for similar use cases. By reusing the exact same algorithms implemented for our industrial use case, we yield a verification accuracy of above 80% for the additional datasets from the cities of London and San Francisco.

Distribution of this paper is permitted under the terms of the Creative Commons license CC-by-nc-nd 4.0.

- We discuss how to extend the approach to include a-priori risk factors extracted from external sources, such as news articles and social media postings, that potentially cover incidents related to alarms ("hybrid approach"). These sources usually provide unstructured, free-text data. In our prototype implementation, we focus on reports about fire and intrusion incidents. Even though we had only limited external data available, we increased the accuracy of our classifications from a baseline of 86.56% for the subset of fire and intrusion alarms to 87.56% when including the a-priori risk in the machine learning model.

The rest of this paper is organized as follows: We introduce Related Work in Section 2. In Section 3 we present the industrial use case for alarm management. We discuss the architecture as well as the design of our system in Section 4. We describe our experiments with various machine learning algorithms as well as end-to-end performance results based on stream processing, batch processing and machine learning in Section 5. Finally, we present an extensive list of lessons learned in Section 6 and conclude in Section 7.

2 RELATED WORK

2.1 Stream Processing

Stream and continuous event processing for real-time analytics has been a major topic of the database community for more than a decade with Aurora [9] being one of the pioneers. Other popular systems are Gigascope [13], Esper [16] or Stream Base [40]. Common to these systems is that they provide a declarative query language based on SQL to process data streams. The advantage of these systems is that end users can formulate analytics queries using the expressiveness of SQL rather than learning new APIs. Moreover, since SQL is declarative, the end-users need not care of how they would optimize the system performance since the stream systems can apply query optimization techniques by understanding the query patterns.

Common to all these systems is that they are highly specialized for one particular functionality, namely stream processing with short time windows. However, they are inadequate for combined stream and batch processing since they only focus on stream processing.

2.2 Real-time Data Warehousing

Typical data warehouses of large enterprises are used for reporting, analytical and predictive purposes. In order to optimize query performance, these systems organize data in a star schema [10]. Moreover, data is usually ingested on a daily or subdaily basis. Common to all traditional data warehouses is that they are very efficient for processing historical data but not particularly well suited for processing streams of data.

In order to overcome these problems, recently so-called data stream warehouses have been proposed to handle both big and fast amounts of data within one single system. In other words, the idea is to use one, combined system for stream and historical data analytics. Examples of such systems include Borealis [1], DataDepot [17], DejaVu [14], Moira [6] or TruViso [24].

The advantage of these systems over streaming-only systems is that they can handle combined workloads of both stream and batch processing.

2.3 Combined Stream and Batch Processing

As part of our previous work we have used bitmap indexes to enable stream and batch processing in TelegraphCQ [35]. We have demonstrated the approach for analyzing a large set of network traffic data.

To tackle the problem of combined stream and historical data analytics for more recent Big Data systems, the Lambda architecture [31] was introduced that currently sets the standard in system design for building big data real-time analytics environments. It is trying to provide a solution to compensate latency and waiting time when accessing and analyzing batch processed data through the availability of real-time data streams. However, criticism on the Lambda architecture revolves around the operational complexity of systems implementing this architecture. This does not only include operations of the systems but especially also implementing and maintaining an efficient code base for the two different data processing approaches - stream and batch processing - used in systems built according to the Lambda architecture.

Real-time processing for NoSQL systems has recently been introduced in Muppet [25], SCALLA [29] and Spark Streaming [44]. In particular, structured streaming seems very promising. Another system that provides both stream and batch processing is Apache Flink [7]. However, it is still difficult to smoothly integrate different technologies to develop a system for complex scenarios that can leverage existing legacy systems. A more recent reflection on main memory vs. stream systems can be found in [23].

2.4 Machine Learning for Anomaly Detection

Machine learning has been widely used for classification and anomaly detection. The research closest to ours has been done in intrusion detection systems in the field of computer and network security [26]. Subsequently, in order to make these systems usable in practice, a lot of work has focused around means to reduce their false positives [27], [4], [12]. The recent shift of the alarm industry towards IoT and smart connected sensors has opened the path for applying the same algorithms in a relatively new context, namely that of physical security, which is our focus in this paper. There is to-date surprisingly little published data on the effectiveness of these techniques for physical IP-connected alarm systems.

Most of the related work published either in research papers or in industrial patents aims at reducing false alarms by means of verification through a secondary channel - e.g. a video camera or additional sensors, such as temperature, shock or vibration sensors. In [30], an intelligent home security system based on the ZigBee protocol is presented. The system detects false alarms by means of image processing from surveillance cameras. However, we do not rely on any other information apart from alarm device properties, the type of supervised premise, location and time.

Similarly, a patent issued by Honeywell AG presents a system that reduces false alarms in a home security system by using information provided by additional sensors, such as an acoustic glass break sensor, shock sensor and vibration sensor [3]. More recently, Honeywell extended their systems with a video-verification step to reduce the number of false alarms [19]. In contrast, our approach has the advantage of being more generic, given that it relies only on information provided by basic sensors and a model trained offline (from the history of alarms received

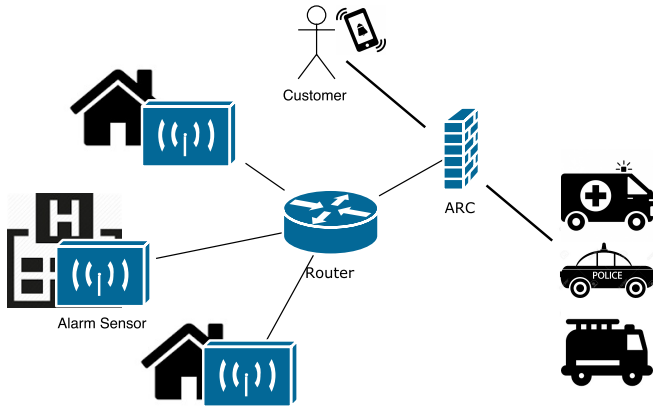

Figure 1: Alarm System Architecture. ARC = Alarm Receiving Center.

from these same sensors), even in the lack of more contextual information (camera images, weather sensors etc).

An interesting approach is presented in [32], where the most suitable machine learning algorithm is chosen adaptively based on the performance of the currently used one - this could be an interesting path for future work in our system, as we have already implemented 4 machine learning pipelines, therefore we would only require the logic to adaptively choose among these at run-time. Another angle to consider would be a majority vote among the different classifiers, providing the overall verification and probability as an aggregate of the information provided by all 4 classifiers.

In a recent publication, Spark Streaming [44] and Apache Kafka [21] were used to detect anomalies in Big Data streams by applying various metrics based on entropy theory and Pearson correlation [36]. In our project we partially build on these results. Our initial machine learning experiments showed promising results [37].

3 ALARM VERIFICATION USE CASE

In a typical security installation, transmitting an alarm originating from a sensor (e.g. motion or smoke detector) to a security organization involves a chain of equipment and people. A simplified view of this setup is shown in Figure 1. An alarm triggered at a supervised premise (a home or enterprise) will reach the security organization (also called Alarm Receiving Center - ARC), where the alarm is handled by one of multiple operators who take predefined actions based on the so called action plan which was previously elaborated together with the customer. This usually involves trying to contact the customer by phone to verify the alarm. This is an important step because more than 90% of all alarms are false positives [34]. If the operator is not able to reach out to the customer or the alarm was verified, he sends out intervention personnel (police, ambulance or firefighters) to go on-site.

The high amount of false alarms makes alarm handling costly. Certas AG, one of the major companies in the alarm monitoring market, processes nearly 5 million alarms and over 2 million phone calls a year, as they report in the Alarm Management Symposium in 2017 [11]. Our industrial partner, Sitasys, operates a platform that connects hundreds of such monitoring centers. Today, a large number of messages are generated from a relatively small amount of sources (like fire sensors or motion detectors).

With the advent of Smart Homes and IoT technologies, the number of sensors and therewith the number of alarms is expected to increase drastically. Meanwhile the demand for security also increases. The security industry in Austria, for example, has grown almost 45% between 2010 and 2016 (as indicated in the yearly security book 2017 published by VSO [42]). With these trends, the monitoring centers risk to get flooded with alarm messages. Keeping in mind that the rate of false alarms is above 90%, it becomes clear that there is a need for improvement.

Uncovering false alarms through machine learning is challenging, since there may not even be a clear definition on whether an alarm is worthy of investigation or not, thus rendering a 100% accuracy a hypothetical goal. However, by changing the process of alarm handling, there might be a way to use predictive modelling in a safe way in order to reduce costs significantly. The way this could be achieved is to transfer the verification of the alarm partly to the customer. The idea is to transmit alarms with a high probability of being false positives to the customer's mobile phone first. The customer can then decide within a time window whether the alarm is real or false and whether it should be sent to the alarm receiving center. Only alarms with a high probability of being true (and those for which a timely answer could not be received directly from the customer), are forwarded to the monitoring center, which can then send out intervention personnel.

With this approach, the number of alarms arriving at the monitoring center decreases, while the handling of the particular alarm becomes more effective, since the manual verification can be omitted. With this self-monitoring solution, the customer can actively take part in the alarm processing chain, which will decrease the workload at the monitoring center and consequently potential errors caused by overwhelmed operators.

Furthermore, the probability for true and false alarms can be used by the monitoring center in order to effectively prioritize alarms. This is especially helpful in the case of large events, which generate a spike of messages that need to be processed fast. An effective prioritization of alarms allows a more effective use of intervention personnel. This ultimately benefits the customer as well, because it reduces the fees he has to pay if the police or fire brigades respond to false alarms repeatedly.

The solution envisioned by Sitasys involves an online portal called "My Security Center". Using "My Security Center" the customer can configure the threshold for the probability of alarms being classified as true. The customer thus decides which alarms should be sent to the monitoring center and which should be sent to his mobile phone first. He can also decide not to send technical alarms, like connection interruptions, to the monitoring station at all. Based on his settings, the alarm handling can be offered for about 40% of the price that is currently common in the market - without any sacrifice concerning security. Since "My Security Center" allows dynamic changes of the rules how and where alarms are being transmitted, it will also allow the offering of more custom tailored services.

4 SYSTEM DESIGN

In this section we motivate the main workflow, the system architecture for our alarm verification application and discuss our design choices.

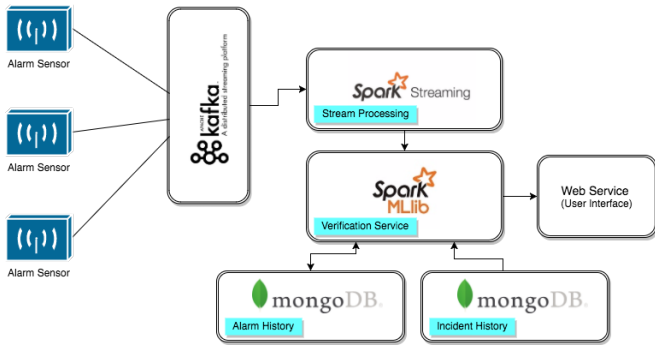

Figure 2: System design consisting of four components: (1) Stream Processing, (2) Batch Processing (Alarm History), (3) Machine Learning (Verification Service) and (4) Hybrid Approach (Incident History).

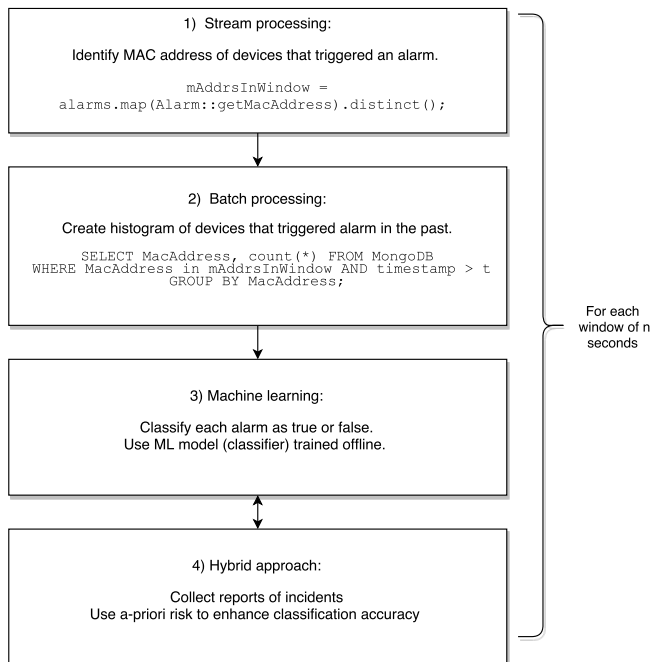

Figure 3: Workflow diagram.

4.1 Workflow

The workflow for alarm verification, shown in Figure 3, consisting of stream processing, batch processing and machine learning, can be characterized as follows.

The stream processing part identifies all devices that trigger an alarm within a certain observation period (the streaming window). As part of the batch processing part, all devices that triggered an alarm are analyzed in more detail by producing a histogram of the number of alarms starting from a specific time t . Finally, for all the new alarms in the given time window, a machine learning algorithm verifies whether the alarm is true or false, based on a classifier trained periodically offline (for example, once per day during idle periods, such as after midnight).

Figure 4: System Architecture and Process Flow

4.2 System Architecture

An overview of the system we developed for handling the above mentioned workflow is shown in Figure 2. The four main components we developed are:

- (1) Streaming Component.** This component is responsible for transmitting and receiving alarms. The simplified format of an alarm sent by a Sitasys sensor through a Kafka stream is shown on the left hand-side of Figure 4. We chose Apache Kafka [21] for this component as it is the state-of-the-art distributed streaming platform, highly scalable and also easy to integrate with Spark. We coupled Spark with Kafka through Direct Dstreams [44], which offers exactly-once semantics "out-of-the-box". This is crucial in our case in order to ensure that we neither miss an alarm, nor process the same one multiple times. For more details refer to [22].
- (2) Batch Component (Alarm History).** This component is responsible for long-term storage of alarms and for doing batch analytics on the history of alarms. For this component we chose to use MongoDB [33], both because of its flexibility (we can store alarms directly as JSON-like documents and query by fields, such as by location of the alarm in order to compute a histogram) and because of its scalability.
- (3) Machine Learning Component (Verification Service).** The reception of a new alarm through the stream immediately triggers the computation of a classification (true/false alarm) and the associated probability (confidence), based on a machine learning model trained offline. The verifications will be used by the Alarm Receiving Centers in order to prioritize incidents where an intervention (police or fire department) is highly likely to be required. We chose to implement this component using Apache Spark, first because it is easy to scale-out when required - for example, if more customers install alarm systems - and second, because of its fault tolerance guarantees. Coupling Kafka with Spark results in an exactly-once semantics streaming application.
- (4) Hybrid Approach (Incident History).** For the hybrid approach we collect reports about fire and intrusion incidents in Switzerland. The incidents are reported as textual data, for example in RSS feeds, Twitter messages or web-pages (see Figure 5). The goal is to use this historical data in order to calculate an a-priori risk factor per each location (village or city in Switzerland) and incorporate it in the machine learning model. Our pipeline collects as many reports as possible and then filters those pertaining to relevant topics (fire and intrusion), based on a set of keywords defined in the pipeline. Each incident report is then annotated with a time and location, extracted directly

Figure 5: Schema of the incidents history pipeline. In a first step, reports from different sources, such as Twitter, RSS feeds and web pages are collected. Next, reports related to relevant topics (e.g. fire, intrusion) are selected (filtered). The remaining relevant reports are annotated with a date, a location and a language and saved in MongoDB.

from the textual data or from the metadata (if available). Finally, similar to the alarm history, we store the incident history in MongoDB. The a-priori risk factors are defined as the number of incidents per capita on location level.

4.3 Reflection on Design Choices

One of the major design choices was the architecture and technology used for streaming processing, batch processing and machine learning. For stream processing the main options available were Apache Storm [39], Apache Kafka and Apache Spark Streaming [44]. We have decided for the combination of Apache Kafka and Spark Streaming due to the good integration and the scalability of both systems. Even though Storm allows topologic modelling of streaming tasks, we decided against it since our application does not have a complex dependency between tasks.

In order to combine stream and batch processing, the design choices would be either the more traditional Hadoop stack for batch processing combined with Storm for streaming processing, or the more recent, in-memory, Apache Spark technology. We have chosen the latter due to its tighter integration of functionality (stream and batch processing as well as machine learning available in a single framework). This was an important advantage for our industry partner Sitasys, in order to decrease the complexity of the overall system architecture, as well as to reduce maintenance costs and required skills of their workforce.

At the start of our project, Spark Structured Streaming was marked experimental, therefore not yet production ready, hence we decided against it. Moreover, our industry partner has a large collection of alarm data stored in MongoDB which should be leveraged. After analyzing the integration of Spark with MongoDB, we decided for this design option since it allowed us to re-use technology already existing at our industrial partner and

to effectively combine it with state-of-the art stream processing. Moreover, MongoDB is flexible to schema changes, which makes it a better option for long-term storage than a traditional Relational Database, given that in our use case the structure of an alarm differs across sensor types and even across software updates. Using MongoDB allowed our industry partner to easily ingest data from new alarm installations, even when the structure of the new alarm data did not match the structure from previous installations. In our experiments we achieved satisfying scalability results of MongoDB queries for large datasets. For more details see Section 5.

Using Spark ML for machine learning was a natural choice since it is readily integrated within the Spark technology stack. However, since Spark ML did not provide deep learning algorithms at the start of our project, we used various other deep learning frameworks such as DeepLearning4J [15] as well as Theano [41] and Lasagne [28].

5 EVALUATION

In this section we first describe the alarm datasets we used for our experiments, namely from Sitasys, as well as from the cities of London and San Francisco. Next, we describe the incidents dataset we used for the hybrid approach to enrich the Sitasys alarm dataset. This is followed by a description of our machine learning experiments in order to classify false alarms and a description of our experiments using the hybrid approach in order to improve the machine learning pipeline. Finally, we present the end-to-end evaluation of our system, which includes stream processing, batch progressing, as well as machine learning. Our results show that using production data we can process 30K alarms per second with an accuracy of above 90%.

5.1 Alarm Datasets

In order to build and evaluate a model for false alarm verification, we started by analyzing the alarm data provided by our industrial partner, Sitasys. This data is presented in Section 5.1.1. First, we selected the set of features best suited for verification. We describe this in Section 5.3. Then, in order to evaluate how well we can extrapolate using this set of features for similar use cases, but also to see how well our algorithms scale, we looked for larger datasets available online. We identified two candidates, namely the London Fire Brigade Data and the San Francisco Fire Department Data. The most relevant features from all 3 datasets are shown in Table 1. In the next sections we describe each dataset in more detail.

5.1.1 Sitasys Production Data. Real alarm data from October 2015 to April 2016 was collected and anonymized by our industrial partner Sitasys, gathering a total of 350K alarms in roughly equal proportions of true and false alarms. The main types of information provided are location (ZIP code), device address (MAC and IP address), timestamp, alarm duration, type of incident (fire, intrusion, etc.) and a few other sensor-specific information (type of sensor, software version, etc). The ObjectType feature classifies the type of supervised premise the alarm originates from: industrial, residential etc. The location information was anonymized (hashed) for privacy reasons. One important challenge we faced when using this data is the lack of real labels (i.e. indications about true and false alarms). These could not be provided to us in due time from the Alarm Receiving Centers that register them. However, in collaboration with Sitasys we have defined a heuristic to infer the labels, which is to consider the duration of

Dataset	Location	Time	Type of Location	Incident Type	Label
Sitasys	ZIP code	Timestamp	ObjectType	Alarm Type	Alarm Duration
London	ZIP code	Date/TimeOfCall	PropertyType	PropertyCategory	Incident Group
San Francisco	Zip code Of Incident	ReceivedDtTm	-	Call Type	Call Final Disposition

Table 1: Features of the three data sets

Figure 6: London Fire Brigade Statistics

the alarm as a threshold - the more quickly the alarm was reset after being triggered, the higher the likelihood that the alarm was false, given that the customer was able to reset it in a short period of time. We chose several different values for the alarm reset duration threshold between 1 and 10 minutes. We used 50% of the alarms for training (roughly equal amount of true and false alarms) and the remaining 50% for testing. Moreover, we were interested in the response time for an incoming alarm on a data stream, therefore we also simulated a stream of new alarms from the testing data and tested the performance of our verification system. Details are given in Sections 5.3 and 5.5.

5.1.2 London Fire Brigade Data. The London Fire Brigade (LFB) is the busiest fire and rescue service in the United Kingdom and one of the largest firefighting and rescue organizations in the world. We used the open data of every incident reported since January 2009, available online¹. The dataset provides information about the location, time and type of incident for all records.

Figure 6 shows the high-level statistics of incident groups between 2009 and 2016, as well as the ratio of false vs. true alarms recorded. In total, 885K incidents were recorded, out of which 430K (48%) were false. This dataset is therefore very convenient to use for our classification algorithms, because the true and false classes are almost equally balanced, which makes it suitable even for algorithms that are very sensitive to unbalanced data (e.g. Random Forest).

This dataset is useful for two purposes: first, it allows us to test hypotheses on a coarser time-scale, since the incidents are recorded from 2009 until today, meaning that for example we can try to draw statistics and make verifications based on the days of the year with peaks of incidents. Second, it serves as a scalability test as the number of incidents is twice as large as those provided by our industrial partner.

5.1.3 San Francisco Fire Department Open Data. In an attempt to extend our study, we also considered the San Francisco Fire Department Dataset (available online²), which contains 4.3 million incidents from the city of San Francisco from the year 2000 until today. We found that, in contrast to the London Fire Brigade Data, the quality of the San Francisco dataset is lower, given that more than half of the records (2.5 million) are not properly labeled, the Call Final Disposition - which denotes the final classification of the incident - marked "other". Only 105K are explicitly labeled as "No Merit" (false alarm), i.e. less than our production data from Sitasys from 2015 and 2016 only. Moreover, as shown in Table 1, there is no entry in the dataset that indicates the type of property, which in our study of the Sitasys alarms proved to be an important feature for the classifier. An added problem is the diversity of the types of incidents recorded. For example, more than half of the entries are medical incidents, which are not present at all in the other two datasets. Around 1 million incidents are alarms and fire incidents and only a small fraction of these are properly labeled.

All in all, in our study we could only consider incidents of type "alarm" and "fire" that have a proper label indicating either true or false alarm. Unfortunately, this only results in around 12K incidents, much less than we initially expected. We report results from this small subset in the next section. Finally, we note that we have tried our classification algorithms against *all* properly labeled incidents (including medical, hazards etc) but for this purpose we did not obtain meaningful results - only around 53% accuracy.

5.2 Incidents Dataset

This dataset is a collection of reports about real fire and intrusion incidents, gathered from online resources, such as RSS feeds, Twitter or relevant web pages (police, fire brigades etc.). This external data is used in order to enrich the knowledge base provided by the *Sitasys Production Data*. In particular, we annotate alarms with an a-priori risk factor, based on their location. Since the *Sitasys Production Data* only consists of data from Switzerland, we focus on collecting reports about Swiss incidents. For example, we collected messages related to incidents from 50 different Twitter accounts (cantonal police, fire brigade departments and others) from January 2015 until end of October 2017. Our pipeline checks, for each message, whether it contains information about intrusions or fire (see Figure 5). Next, it identifies the language, the date and the location of the incident, either from the metadata (if available) or directly from the textual data (the message). However, since the metadata does not contain information about ZIP codes, the granularity of each location is either a city or a village. In turn, the granularity of our alarm data set is slightly more detailed, namely, at the level of ZIP codes. For example, some larger cities, such as Basel and Zurich, have multiple ZIP codes for different districts of the city. Since the incidents dataset does not have the same level of granularity as the alarms dataset,

¹<https://data.london.gov.uk/dataset/london-fire-brigade-incident-records>

²<https://data.sfgov.org/Public-Safety/Fire-Department-Calls-for-Service/nuek-vuh3/data>

Figure 7: Discrepancy between the amount of incidents and amount of true fire and intrusion alarms in the two data sets.

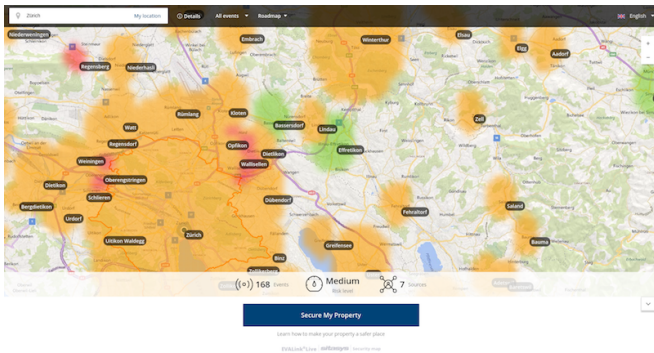

Figure 8: Screenshot of the security map with focus on Zurich (Switzerland). Red areas imply a higher risk level.

we can only approximate an aggregated risk over all districts of a large city with several ZIP codes (see Table 2).

The dataset contains 5,056 descriptions of incidents, out of which 2,743 are in German, 1,516 in French and 797 in English. The corresponding incidents are located in 1,027 distinct cities and villages of Switzerland, covering around 1/4 of all cities and villages in Switzerland. The discrepancy between the number of incidents in the dataset and true fire and intrusion alarms in the *Sitasys Production Data* is shown in Figure 7. For example, the first entry in Figure 6 shows the number of true fire and intrusion alarms for the location with ZIP code 3013 provided from the *Sitasys Production Data* (lower bar shown in light gray). However, the number of reports about fire and intrusion incidents is significantly smaller (upper bar shown in black).

Finally, we use the incidents dataset to build and display a security map of Switzerland, shown here in Figure 8. The figure shows the risk of different areas in the canton of Zurich, Switzerland. Green areas indicate safe regions, whereas yellow indicate medium-risk and finally, red implies higher risk. For a detailed discussion on the calculations of the risk levels we refer to Section 5.4.

ZIP codes Basel	#-true-alarms		#-incidents	
	intrusion	fire	intrusion	fire
4001	43	3	[unknown]	
4051	142	3	[unknown]	
4057	304	0	[unknown]	
4058	0	55	[unknown]	
Total for city of Basel	489	61	10	464

Table 2: Divergence between the number of true alarms in different districts in Basel (Switzerland) in the Sitasys Production Data and the number of incidents collected in the Incident Data. The Incidents Data only contains location information at a coarser granularity (per city / village) than the Sitasys alarm data (per ZIP code).

5.3 Machine Learning

We chose 4 of the most commonly used algorithms for machine learning: Random Forest, Support Vector Machine, Logistic Regression and Deep Neural Networks (DNN). For the first 3 we used the readily available implementations from Spark ML, whereas for DNNs we developed an application using DeepLearning4J [15] as well as Theano [41] and Lasagne [28].

For feature selection we first evaluated which of the alarm fields best separate true from false alarms. We used the Pearson correlation inspired by [36] to find dependencies between features and labels as well as dependencies among features. In addition, we ran a grid search for each algorithm, varying the features used to train the models, and finally selected the following most promising features: location (for privacy reasons we only received hashed location information), day of week, hour of day, alarm type and property type.

Although in our experimental evaluation we only take into account accuracy in terms of number of correct verifications, we note here that, given that our main use case is a decision support system for human operators in the Alarm Receiving Centers, not only is the verification important, but also the probability (confidence) associated with it, as the human operator will likely take a decision according to this metric rather than just the verification.

For our experiments we used the following hardware setup:

- For initial experiments using a single Producer, single Consumer workflow, described in Section 5.5, we used two Intel Xeon E5-2620 machines at 2.4 GHz with 8 GB RAM.
- For multi-node Spark experiments we used a cluster of 4 Intel Xeon E5-2640 CPUs at 2.5 GHz with 16 GB of RAM each.
- For the DNN experiments we used 1 Intel Xeon E5-2650 with 1 Titan X GPU.

5.3.1 Accuracy. As our main use case is to verify false alarms based on the alarm data from our industrial partner, we focused on extracting the features that best separate true from false alarms in the Sitasys dataset. We then investigated how well the equivalent set of features in the open data sets from London and San Francisco can be used to verify false alarms. We show in the next subsections that our approach can be easily transferred to these 2 similar use cases with good accuracy results.

5.3.2 Parameter Tuning. The first important parameter we investigated for the Sitasys alarm dataset was the threshold for

Figure 9: Verification Accuracy vs. Δt (Sitasys Dataset)

the alarm duration. This parameter is used as a heuristic to determine whether the alarm is true or false. For example, when using a threshold of 1 minute, all alarms with a duration smaller than 1 minute are considered false. The intuition is that an alarm that was reset (turned off) within a very short time is likely false (the owner immediately shut it off). In order to evaluate the effectiveness of our machine learning approach, we experimented with various values for delta t ranging between 1 and 10 minutes. The goals of our evaluation were as follows: (1) Evaluate the accuracy of four different machine learning algorithms. (2) Study the impact of various deltas t on the verification accuracy. The idea was to show that the results are stable with respect to changes in the choice of delta t. The results are shown in Figure 9. We can see that on average the best classification quality among all algorithms is achieved with the smallest threshold, of 1 minute, and that moreover in all cases Random Forest and Deep Neural Networks achieve the best performance, of over 90% accuracy, independent of the choice of delta t, which means the accuracy results are stable across changes in the choice of this parameter.

Next, the selection of hyper parameters for each of the learning algorithms (e.g. architecture of neural network) was essential for the verification accuracy. We used grid search to tune the hyper parameters. Tables 3, 4, 5, 6 and 7 show the best ones for each of the 4 algorithms we tested.

Parameter	Value
Maximum depth of a tree	30
Number of trees to train	50

Table 3: Parameters for Random Forest

Parameter	Value
Maximum number of iterations	2,000
Step size	1.0
Mini batch fraction	0.2
Regularization parameter	1e-2
Kernel	Linear
Update Function	Squared L2

Table 4: Parameters for Support Vector Machine

5.3.3 *Training Time.* One important factor we investigated to ensure that our prototype is usable in practice is the training time. Essentially, this determines how fast we are able to

Parameter	Value
Maximum number of iterations	500
Convergence tolerance of iterations	1e-6

Table 5: Parameters for Logistic Regression

Hidden 1	50 Nodes	Fully connected	ReLU
Hidden 2	2 Nodes	Fully connected	ReLU
Output	2 Nodes	Fully connected	Softmax

Table 7: Architecture of Deep Neural Network

rebuild our models, a step that is required periodically (ideally, upon reception of a large enough number of new events, for example once per day). Table 8 shows the training times for our classification algorithms, using the 3 datasets: Sitasys, London Fire Brigade (LFB) and San Francisco Fire Department (SF). The short training time for the San Francisco dataset is explained by the fact that we can only use around 12K incidents properly labeled from the alarm and fire categories. Another observation is that for all the datasets, the smallest training time is required for Logistic Regression, while Deep Neural Networks take much longer to train. Moreover, we use the One Hot Encoding for this algorithm, which means we end up with twice as many input features (around 800) for the Sitasys dataset than for the others (around 300), given that we also use some sensor-specific categorical features in the case of Sitasys (each of the values of these attributes becomes a separate feature when using One Hot Encoding).

Algorithm	Sitays	LFB	SF
Random Forest	600	1200	75
Support Vector Machine	200	480	20
Logistic Regression	100	60	10
Deep Neural Network	5100	2460	60

Table 8: Training Time [sec] for Machine Learning Algorithms

5.3.4 *Accuracy Results.* Figure 10 presents a comparison of the accuracy obtained for the 3 datasets we tested. We can see that the best results are obtained for the Sitasys dataset with a classification accuracy of up to 92% for Random Forest. The promising results can be explained by the fact that, apart from the generic features (Location, Property Type, DayOfWeek and HourOfDay), the Sitasys dataset contains a few other features that can identify technical faults more easily (sensor-specific information), which allows the algorithms to better classify false alarms. By contrast, for the LFB and SF datasets we could only use

Figure 10: Verification accuracy comparison using four different machine learning algorithms for three Sitasys, London Fire Brigade (LFB) and San Francisco Fire Department (SF) Datasets. RF = Random Forest, LR = Logistic Regression, SVM = Support Vector Machine, DNN = Deep Neural Network

the generic features. However, it is interesting to note that this still results in fairly good accuracy, of around 85%, for the LFB dataset (best result is obtained for the Support Vector Machine) and 80% for the SF dataset (Random Forest). As mentioned previously, the San Francisco dataset does not contain information regarding the type of property an alarm originates from, which could explain the lower accuracy. Furthermore, the volume of the training data we could select from the SF dataset is generally too low (only around 12K alarms).

Another interesting result is that, although there are some differences among the accuracy results for the 4 algorithms we tested, they are never higher than 5%. This is encouraging for two reasons. First, because some algorithms require less training time and less resources to run (Logistic Regression), therefore they could be chosen over the others in case response time is more crucial than accuracy. Second, because more generally this validates our approach, given that the good accuracy is not an artifact of a particular choice of machine learning algorithm, but rather a consequence of the feature selection, which accurately describes the problem we aim to solve. On the other hand, a 5% improvement in classification accuracy (from 85% to 90%) effectively means reducing the error rate by 50%, which means the best algorithms perform significantly better.

5.4 Hybrid Approach

For the hybrid approach we collected descriptions of fire and intrusion incidents from different online resources, such as Twitter, RSS feeds, or web pages collected through a provider of web-based data feeds, webhose.io. Each incident is annotated with the time and location, extracted from the original message or web page. We use this information to calculate an a-priori risk factor for intrusion and fire alarms, based on the number of incidents that happened in a certain location (village or city), normalized by the population size. Next, we evaluate the impact of the inclusion of a-priori risk factors on the accuracy of the machine learning model.

We chose three different ways to include the a-priori risk factors into our machine learning pipeline:

- (1) absolute risk factor
- (2) normalized risk factor

(3) binary risk factor

(1) The absolute risk factor is calculated by dividing the number of incidents found in various resources by the population in the annotated location. (2) The normalized risk factor has a range of 0 to 1, and is calculated as $x' = \frac{x - \min(x)}{\max(x) - \min(x)}$, where x is the absolute risk factor of a location. (3) The binary risk factors are either 0 or 1. The risk factor is 1, if the incident is in the most frequent 25% locations, otherwise the risk factor is 0.

Our efforts for the hybrid approach are still in the early stages, and the data we have collected so far is limited. As a consequence, for the evaluation we only use alarms with a ZIP code where we have corresponding reports about incidents. This reduces the number of alarms from about 350,000 to 130,958 (see Figure 7). As mentioned previously, the granularity of the alarm data is on ZIP code level, while the granularity of external reports about incident data is on city or village level. To analyze the influence of this discrepancy in granularity, we run additional experiments where we only select alarms about small cities or villages that have one ZIP code rather than multiple ones. This reduces the number of alarms from around 130,958 to 37,241 and further the number of incidents from 5,056 to 4,379 (see Table 9). Moreover, the *Sitasys Production Data* provides more alarm types than fire and intrusion. Hence, we needed to filter only those alarms that are triggered due to fire or intrusion.

Table 9 shows the experimental results for alarm classification of four different scenarios (a-d) and three different a-priori risk factors, compared to a baseline approach. The baseline shows the alarm classification accuracy without a-priori risk factors (as reported in Section 5.3). The results are averaged over 10 runs for each experiment. In the scenario (a), using all locations and all alarms, we have around 130,958 alarms. This scenario only shows a small increase of 0.04% of the classification accuracy using the normalized risk factor. Scenario (b) uses all locations, but only the fire and intrusion alarms, which reduces the training data to 24,934 alarms. In this scenario, the results show that the absolute risk factor leads to an increase of 0.22% in accuracy compared to the baseline.

The scenarios (c) and (d) use only locations with a single ZIP code attached. Therefore we make sure that the a-priori risk factor does not contribute wrong information to larger cities with multiple ZIP codes. Out of the total of 130,958 alarms, 37,241 refer to cities with single ZIP codes. This implies that around 2/3 of the alarms are located in larger cities. The results of scenario (c) show an improvement of 0.4% for the absolute risk factor, compared to the baseline. The normalized and binary risk factors also have a slight positive impact. Finally, scenario (d) uses only fire and intrusion alarms for cities with single ZIP codes. Therefore, the number of alarms is reduced to about 10,000 alarms. In this scenario, the impact of applying a-priori risk factors is the strongest, with an increase of 1% compared to the baseline.

Overall, the results obtained by including the external, unstructured data are still preliminary. The scarcity of this data, coupled with an uneven distribution of the reported incidents makes it difficult to measure a significant impact. We still consider the results promising, as they show a) that adding in potentially noisy textual information from third-party sources does not degrade the results even though we are using a limited set of collection and filtering approaches and b) that a small positive impact can already be seen when focusing the analysis on the subset of alarms for which we have matching unstructured data.

scenario	all locations		single ZIP code locations	
	all types (a)	F/I alarms (b)	all types (c)	F/I alarms (d)
<i>baseline</i>	89.35	85.73	87.16	86.56
ARF	89.29	85.95	87.56	87.45
NRF	89.39	85.67	87.41	87.56
BRF	89.31	85.79	87.51	87.48
#-incidents	5,056		4,379	
#-alarms	130,958	24,934	37,241	10,036

Table 9: Accuracy of alarm classification using three different a-priori risk factors and four scenarios: (a) all locations, all alarm types, (b) all locations, only fire & intrusion alarms, (c) single ZIP code locations, all alarm types and (d) single ZIP code locations, only fire & intrusion alarms. ARF = absolute risk factor, NRF = normalized risk factor, BRF = binary risk factor.

5.5 End-to-End Data Processing

Once we have trained and tested the machine learning algorithms, the next step was to build the end-to-end pipeline to integrate machine learning into stream and batch processing. In particular, as soon as an alarm arrives, a machine learning algorithm classifies in real-time whether the alarm is true or false. In addition, historical data analysis is performed on the sensors that triggered the new alarms. The goal of our experiments was to evaluate the maximum throughput of our system, identify potential bottlenecks and to derive lessons learned from building such a production system.

5.5.1 Setup of Streaming System. In order to test the scalability of our prototype, we handcrafted a Producer application, which simulates a stream of new alarms. The stream is created by randomly selecting alarms from the test set (alarms from our production data, that have not been used for training the machine learning model) and writing them into Kafka, at a controlled rate (alarms per second). We aim to evaluate the response time of our system, which runs as a Consumer application.

First, we are interested in measuring the maximum throughput (number of verified alarms per second) on the consumer side. We assume that the training phase has already been completed offline and the model is readily available for computing classifications. Second, we must take into account the maximum latency (system response time) per alarm, as it is critical to ensure that a human operator in the Alarm Receiving Center can get a timely verification result. Currently we set the goal of responding in at most 10 seconds since the reception of the alarm at the ARC.

5.5.2 Identifying Bottlenecks.

Throughput of Producer-Consumer. With a setup as simple as just one producer and one consumer application (running each on a separate machine connected through a 1 GB Ethernet network), we were able to identify several bottlenecks in our system. First, our tests showed that both the producer and the consumer were processing events at an unexpectedly low rate (about 12K alarms produced per second, where one alarm is less than 1KB in size), even if Kafka benchmarks made us expect much higher throughputs. After further investigation we found that the bottleneck in both applications was in fact the serializer used for writing alarms into, and reading them from, the Kafka stream. At first, our implementation used the Jackson serializer, which turned out to be a poor choice for small objects [18], where the Gson serializer is more appropriate. We were surprised to find

Figure 11: Scalability Jackson vs Gson serializer

that just replacing this led to a 2x speedup in both applications. Figure 11 shows the results. We can see that by switching from the Jackson serializer to the Gson serializer the throughput of the producer more than doubled to about 25K alarms per second. On the consumer side, the increase was slightly less than double. This is due to the fact that the consumer has a higher computing load than the producer.

Detailed Analysis of Consumer. Next we analyzed the computing time of the consumer in more detail (Figure 12). In particular we were interested in the time contribution of stream processing (Spark Streaming), batch processing (MongoDB query) and machine learning (Spark ML). The breakdown of time per component using a 10 second window of alarms shows that the majority of time is spent in the machine learning part (around 80% of the total time) to classify. We also notice that an insignificant factor goes to the historic component (retrieving the histogram of alarms originating from the same addresses as those in the time window). The remaining time goes to the streaming component: first, for deserializing alarms into the native Spark data format, RDDs (Resilient Distributed Datasets [43]), then for extracting all distinct addresses from the RDD etc.

Kafka Optimization. After this step, we further noticed that although our consumer machine has 8 cores, none of the computations were parallelized, although Spark was configured to use all the cores on the local machine. After investigating this we found that by default, Kafka streams are not partitioned, meaning that all RDDs will be processed on a single execution thread. To fix this, there are 2 options available: first, creating multiple streams and reading from them in parallel - this would be useful for the case where, for instance, different customers would be registering alarms to different Kafka streams. However, since for the moment we collect all alarms on the same stream and aim to test per-stream scalability, we chose the second option, which is to configure the repartition number of the Kafka stream, when creating it from the Spark application. In order to test the maximum throughput on the Consumer side, we created multiple threads in the Producer application (to make sure that this does not become the bottleneck) and were in this way able to reach a maximum throughput per consumer of around 30K alarms per second.

6 LESSONS LEARNED

In this paper we have presented an end-to-end system for verifying false alarms in real-time based on a combined stream and batch processing approach. Our results demonstrated that for

Figure 12: Breakdown of time per component in the Consumer Application

the real production data our machine learning algorithms gained an accuracy of more than 90%. However, even a 99% verification accuracy might not be good enough and could potentially result in missing a fire that burns down a building when no intervention force is deployed. For our industry partner this was the major issue about accepting our approach in a real-world setting. In order to overcome this problem, we introduced the following solutions: (1) The end user (property owner) is in the loop to verify alarms. For instance, before an alarm is sent to the alarm receiving center, the end user can verify it. As an example, let us assume apartment X systematically triggers fire alarms after midnight. A closer inspection shows that the alarms were triggered by the kids since the family has forgotten to de-activate the alarm during the periods the kids went to the bathroom. In this case, the property owner could verify the false alarm and hence no intervention force would be sent. (2) Every alarm is prioritized and evaluated by a human operator. This gives the human operator more time to react to the most critical alarms first and has the potential to drastically decrease human error due to information overload within a short time interval. (3) We provide histograms about historic alarms that help identify recurring problems.

In the next few sections we will report on further lessons learned in the areas of machine learning and Spark processing.

6.1 Machine Learning

- **Provide probability of verification**

Although in our experimental evaluation we only take into account accuracy in terms of number of correct classifications, given that our main use case is a decision support system for human operators in the Alarm Receiving Centers, not only is the verification important, but also the probability (confidence) associated with it. This allows human operators to take a decision according to this metric rather than just the classification. Luckily, most implementations of machine learning (classification) algorithms provide this confidence factor by default. We used the probabilities associated with verifications for the Random Forest or Logistic Regression classifiers from Spark ML as well as for the Neural Networks implementation from the Theano library. Moreover, we provide operators a way to analyze the history of the sensors that triggered alarms in order to get a better understanding about the nature of the new incoming alarms.

- **Keep it simple**

Our experience in testing different machine learning algorithms proved that, while the accuracy was similar for all 4 algorithms we tested, there was a big difference in the training time (from a couple of minutes for Logistic Regression to more than 1.5 hours for Deep Neural Networks). It is therefore crucial to always try out the simplest hypotheses first (even when new advances in the field make it tempting to start with the latest, but much more complex algorithms). This is even more so the case in time-critical applications, where it could be desirable to trade off some accuracy in order to gain in response time.

- **Design for reusability**

While evaluating our prototype we found it extremely useful to have a generic data type that describes our problem, e.g. *LabeledAlarm*, that would not be tied to our particular use case (the data set from Sitasys). We therefore crafted a generic class with categorical features like Location, Property Type, HourOfDay, DayOfWeek, which generally describe alarms (and which can be enriched with other features by extending the class if needed). This minimized the efforts required to adapt and validate the algorithms for new, similar, datasets such as the London Fire Brigade or the San Francisco dataset. Moreover, even if you do not foresee using the algorithms in a new context, it is very likely that the structure of the input data from the initial use case will change over time (in fact, this happened during our project's lifespan), either because of technology changes, software updates or because new components are added in the system (e.g. new types of sensors). Therefore having code that describes the problem in a generic way allows for reusability and adaptability whenever the structure of the input data changes.

6.2 Spark Processing

Although Spark can be very convenient to use, allowing for rapid productivity thanks to its integration of different components in a single platform, it may also lead to suboptimal performance when misconfigured or improperly used. When using Spark we found the following considerations useful:

- **Cache data that will be reused**

Spark's lazy evaluation leads to unnecessary re-computations for data that is not explicitly cached. This side effect is not apparent by just reading the code. We first noticed this problem when evaluating the deserialization mechanism on the consumer side - not only did we notice this step was too slow, it was also executed *twice*, because we reused the input streaming data for both machine learning and for querying historic data, without explicitly caching it.

- **Make use of the monitoring UI**

Spark provides an extremely useful set of statistics, both for batch and streaming, which makes it easy to monitor the application while it is running. The most important statistics we used were the level of parallelism for batch computations and the average delays for stream processing. Both offered insights into points in the application that performed suboptimally.

- **Make sure the parallelism level is the expected one**

One of the problems we noticed by examining the stats in the Spark UI was that input data read from Kafka was always processed serially instead of in parallel. After reading through the documentation, we found that by default,

Kafka streams are not partitioned. Therefore, Spark will not process incoming data in parallel, unless explicitly configured in the code when setting up the Kafka stream.

6.3 Hybrid Approach

The lessons we can draw from our experiments with the hybrid approach are still limited. We believe there is great potential in integrating information from third-party sources into the verification, but to fully leverage this potential, substantial additional research is needed. In this spirit, the following lessons should be read more as suggestions on how to improve on our initial approach:

- **Integrate as many external sources as possible**
Thus making sure the sources cover the alarms as broadly as possible. We have shown that the highest impact can be measured when restricting analysis on the alarms that have corresponding incidents in the external sources. Moreover, our preliminary results show that this has the potential to positively impact classification accuracy.
- **Localize incidents with finer granularity**
This will allow combining incidents and alarms more directly, which should be especially beneficial in heavily populated (urban) areas, where a-priori risks for incidents such as intrusions may vary significantly from one area (neighborhood) to the next.

7 CONCLUSIONS

In this paper we presented the design and evaluation of an alarm verification system using real data from an industry application. The problem is very challenging since it requires a combination of stream processing, batch processing and machine learning. We have built the system using Spark Streaming (stream processing), MongoDB (batch processing) and Spark ML (machine learning). Our experiments with various machine learning algorithms show that the system can classify alarms with an accuracy of more than 90% at a streaming rate of about 30K alarms per second, including historical data analysis. To further extend our system, we also presented preliminary results of an integration of unstructured data to increase the classification accuracy. We concluded with an extensive list of lessons learned that give insights for both academics and practitioners who want to build a similar system.

ABSTRACT

Enterprise customers of cloud services are wary of outsourcing sensitive user and business data due to inherent security and privacy concerns. In this context, storing and computing directly on encrypted data is an attractive solution, especially against insider attacks. Homomorphic encryption, the keystone enabling technology is unfortunately prohibitively expensive. In this paper, we focus on finding k -Nearest Neighbours (k -NN) directly on encrypted data, a basic data-mining and machine learning algorithm. The goal is to compute the nearest neighbours to a given query, and present exact results to the clients, without the cloud learning anything about the data, query, results, or the access and search patterns. We describe a novel protocol in the two-party cloud setting, using an underlying somewhat homomorphic encryption scheme. In comparison to the state-of-the-art protocol in this setting, we provide asymptotically faster performance, without sacrificing any security guarantees. We implemented our protocol to demonstrate that it is efficient and practical on large and relevant real-world datasets and study how it scales well across different parameters on simulated data.

1 INTRODUCTION

Finding k -Nearest Neighbours (k -NN) is viewed as one of the simplest data mining algorithms for discovering patterns. It is non-parametric, making no assumptions about underlying data distributions. It is also a lazy learning technique, where no attempt is made to generalize the data until a query is presented. The goal of a k -NN algorithm for a given query is to find its k “nearest” neighbours according to a suitable measure of nearness or distance. It has applications in finding candidate patterns for image segmentation, location-based search, and in the classification of symptoms and diagnosis over medical records, to name a few. These patterns may be subsequently used as inputs for more sophisticated learning algorithms.

In the context of cloud computing services, client data records stored on clouds are increasingly confidential in nature, from customer transactions, order histories, credit card numbers and other personally identifiable information (PII). Algorithms, and

especially algorithmic parameters, e.g., in recommendation systems, are also proprietary and sensitive. Inadvertent or unauthorised disclosure of data or computation can have serious legal or business consequences. In order to protect the confidentiality of sensitive information, clients can store encrypted data in data centres. However, it is not cost effective to import back all the data to the client, decrypt and perform computations, as this negates the advantages of moving to the cloud platform in the first place.

The Secure k -NN problem for encrypted data has been a topic of active research [13, 14, 34, 39–41]. The goal is to compute k -NN over encrypted data stored in the cloud, given a query, with the requirement that the cloud provider does not get any information about the plaintext values in the database, the query, the results, the access patterns during query evaluation, and search patterns. The technology to work effectively on encrypted data is provided by a class of encryption schemes called homomorphic encryption (HE), which allow one to compute arbitrary functions on encrypted data and produce encrypted results. Clients, who have the secret keys can decrypt and use these results safely, without revealing the data or results to the servers. Fully HE [16] schemes are expensive and impractical for now [12]. Existing solutions for Secure k -NN, therefore, work in one of two models: the centralised (private) or the two-party (public with multiple servers) cloud model. These solutions rely on a combination of partially or somewhat homomorphic schemes (PHE or (S)HE) for computation [14, 28, 39] of simpler mathematical functions, such as order preserving encryption, homomorphic addition, computation of limited degree polynomials, etc., which are faster to compute. These choices impose different tradeoffs on computation and communication overheads, and provide different security guarantees, making this a rich field for new research.

We present a new protocol in the two-party honest-but-curious cloud model for computing k -NN on encrypted data, which is *asymptotically faster* than the current state-of-the-art protocol [14], without compromising on strong security guarantees. We use LFHE (leveled fully homomorphic encryption) [9], and compute squared Euclidean distances directly on encrypted data. In order to compute the ranking among the distances, we transform the distances suitably to preserve their order and offload the comparison to a federated public cloud, who has secret keys. Since this cloud has access only to transformed results of computations performed on plaintext data, we show that in spite

of this knowledge, this honest-but-curious cloud does not learn anything useful about the original database, the results, or the query.

We implement our protocols and run experiments on two real-world datasets from the UCI machine learning repository¹: the cervical cancer (risk factors) dataset, and the default of credit card clients dataset. Both datasets have a large number of dimensions (32 and 23 respectively). Our implementation shows that we are able to find k -NN very efficiently: 166 s on the cancer data and 373 s for the credit card dataset for our secure version for an 8-NN query, making our implementation practical for real-world applications. This trend is also echoed in the simulation results on synthetic datasets, to study the sensitivity of our protocol to various parameter choices empirically.

The rest of the paper is organized as follows: In Section 2 we present background information about our adversary and cloud models as well as a brief tutorial on homomorphic encryption. In Section 3 we present our protocol in detail, followed by a security analysis in Section 4. We describe our implementation and experiments in Section 5, relevant related work in Section 6, and conclude with future work in Section 7.

2 BACKGROUND

In this section, we present our two-party cloud architecture and describe our adversary model and trust assumptions. We also specify the Secure k -NN problem in terms of what functions need to be computed on encrypted data, and briefly introduce homomorphic encryption, with the goal of making this paper self-contained.

2.1 Cloud Architecture

The security implications of outsourcing data or computation to cloud servers need to be studied carefully. There are many deployment choices, including private clouds, public clouds and hybrid clouds. For enterprises that place a high value on data confidentiality and computational integrity, outsourcing data and computation may not be a justifiable risk. Private cloud solutions address this need, with services being accessible only within enterprise intranets, with limited benefits of cloud computing such as on-demand scaling and load balancing, as well as added initial infrastructure and set-up costs to new services. At the other end of the spectrum are the public clouds, where large third-party owned server farms and data centres host client data and computation services for hire. Two concerns stand out here: *insider attacks*, where employees within the public cloud enterprise can observe and infer trade secrets, and *side channels*, e.g., inadvertent or indirect information leaks when data belonging to different companies who may be competitors share the same bare metal. Analysis of side channels is outside the scope of this paper. A third model, the hybrid cloud model adopts a best of both worlds where depending on the sensitivity of the data and computation, enterprises may choose to offload only a part of their services on public clouds.

Our Secure k -NN solution is specifically targeted at public clouds. In particular, we work in what is called the two-party federated cloud setting, with two non-clustering public cloud servers, which is introduced in Twin Clouds [11] and subsequently used by the current state-of-the-art secure k -NN solution [14]. Federated clouds are an example of what are called interclouds [20], a collection of global stand-alone clouds. Interclouds allow better

load balancing and allocation of resources and help in addressing specific scenarios, e.g., services that are region-specific and require the data to be stored in a particular geography. Coordination of services across the intercloud can be centralized, or peer-to-peer as in the case of federated clouds. A detailed survey of the taxonomy of intercloud architectures is presented in [20].

2.2 Trust Assumptions

With federated clouds, as with public clouds, the trust model is of an *honest-but-curious* or the semi-honest adversary, who does not tamper directly with the computation or data. However, the adversary is free to observe inputs and outputs, as well as side-effects of computation and other behavioural characteristics on the cloud networks and servers. This type of adversary is different from the passive observer or the malicious adversarial model traditionally considered in the past, as the adversary is trusted to perform the computation correctly, but in addition has access to the internal state of the service, which includes client data. Such an adversary can observe the state of memory, and network traffic, or study operating systems behaviour in response to client queries. The choice of this particular type of adversary is justified, as data owners have to relinquish this control to the cloud service providers. While these exposures can be limited and controlled by legal contracts and liabilities, the threat of a curious insider can never be ruled out. This is where computing directly over encrypted data fills the gap. The goal is that even though we operate in the honest-but-curious adversary model, a malicious insider cannot obtain meaningful information from the data or the computation by observation. Further, we want to prevent the adversary from learning database access patterns, such as the set of (encrypted) result tuples returned corresponding to a particular input query, as well as the search patterns of queries, which may reveal information such as how many times the same query was issued.

Given an honest-but-curious adversary, the task of computing the k -nearest neighbours (k -NN) of a given query using a public cloud server, with the objective of achieving the above security goals in the cloud environment is difficult. One of the most attractive solutions is to use homomorphic encryption (HE). FHE (fully homomorphic encryption) [16] schemes allow the computation of arbitrary functions on encrypted data. Using FHE, data owners can offload their encrypted data to the public cloud, keeping all private or symmetric keys secret. When a client sends a query, the query is also encrypted using the same secret key and sent over to the cloud server. All computation on the cloud server is done on encrypted data and the resulting encrypted result is sent back to the clients, without compromising data confidentiality or the integrity of computation, even in the honest-but-curious adversary setting. Note that in this model, however, the actual algorithm, which is the sequence of computational steps on the data, is known to the insider, and is considered public. Care must be taken to design the algorithm to prevent leakage of search patterns and access patterns. Knowledge of the algorithm should not reveal anything about the data, query or results. Such FHE schemes however come at a significant operational cost and are not currently practical. For example, the state-of-the-art homomorphic sorting algorithm [12], takes 2 minutes to just sort 64 data items (32 bit), whereas as we show in our paper in Section 5, we are able to compute k -NN securely, with $k = 2$ for 30000 real-world data points (each point having 23 dimensions) in the same time.

¹<http://archive.ics.uci.edu/ml/>

To address performance issues of FHE, somewhat and partial HE ((S)HE and PHE) schemes have been proposed, which allow a restricted set of operations or sequences of operations on encrypted data, and are therefore more efficient. Examples include Paillier encryption [27] (which allow encrypted additions), LFHE [9], and BGN [8] (which allow computing restricted depth functions on encrypted data). While using simpler and more efficient schemes with restricted functionality, only a part of the computation is performed directly on the encrypted data. When more complex calculations are called for, these have to be done on plaintext values of intermediate results. To do this, another cloud provider is incorporated in the protocol. This cloud service provider is also assumed to be honest-but-curious and has access to secret keys which will allow it to decrypt the result of partial computations. Using intermediate plaintext values, more complicated operations are performed on these partial results, re-encrypted and sent back to the original cloud. The two clouds do not collude, the assumption is justified as these are public servers governed by legal contracts, and may even be business rivals. Colluding with each other will affect their reputation. This setting is called the *federated cloud model* as explained earlier.

The challenge now is to show that knowledge of such intermediate results does not leak information about the original data, query, and results as well as the access and search patterns. In this context, the state-of-the-art algorithm designed by Yousef et al. [14], shows that it is possible to design a secure k -NN scheme, where some of the secrets are given to one of the cloud servers, but both cloud servers do not learn anything about the original data. Our work also takes advantage of this model but explores a novel construction using a (S)HE scheme, and a more efficient protocol, allowing for asymptotically more efficient implementations for real-world scenarios.

2.3 Encrypted Computation

To find k -Nearest Neighbours, the distance between a given query point and all the other points in the database needs to be computed (in some appropriate dimension and measure). For computing Euclidean distance say in a two-dimensional space i.e., between two points (x_1, y_1) and (x_2, y_2) we need to compute $\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}$. In the interest of efficiency of computation, we can avoid the square root operation and work with squared Euclidean distances. This computation requires subtraction, squaring and addition operations in that order. After we compute the squared Euclidean distances in the cloud, we need to find the k minimum values. This requires us to order encrypted values.

Order Preserving Encryption (OPE), first proposed in [7] is also emerging as an important area of new research. Using OPE, it is possible for an observer to compute the order between two ciphertexts without having to decrypt them. Any OPE solution therefore necessarily leaks the original plaintext order among the encrypted ciphertexts [2], even if it does not reveal the value of the plaintexts themselves. OPE solutions by themselves are not sufficient for our problem, since our definition of Secure k -NN does not allow the adversary to learn anything about the original points or the query, and points have to be in plaintext for the server to order them after computing the distances. In [40], it is shown that solving Secure k -NN in the single cloud model securely implies that a secure OPE solution exists in this context, one which does not leak any information, including the very order, which is leaked by definition, and this is not possible.

(S)HE schemes on the other hand offer more functionality (rather than simple OPE) on encrypted data, and can be used cleverly to build a secure k -NN scheme.

2.4 Homomorphic Encryption and the LFHE scheme

We now give a brief description of the salient features of HE schemes and highlight the features of the leveled FHE (LFHE) [9] scheme we used in our implementation. HE allows direct computations to be performed on encrypted values, giving an encrypted result, which when decrypted gives the same plaintext results as if the same computations were performed on the plaintext values. An FHE scheme allows the computation of arbitrary functions on encrypted data.

A public key FHE scheme is an ensemble of four polynomial time algorithms:

- $(sk, pk) \leftarrow \text{KeyGen}(\$)$, the generation of a random public key and corresponding secret key pair.
- $c \leftarrow \text{Enc}_{pk}(m)$, the encryption of the a message m with the public key pk to produce a ciphertext c .
- $m \leftarrow \text{Dec}_{sk}(c)$, the decryption of the ciphertext with secret key sk to produce the same plaintext m .
- $c' \leftarrow \text{Eval}_{pk}(\phi, c_1, \dots, c_n)$ where ϕ is an arbitrary function in the message space, c_1, \dots, c_n are encryptions of inputs m_1, \dots, m_n to function ϕ . The result c' is the encryption of $m' = \phi(m_1, \dots, m_n)$, the encrypted output of application of the function on the plaintext inputs.

A partial homomorphic encryption scheme PHE is an HE scheme with a pre-defined function ϕ' , a restriction on the arbitrary function allowed in FHE. This restriction can be one function, such as addition or a sequence of functions in order, leading to a somewhat homomorphic encryption scheme ((S)HE) such as BGN, or a restriction on the kind of function (degree of the polynomial it can evaluate), for performance reasons. We assume that PHE and (S)HE satisfy the standard notion of security, whether it is against chosen plaintext attacks, which guarantee that ciphertexts output by the chosen HE scheme are indistinguishable from random, even to an adversary with access to an encryption oracle.

The (S)HE scheme we use in this paper is the Levelled FHE (LFHE) scheme implemented in HELib [17]. This LFHE scheme is based on the Brakerski-Gentry-Vaikuntanathan (BGV) scheme[10], and includes optimizations to make homomorphic evaluation runs faster, focusing mostly on the effective use of the Smart-Vercauteren [33] ciphertext packing techniques and the Gentry-Halevi-Smart [18] optimizations, with support for bootstrapping. The scheme is based on the ring learning with errors (RLWE) and the LWE problem, which have 2^λ security against known attacks. In addition to the **KeyGen**, **Enc**, and **Dec** functions, picking a level in the implementation L picks a depth L arithmetic circuit in **Eval**, with the computation quasilinear in the security parameter λ , lower levels corresponding to lower overheads. Further details of the LFHE scheme are presented in Appendix A.

3 SECURE k -NN

In this Section, we now describe our new Secure k -NN protocol in the non-colluding two-party setting described in Section 2. Section 3.1 presents the entities involved and Section 3.2 lays down the notation. Section 3.3 gives protocol details. The security guarantees of our protocol are discussed in detail in Section 4

and the performance characteristics are explored in detail in Section 5.

3.1 Entities

The main entities in our protocol are shown in Figure: 1.

- **Data owner** : The data owner is a trusted entity, the legal owner of the plaintext database, who outsources the storage of the encrypted data to Party A for k -NN computation, i.e., the plaintext database is not revealed to the party A. Once the data is outsourced, the data owner can be offline.
- **Party A** : Party A implements the storage and computation on an encrypted database. It receives encrypted query inputs and responds with k encrypted database points that represent the k -NN of the query point. It does not have access to any secret keys and works only on the encrypted data. Party A is assumed to be an honest-but-curious adversary, who will not tamper with the normal execution of the protocol, but has access to the internal state of its implementation, and could attempt to infer additional information about the characteristics of the plaintext data, query, results, or access and search patterns.
- **Party B** : Party B has access to the secret keys used to encrypt a given database, and does not have access to the encrypted database or query directly. Instead, it only has access to (partial) results of computations done on the encrypted data. Similar to Party A, Party B is honest-but-curious and does not tamper with the computation. However, it can use any information provided to infer characteristics about the plaintext database and query. A Secure k -NN solution will show that this information cannot be learned by Party B even if it has the secret key.
- **Clients** : These are users who are authorised by the data owner to interface with Party A and ask k -NN queries on the outsourced database. Clients have access to keys which allow them to send encrypted queries and decrypt the corresponding responses.

As the name suggests, in the non-colluding two party setting, Party A and Party B do not collude to expose the plaintext database to each other.

3.2 Notation

Our database P consists of n points $p_1, p_2 \dots p_n$. Each point is d -dimensional. The query Q is also a d -dimensional point.

- $D(p_i, Q)$ represents the squared Euclidean distance between p_i and Q .
- (S)HE: is a somewhat homomorphic encryption scheme which allows computation of this distance measure in the encrypted domain itself. For the distance measure used in this paper i.e. Euclidean Distance, we use the LFHE scheme [9]. Depending on the level chosen, e.g., with level 2, we can compute other measures such as Manhattan distance etc.

3.3 Setup

Figure 2 shows the entities, the communication and the computation phases in our main protocol. The Setup phase is executed once at the time of transferring the encrypted data to Party A. Let $(sk, pk) \leftarrow \text{KeyGen}(\$)$ be the secret-key and public-key respectively for the chosen (S)HE.

- Party A receives the public key pk from the data owner, as shown in label 1 in Figure 2.
- Party A also receives the encrypted database P' from the data owner, where the magnitude of each dimension d of each point p_i is encrypted under (S)HE using Enc_{pk} . These d encrypted values together constitute the d dimensional encrypted data points p'_i .
- Party B receives both sk and pk , as shown in label 2 in Figure 2.
- Clients receive both sk and pk , as shown in label 3 in Figure 2.

The inputs to our Secure k -NN protocol are the n encrypted points in P' and an encrypted d -dimensional query point $Q' \leftarrow \text{Enc}_{pk}(Q)$, of the plaintext query point Q computed by the client as shown in label 4 in Figure 2.

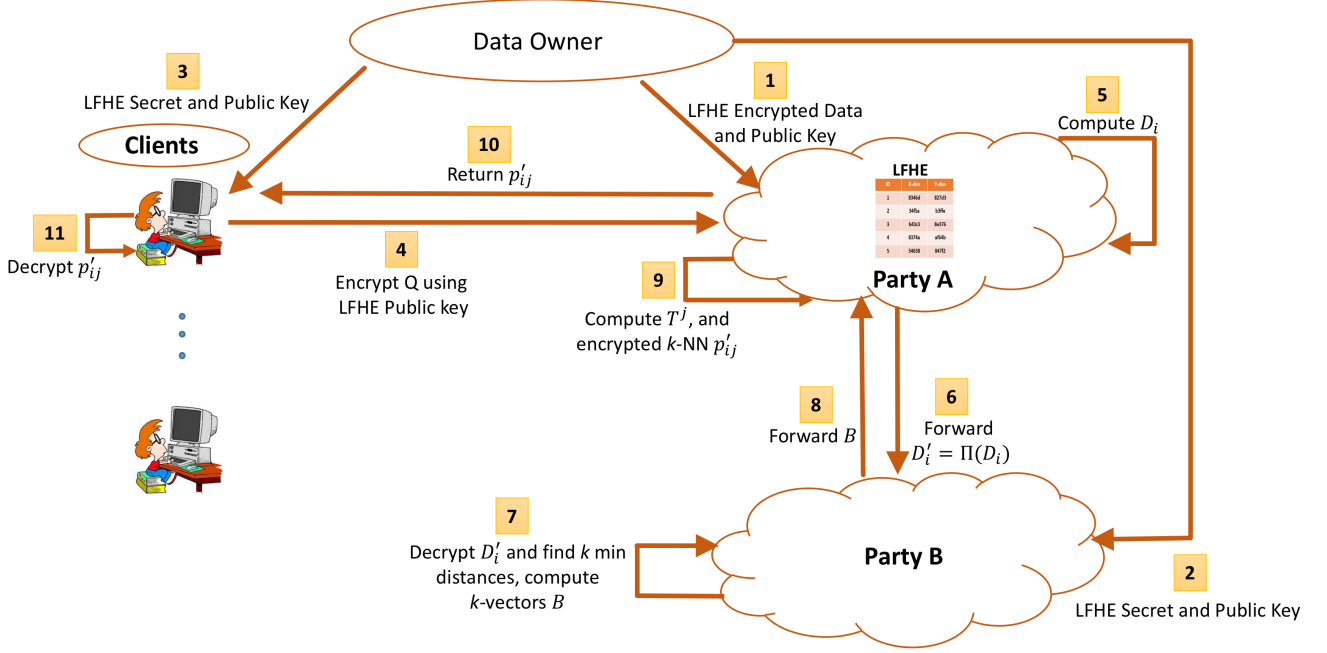

The output of the protocol, returned by Party A to the client, is the set of k encrypted points $\langle p'_{i_1}, p'_{i_2}, \dots, p'_{i_k} \rangle$, which are the encrypted k nearest neighbours to query Q in database P .

3.4 Secure k -NN Protocol

We describe our Secure k -NN protocol, which involves only one round of communication between the two parties, alternating between computations performed at Party A and Party B. At Party A, the computations are performed on encrypted data, and we show how no information is revealed to a curious insider apart from the protocol parameters, which are inputs to the algorithm itself. Party B has the secret key, but only sees values that are obtained by applying some function derived from the points in the database. We present the security guarantees of our protocol in detail in Section 4.

Compute Distances: In the first phase of our protocol after Setup at Party A, as shown in label 5 in Figure 2, we are given the encrypted database P' , and encrypted query Q' . For each d -dimensional point $p'_i \in P'$, i.e., the for all the n points in the encrypted database, we find the squared Euclidean distance between the given point and the query using our (S)HE with Eval_{pk} as shown in Steps 2–4 in Algorithm 1. Each ED_i is the encrypted value of the (square of the) distance between the given query and the i -th database point. In Step 5, we pick a polynomial $m(x)$ of the form $a_0 + a_1 \cdot x + a_2 \cdot x^2 + \dots + a_p \cdot x^p$ for some random $p \in \mathbb{N}$, where the coefficients a_0, \dots, a_p are picked uniformly at random within the range of the values of the (S)HE domain. For example, in our prototype implementation presented in this paper, we use positive random values picked from the range of points in $[1, 2^{32} - 1]$. We evaluate this monotonically increasing

Figure 2: Secure k -NN Protocol

1 Compute Distances: Party A

Data: P', Q'

Result: D'_i , the D_i in random permuted order

```

1 begin
2   for Each  $p'_i \in P'$  do
3      $ED_i \leftarrow \text{FindEncryptedDistance}(p'_i, Q')$ 
4     FindEncryptedDistance uses  $\text{Eval}_{pk}$  to compute
        $\sum_{i=1}^d (p'_i - Q'_i)^2$ 
5     Pick  $m$  a monotonically increasing polynomial with
       random coefficients
6     for  $i \leftarrow 1$  to  $n$  do
7        $D_i \leftarrow \text{EvalPoly}(m, ED_i)$ 
8       EvalPoly uses  $\text{Eval}_{pk}$  to evaluate  $m$  with  $ED_i$ 
9     Pick permutation  $\Pi$  over  $i$  points
10    Send  $D'_i \leftarrow \Pi(D_i)$  to Party B

```

polynomial transformation on each encrypted database point using **EvalPoly** to obtain the D_i s in Steps 6–8. Finally, we pick a permutation Π uniformly at random over the $n(n-1)/2$ points D_i s as $D'_i \leftarrow \Pi(D_i)$, in Steps 9–10 and send the distances to Party B out of order, as shown in label 6 in Figure 2.

Find Neighbours: In the second phase of our protocol at Party B, as shown in label 7 in Figure 2, the transformed points D'_i are received in random permuted order. We now form two vectors (arrays) of size k : NN and $NNindex$. In Steps 2–5 in Algorithm 2, we initialize $NN[i]$ to the first k points by decrypting the D'_i s (since we have the secret key sk), and store the corresponding index values $(1, \dots, k)$ in $NNindex$ as shown. For the remaining $k-n$ points, in steps 7–10, we first find the point with the maximum distance in NN and its corresponding $maxindex$ as

2 Find Neighbours: Party B

Data: D'_i , the D_i in random permuted order

Result: $\mathcal{B} = B^{i1}, \dots, B^{ik}$

```

1 begin
2    $NNindex[i] \leftarrow 0$ 
3   for  $i \leftarrow 1$  to  $k$  do
4      $NN[i] \leftarrow \text{Dec}_{sk}(D'_i)$ 
5      $NNindex[i] = i$ 
6   for  $i \leftarrow k+1$  to  $n$  do
7      $max \leftarrow NN[1], maxindex \leftarrow 1;$ 
8     for  $j \leftarrow 2$  to  $k$  do
9       if  $NN[j] > max$  then
10         $max \leftarrow NN[j]; maxindex \leftarrow j$ 
11     if  $(d \leftarrow \text{Dec}_{sk}(D'_i)) < max$  then
12        $NN[maxindex] = d$ 
13        $NNindex[maxindex] = i$ 
14    $\mathcal{B} \leftarrow \emptyset$ 
15   for  $j \leftarrow 1$  to  $k$  do
16     for  $i \leftarrow 1$  to  $n$  do
17       if  $i = NNindex[j]$  then
18          $B_i^j \leftarrow \text{Enc}_{pk}(1)$ 
19       else
20          $B_i^j \leftarrow \text{Enc}_{pk}(0)$ 
21      $\mathcal{B} \leftarrow \mathcal{B} \cup B^j$ 
22   Send  $\mathcal{B}$  to Party A

```

shown. Next, in Steps 11–13, for the new point in the i th position, we decrypt the value D'_i and check if it is smaller than the max distance we have seen so far. If it is, then we replace

the maximum value in NN with this and update the index value appropriately. At the end of this outer loop, the array NN will contain the k smallest values and the corresponding $NNIndex$ will track the index of these points. It is easy to see that the points corresponding to these permuted indices will be the k nearest neighbours for the query point in the original database, however, we need to transfer this information to Party A without revealing either the permuted indices or these values directly.

To do this, we construct the set \mathcal{B} of k row vectors B^j , where each B^j is a n -vector. For each permuted index value in $NNIndex$, we populate the array B^j as follows: for the position i in B^j at the $NNIndex[j]$ value, i.e., $i = NNIndex[j]$ we store an encryption of the value 1 (Party B also has the public key pk), and in the remaining $n - 1$ i -positions we store an encryption of the value 0 as shown in Steps 15–21. This new vector B^j is added to the set \mathcal{B} . We repeat this k times until all indices in $NNIndex$ have been processed. At the end of this phase, as shown in label 8 in Figure 2, we send the k row vectors \mathcal{B} to Party A (Step 22 in Algorithm 2).

3 Return kNN: Party A

Data: $\mathcal{B} \leftarrow B^1, \dots, B^k$
Result: $p'_{i1}, p'_{i2}, \dots, p'_{ik}$

```

1 begin
2   Receive set of  $k$   $n$ -dimensional vectors  $\mathcal{B}$ 
3   for  $j \leftarrow 1$  to  $k$  do
4      $T^j \leftarrow (\Pi(P^j)) \cdot B^j$ 
5      $p'_{ij} \leftarrow \text{Enc}(0)$ 
6     for  $l \leftarrow 1$  to  $n$  do
7        $p'_{ij} \leftarrow p'_{ij} + T_l^j$ 
8   Return  $p'_{i1}, p'_{i2}, \dots, p'_{ik}$ 

```

Return kNN: In the next phase of our protocol, Party A receives k n -dimensional row vectors (Algorithm 3 Step 2). As shown in label 9 of Figure 2, and Step 4 of the algorithm, we first apply the permutation Π selected by Party A in Algorithm 1 to the encrypted database points P^j . Applying the permutation Π on the points corrects the order of the 0s and 1s in B^j that was derived from the permuted sums in Party B. Next, we compute the scalar dot product (pointwise multiplication) between this permuted row vector with each of our B^j s, giving us an n -dimensional vector T^j . After this multiplication, the original point that is one of the k -NNs, i.e., p'_{ij} , will remain (in encrypted form) in T^j , all other entries will become (encrypted) zeros. We sum the n elements of each of the T^j row vectors as shown in Steps 5–7. The k vector sums are the encrypted k -NNs, i.e., the points $p'_{i1}, p'_{i2}, \dots, p'_{ik}$, which can now be returned as the final result in Step 8 of algorithm and label 10 in Figure 2. Clients can decrypt these p'_{ij} s using sk to obtain the plaintext points that correspond to the k nearest neighbours as shown in label 9 in Figure 2.

There are two main *novel* ideas in our protocol:

- The use of m , a monotonically increasing polynomial with uniformly random coefficients, which effectively masks the database values to Party B.
- The construction of vectors B^j along with the uniformly random permutation Π , which prevents Party A from learning the query results, as well as the access pattern and query search pattern.

The communication and computation overheads in our protocol are as follows. Party A computes $O(n)$ encrypted values, and sends one set of n values to Party B. Party B computes n decryptions and $O(nk)$ encryptions and returns $O(nk)$ encrypted values to Party A. In the last phase Party A performs $O(nkd)$ operations on the ciphertexts.

3.5 Comparison of Performance and Efficiency with Yousef et al.

We present an algorithmic comparison of the efficiency of our protocol with that of Yousef et al. [14], the current state-of-the-art scheme for Secure k -NN in the two-party model. Both schemes involve a pair of non-colluding parties, one of which is in possession of the secret key of the somewhat homomorphic encryption scheme underlying the respective protocol. The first major advantage of our protocol is the reduced number of round communications - one, as compared to k for Yousef et al., where k is the number of nearest neighbours requested by the client. Thus, the cost of round communication in their protocol depends on the query, while in our protocol it is constant. Additionally, the construction of Yousef et al. performs bit-level decomposition operations on the encrypted data, which are costly and require specific capabilities which only certain (S)HE schemes can afford (e.g. Yousef et al. use the Paillier cryptosystem-based (S)HE). On the other hand, our protocol only exploits the basic capabilities that any (S)HE scheme can afford. In other words, our protocol uses the (S)HE scheme as a black-box, which can be easily instantiated using known (S)HE schemes such as LFHE (leveled fully homomorphic encryption) with optimized implementations. The comparison in terms of computational overheads is presented in Table 1 for computing k -NN over n data points, each of dimension d such that each dimension takes l bit values and m is a degree D polynomial in our solution.

4 SECURITY GUARANTEES

In this section, we discuss the security of our protocol in detail. We begin with the assumptions. In our secure k -NN protocol, Party A and Party B are assumed to be honest-but-curious, as described earlier. Party A will follow the protocol steps correctly, but we cannot rule out insider attacks. As discussed earlier, we do not address side channels in this paper. We also assume Party A and Party B do not collude. Party B additionally is trusted with the secret key of the (S)HE scheme. Party B again is honest-but-curious, and anything that Party B has or can compute is also assumed to be exposed to an insider. Informally, our protocol is secure in the following sense: even if this key is compromised and the data values exposed to an insider in Party B, the original database, query, and results are still secret to both Party A and B. For emphasis, we recall that Party B and Party A do not collude, and Party A does not have the decryption keys.

We present our security arguments focusing on the views of the two untrusted parties - Party A and Party B, under the assumption that they are mutually non-colluding. All other parties (clients and database owners) are trusted.

4.1 Leakage Profile for Party A

We explicitly enumerate the leakage to Party A at different phases of the overall protocol. Observe that Party A is involved in **Compute Distances** and **Return kNN**, we focus on the leakage to Party A during each of these:

Table 1: Computational overheads

	Yousef et al	Our Secure k -NN protocol
Number of Homomorphic operations	$O(n(2kl + d))$	$O(n(k + d + D))$
Number of encryptions	$O(nkl)$	$O(nk)$
Number of decryptions (Party B)	$O(n(kl + d))$	$O(n)$
Number of round communications	$O(k)$	1
Communication overhead per round	$O(nl + d)$ bits	$O(nl)$ bits

- Compute Distances:** In this phase, Party A computes the set of encrypted distances ED_i between each encrypted data point p_i and the encrypted query point Q' (Steps 3–4). Each of these computations is performed using the **FindEncryptedDistance** function, which in turn uses the homomorphic evaluation function **Eval** of the (S)HE scheme. Hence, the CPA security guarantees of the underlying (S)HE ensures that none of these computations reveal any information about the underlying data points or the plaintext distances to Party A. Subsequently, Party A homomorphically evaluates a randomly chosen polynomial m on each ED_i using the **EvalPoly** function to obtain the corresponding encrypted output D_i . Again, since all polynomial evaluations are on encrypted data, any non-negligible leakage to Party A from these computations amounts to a violation of the CPA security of the (S)HE scheme.
- Return kNN:** This phase is an oblivious transfer of the knowledge of the k -nearest data points to Party A. Specifically, we argue that Party A does not learn which k points in the encrypted database correspond to the output set of points p'_{i1}, \dots, p'_{ik} . The first observation that we use is that the set of k n -dimensional vectors B^1, \dots, B^k received by Party A contain encryptions of 0 and 1. As already mentioned, the CPA security guarantees of the underlying (S)HE ensures that Party A cannot distinguish between these 0 and 1 entries. Hence the vectors themselves do not reveal to Party A their correspondence to the respective points in the database. The inner product computations in Steps 4–7 are again performed homomorphically and leak no information to Party A. Finally, observe that multiplying an encrypted point by an encryption of 1 essentially results in a randomized re-encryption of the same point. Since, Party A has no knowledge of which entry in the vectors B^1, \dots, B^k corresponds to 1, the output points p'_{i1}, \dots, p'_{ik} cannot be traced back to the originally encrypted points in the database. Once again, any violation of the above guarantee amounts to a violation of the CPA security of the (S)HE scheme.

The aforementioned leakage profile for Party A leads to the following security guarantee with respect to Party A:

THEOREM 4.1. Secure k -NN Guarantee: Party A: *Our secure k -nearest neighbour protocol leaks no information to Party A except the number of nearest neighbours k returned by the protocol. In particular, Party A gains no knowledge of the access pattern, that is, the set of points in the database corresponding to the k -nearest neighbour points returned by the protocol, and does not learn the query pattern, which reveals if two queries were the same.*

4.2 Leakage Profile for Party B

In this section, we explicitly enumerate the leakage to Party B in the **Find Neighbours** phase of the protocol. Party B receives

the set D'_i of encrypted polynomial evaluation outputs $m(ED_i)$ in random permuted order. Note that since we have picked a secure pseudorandom permutation, which is computationally difficult to invert, implying that the exact identity of points associated with any given difference value is hidden from Party B. Since the polynomial m is order preserving, Party B can sort the decrypted polynomial outputs. We now examine the possibility of any leakage to Party B from the resulting system of ordered equations. Let $d''_1 < d''_2 < \dots < d''_n$ be the ordered set of plaintext distances, and $m(d''_1) < m(d''_2) < \dots < m(d''_n)$ be the ordered set of polynomial outputs obtained by Party B upon decryption. As mentioned earlier, the polynomial $m(x)$ is of the form $a_0 + a_1 \cdot x + a_2 \cdot x^2 + \dots + a_p \cdot x^p$ for some random $p \in \mathbb{N}$. Party B can formulate the following system of equations:

$$\begin{aligned}
 m(d''_1) &= a_0 + a_1 \cdot d''_1 + a_2 \cdot (d''_1)^2 + \dots + a_n \cdot (d''_1)^p \\
 m(d''_2) &= a_0 + a_1 \cdot d''_2 + a_2 \cdot (d''_2)^2 + \dots + a_n \cdot (d''_2)^p \\
 &\vdots \\
 m(d''_n) &= a_0 + a_1 \cdot d''_n + a_2 \cdot (d''_n)^2 + \dots + a_n \cdot (d''_n)^p
 \end{aligned}$$

where only the left-hand side of each equation is known to Party B. Without loss of generality, we may assume that Party B can guess with high probability the degree p of the polynomial chosen by Party A, as well as the range of values (say $[0, 2^N]$) that each plaintext distance d''_i can take. This is a particularly relevant assumption in the context of real-world datasets, where the adversary may possess some apriori knowledge of the range of Euclidean distances between the data points. In addition, since homomorphic polynomial evaluation in the encrypted domain is a costly operation, the degree p can only take a small range of values, which Party B can also accurately guess in a small number of trials. However, we prove that even if Party B has full knowledge of the aforementioned parameters, it cannot recover the original data points within a feasible amount of computation time. Observe that the system of equations has exactly $n + p + 1$ unknown variables from Party B's point of view, while the number of equations is only n . Hence, Party B must correctly guess the $p + 1$ smallest distances $d''_1, d''_2, \dots, d''_{p+1}$ to recover the polynomial coefficients. The average number of possible values that these distances can take is $\binom{2^N}{p+1}$, which is approximately the same as $2^{N \cdot (p+1)}$ for $2^N \gg (p + 1)$. In other words, the probability that Party B successfully recovers the polynomial coefficients, and subsequently the plaintext distances, is approximately $1/2^{N \cdot (p+1)}$, which is close to negligible. For example, for $N = 16$ and $p = 9$, the probability that Party B is able to recover the plaintext distances is approximately 2^{-160} , which is close to negligible for a security level of 160 bits. Thus even when the range of plaintext distances and the degree of the polynomial chosen by Party A are reasonably small and known apriori to Party B, the information leakage is negligible. Also note that Party A refreshes the polynomial for each query point, implying that Party B gains no

additional information across the queries. Finally, even if Party B is able to recover the plaintext distances in some extreme cases (e.g., when the plaintext distance values follow some specific pattern), it still does not directly reveal the plaintext data points to Party B, as the query point is also unknown.

The only possible leakage to Party B in this round is the presence of such points in the database that are equidistant from the query point Q . This is leaked from the presence of identical values in the set of values $m(d''_1), m(d''_2), \dots, m(d''_n)$. However, since the order of the values is randomly permuted by Party A, Party B cannot map these values back to the original index of the data points in the database.

The aforementioned leakage profile for Party B leads to the following security guarantee with respect to Party B:

THEOREM 4.2. Secure k -NN Guarantee: Party B: *Our secure k -nearest neighbour protocol leaks no information to Party B except the number of nearest neighbours k to be returned by the protocol and the number of equidistant points in the database with respect to a given query point Q .*

4.3 Comparison of Security Guarantees with Yousef et al.

We conclude the discussion on the security of our k -NN protocol with a comparison of our security guarantees with those afforded by the current state-of-the-art scheme proposed by Yousef et al. [14]. Both schemes involve a pair of non-colluding parties, one of which is in possession of the secret key of the somewhat homomorphic encryption scheme underlying the respective protocol. In both schemes, one of the parties (Party A in our case), encounters only encrypted data and consequently, learns nothing about the data access pattern or search pattern from the protocol. In Yousef et al.'s protocol, one of the parties (equivalent to Party B) learns the distance between the query point and the global nearest neighbour at each stage of the protocol. Moreover, the presence of an irreversible permutation implies that this leakage cannot be mapped back to an actual point in the database. This distance value is not leaked by our protocol.

In our protocol, Party B learns the presence of pairwise equidistant points in the database with respect to a given query point. That is, whether there are two or more points that are equidistant is revealed to Party B, not the value of the distances unlike in Yousef et al. Moreover, the pairwise distances in our protocol are randomly permuted, which ensures that these leakages cannot be mapped back to identify the corresponding point pairs in the actual database. In both protocols, in spite of the knowledge of some distance values, or the knowledge of the number of equidistant points, the original database, query, results or access and search patterns cannot be deduced.

In the next section, we describe our reference implementation and show how it is asymptotically faster than the state-of-the-art algorithm and present its performance characteristics on simulated and real-world data sets.

5 IMPLEMENTATION AND EXPERIMENTS

In this section, we present our implementation details and record the experiments carried out to test the performance of the proposed protocol. Our experimental setup consists of four machines, representing the data owner, Party A, Party B and client. The configuration of machines representing Party A and Party B are: 4 core 2.8 GHz processors, 16 GB RAM running Ubuntu 16.04

Figure 3: Running time for real world cancer data set, 858 points with 32 dimensions

Figure 4: Running time for real world credit card data set, 30000 points with 23 dimensions

LTS. The configuration of machines representing Data Owner and Client are: 4 core 2.8 GHz processors, 8 GB RAM running Ubuntu 16.04 LTS.

We used the HELib [17] library, with LFHE as the underlying encryption mechanism. This library is written in C++ and we implemented our protocols also in C++. In our implementation, we set $p = 1099511627689$, a large prime between 2^{40} and 2^{87} , the maximum depth to 10 and the security parameter to 128, i.e., offering 2^{128} bits of security.

5.1 Real world data

Our first set of results is on real-world data from the UCI Machine learning repository [24]. We focus on two datasets: Cervical cancer (Risk Factors) and Default of credit card clients. Our goal is to test how our Secure k -NN algorithm performs when we attempt to find reports that cluster near a chosen query report. The cervical cancer dataset contains 858 data points each having 32 dimensions, representing demographic information, habits, and historic medical records of 858 patients. The default of credit card clients dataset contains 30000 data points each having 23 dimensions including sensitive information such as the amount of given credit, gender, age, education, marital status etc. We pre-processed these datasets so that they contain only non-negative integer values. Both these datasets have PII information and are good candidates for encrypted analytics. Again we emphasize that our goal in this study is not to comment on the predictive accuracy of k -NN by itself as a suitable data mining algorithm for these datasets.

Figure 5: Running time when number of dimensions = 2 and $k = 5$

Figure 3 shows the measured running time of our protocol when we vary k from 2 to 20 on the cancer data set. As shown in the figure, we can compute 2-NN for all the points in less than a minute (45 s), 8-NN in 2 minutes and 45 seconds and 16-NN in 5 minutes and 28 seconds. The function grows linearly with k .

Figure 4 shows the measured running time of our protocol when we vary k from 2 to 20 for the credit card clients data. As shown in the figure, we can compute 2-NN in less than 2 minutes and 20-NN in 14 minutes and 20 seconds, with the function growing linearly in k . In each of these experiments, we generate a random data point to serve as the query point. The experiment is then repeated with multiple such query points and the average time taken to execute a query is recorded. From the figures, it is clear that our protocol scales linearly with k .

Both these experiments show that our implementation overheads are very competitive, making a case for real-world application of our algorithms to perform simple pattern matching on sensitive data. Other applications where this technique can be directly applied include spatial databases and location-based search (for example a taxi-for-hire application), where the query looks for points within a small set of records that are already filtered.

Note that in our protocol, the two parties A and B communicate with each other directly, without going back to the client. The communication cost between the parties, i.e., sending the monotonically increasing function of squared Euclidean distances, is independent of the number of dimensions in the original dataset, i.e., only one value is sent for each pair of points (regardless of the value of d). Response from Party B is also independent of the dimension of the data. The computational overhead of calculating the squared Euclidean distances on Party A depends naturally on the dimensions, which is unavoidable.

5.2 Simulation

There are three varying parameters in our protocol, a) number of data points n b) the number of dimensions d and c) k the number of nearest neighbours. By generating synthetic data we are able to keep two parameters fixed and check the effect of the third parameter on running time of the query. Our simulation-data generator uses a uniform random distribution to generate the data.

Figure 5 shows how the running time varies when the number of data points are increased, keeping the number of dimensions d and k constant (5 in this case). From this figure, we can clearly

Figure 6: Running time when number of data points = 200000 and $k = 2$

Figure 7: Running time when number of data points = 200000 and dimensions = 2

see that the running time of our protocol ranges from 23 seconds up to 3 minutes, and grows linearly with the size of the dataset n , which ranges from 20000 to 200000 points.

Figure 6 shows how the running time varies when the number of dimensions in the data is increased, from 1 to 10, keeping the number of data points n as 200000 and $k = 2$ as constant. The running time ranges from 2 minutes and 17 seconds to less than 9 minutes for 10 dimensions. The figure clearly shows that our protocol scales linearly with the number of dimensions.

Figure 7 shows how the running time varies when k is increased from 1 to 20 keeping the number of data points as 200000 and number of dimensions $d = 2$. The running time ranges from less than 2 minutes to around 8 minutes as shown. The figure clearly shows that the running time scales linearly with k .

From the above experiments, it is clear that the running time of our protocol is linear in k , n and d . Note that our protocol requires only **one** round of communication between Party A and Party B. In comparison, Yousef et al., requires at least $O(k)$ rounds of communication to compute the secure k -NN, with each round sending $O(nb)$ points where n is the database size and b the bit size of every element. Additionally, more rounds are required to compute the squared Euclidean distances and secure bit decomposition, which are used subsequently to compute k -NN.

For a similar machine configuration², for 2000 points and 6 dimensions, with $k = 25$ our protocol runs in 1 minute and 37 seconds, whereas Yousef et al., report a running time of 55 minutes and 39 seconds. We emphasize that while this comparison is

²6 cores, 3.07 GHz processor and 12GB RAM running Ubuntu 10.04 LTS

done on different machines, the trend observed is explained by our efficient one-round communication and the simplified computations on Parties A and B, without compromising security guarantees.

6 RELATED WORK

Finding k - Nearest Neighbours is a fundamental operation in many data mining and machine learning algorithms. In this section, we present an overview of the techniques developed for secure k -nearest neighbour problem (SkNN). SkNN is a specific use case of the much broader problem of secure processing over outsourced encrypted data. This area has been well studied and many techniques have been proposed. Some of the techniques are generic, i.e. they are able to support a wide variety of queries over the encrypted data, while others enable a particular operation, such as k -NN, over the encrypted data. The existing work can be categorized into various buckets depending on the underlying mechanism used, including privacy preserving data mining, garbled circuit implementations of secure k -NN, secure multiparty computation (SMC), private information retrieval (PIR) schemes, secure hardware-based techniques and other solutions that directly implement secure k -NN protocols.

The first three solutions, privacy-preserving data mining, garbled circuits, and SMC, cannot be compared directly with our work, as the goals, assumptions and models are different as discussed next. In privacy-preserving data mining [3] [15] [23] [25] [35] privacy is achieved by transforming the data using anonymization models such as k -anonymity, data perturbation i.e adding noise to the data, suppressing some tuples, etc. The transformed data preserves the ability to answer the required query within an accepted error limit. The drawback of these techniques is that they lead to information loss. Typically a superset of the results are returned and the client has to process the query results further. These techniques outsource the transformed data to the server in plaintext, which leaks information as well.

Songhori et al[34] propose to use Yao's garbled circuit protocol for secure k -NN computation. In their setting, Alice has a query point Q and Bob has the dataset S . They want to jointly compute the k -NN of Q in S such that Bob does not learn anything about Q and Alice does not learn anything about S except k -NN. This solution is not geared to outsourcing as Bob has the data in plaintext.

Secure multiparty computation (SMC) techniques enable multiple parties to securely evaluate a function of their private inputs without revealing the inputs of one party to the others. SMC has been leveraged to compute SkNN by various solutions [32] [31] [37]. They partition the data and give to multiple parties, which then compute k -NN as an SMC. Again, this is fundamentally different from our work because the parties can view the data in plaintext.

Providing secure database-as-a-service has been investigated by CryptDB[30] and Monomi [36]. They use property preserving encryption such as OPE [2][7][6] to handle a portion of the query processing directly on encrypted data stored at the cloud efficiently. The portion of query which cannot be processed by these property preserving encryption schemes is executed at the client side after decryption of data returned by cloud. Monomi [36] shows that such solutions can provide good performance if they are tuned properly for the query workload, though for an arbitrary query the performance can deteriorate significantly.

Also, it needs a full-fledged database engine at the client side which is not always possible, e.g., on mobile devices.

Secure Hardware based techniques, including Cipherbase and others[1] [26] [4] [5] assume the availability of a secure co-processor at the cloud server. These co-processors are specially built such that no outside entity can read the data stored inside it (tamper-proof hardware). The computations performed inside the co-processor are also isolated from the outside world. Data owners upload the keys to the co-processor in a secure manner. The logic for processing, for example, k -NN, is also installed on the co-processor. For query processing, the encrypted data and encrypted query point are sent to the co-processor, which decrypts the data using the keys stored on it and runs the installed logic on the decrypted data returning the final answer in encrypted form to the client. Such techniques give strong security guarantees. However, the co-processors are resource constrained and are less powerful than the regular processors with limited memory available to them. Also, the deployment and maintenance of such co-processors is not straight forward, as some operations have to be performed by the clients, e.g., key refresh, requiring the client to maintain the hardware.

Using PIR (Private Information retrieval) for secure k -NN has been studied in [19] [29]. PIR allows users to retrieve an object X_i from a set $X = X_1, X_2, \dots, X_n$ stored at the server without revealing i to server. Again, PIR schemes work on plaintext data on the server and guarantee that a user's query point will not be revealed, different from our setting.

Wong et al[39] propose a new encryption scheme called ASPE (Asymmetric Scalar Product Preserving Encryption), to compare the distance between a query point and compute the distances required for k -NN. Hu et al[21] propose a secure k -NN method based on provable secure homomorphic encryption. However, the setting used by them is different from us in that the client has the ciphertext while the server has the capability to decrypt. Both solutions are vulnerable to Chosen Plaintext Attacks [40].

Yao et al[40] establish a relationship between the SkNN problem and the order preserving encryption (OPE) problem. They show that SkNN is at least as hard as OPE in a single cloud setting. They propose a solution based on Voronoi diagrams, in which the server returns a superset of results for the k -NN. On the other hand, we return the exact result of k -NN to the client in the two party federated cloud setting.

Sunoh et al[13] provide a solution for secure k -NN which uses mOPE(mutable Order Preserving Encryption). They propose two methods, one based on Voronoi diagrams, which returns the exact k -NNs but is expensive when $k > 1$, and another method based on triangulation, which is more efficient but gives exact results for only $k = 1$. For $k > 1$ it gives false positives which have to be filtered out by the client. Their solution also requires round communication between the server and client to first reduce the potential candidates and to find the k -NN. No security proofs are provided. Also, this solution has an expensive database update procedure which requires changing of encrypted data.

In his seminal work, Gentry [16] proposed a construction for a fully homomorphic encryption scheme (FHE). FHE allows computation of any function directly on encrypted data and a solution for computing k -NN can be developed using this. As discussed earlier, the computational cost of FHE is very high for real world applications.

Yousef et al[14] describe the current state-of-the-art protocol for SkNN in the two party federated cloud model. They use Paillier encryption [27] as the underlying cryptographic tool. Paillier

encryption is additive homomorphic. Using this property they develop protocols which compute k -NN securely in the federated cloud model. Their solution provides very strong security guarantees and is able to hide the data access pattern as well. However, this security comes at the cost of performance, taking minutes to perform queries that we can execute in seconds and milliseconds. We are able to improve upon the performance characteristics as shown in Section 5, while maintaining strong security guarantees, making it more suitable for real-world deployments.

Other recent related work includes Lei et al. [22], a SkNN scheme for 2-D data points using LSH (location sensitive hashing). They first construct the secure index for the data and then outsource the secure index and encrypted data to the cloud. Since the scheme uses LSH data structures, their results contain false positives. Also related to computing on encrypted data, though not k NN, is Seabed [28], where the authors use an additively symmetric homomorphic encryption scheme to compute large-scale aggregations of data in an enterprise setting and prevent against frequency attacks.

7 CONCLUSIONS

This paper describes a new protocol for efficient secure k - Nearest Neighbours on encrypted data. We use LFHE, a somewhat homomorphic encryption scheme as our basic building block, in the two party federated cloud model. Our adversary model captures insider attacks under the honest-but-curious assumption. Our protocol is fast compared to the state of the art, without compromising on security guarantees. Our implementations are fast and scalable, and our experiments on real-world data show how basic data mining on encrypted data can be practical. In the future, we plan to extend our work to other data mining algorithms, including k -Means and Apriori.

A THE LFHE SYSTEM

The general encryption of BGV scheme that can be instantiated to both LWE and RLWE. We will describe RLWE which used by HELib. The RLWE-based public key encryption scheme as follows. Most of the description and equations are taken from[9] [38].

In general, homomorphic encryption scheme is a tuple (HE.KeyGen, HE.Enc, HE.Dec, HE.Eval) of probabilistic polynomial time algorithms. In BGV, the message space of the scheme will always be some ring \mathbf{RM} and our computational model will be arithmetic circuits over this ring (i.e. addition and multiplication gates).

- (1) HE.KeyGen takes the security parameter (and possibly other parameters of the scheme) and produces a secret key sk and a public key pk .
- (2) HE.Enc takes the public key pk a message m and produces a ciphertext c , which is the encryption of m .
- (3) HE.Dec takes the secret key sk and a ciphertext c and produces a message m .
- (4) HE.Eval takes the public key pk , an arithmetic circuit f over \mathbf{RM} , and ciphertexts c_1, \dots, c_l where l is the number of inputs to f , and outputs a ciphertext c_f .

Given the security parameter λ and an additional parameter μ , first choose a μ -bit modulus q . Where q an odd positive modulus $q = q(\lambda)$. For RLWE scheme, chose the degree $d = d(\lambda, \mu)$, a "noise" distribution $\chi = \chi(\lambda, \mu)$, let the "dimension" $n = \lceil 3 \log q \rceil$. Let $R_q = \mathbb{Z}_q[x]/(f(x))$ with $f(x)$ a polynomial of degree d . $f(x) = x^d + 1$ and $d = d(\lambda)$ is a power of 2. To get the secret key, first draw \mathbf{s}' uniformly from χ . The secret key is then

$$\mathbf{s} = (1, \mathbf{s}') \in R_q^2$$

To get the public key, first generate vectors $\mathbf{A}' \leftarrow R_q^n$, $e \leftarrow \chi^n$, then set $b = -\mathbf{A}'\mathbf{s}' + 2e$. Set public key $A = (b|\mathbf{A}') \in R_q^{n \times 2}$. Note that $A \cdot \mathbf{s} = 2e$.

Suppose $m \in \{0, 1\}$ is the bit we wanting to encrypt. To encrypt, we do the following:

- (1) Select a random $r \in R_q^n$ and expand the message $m = (m, 0) \in R_q^n$.
- (2) Output $= m + A^T r \in R_q^n$.

According to $RLWE_{d,q,\chi}$ where χ is a uniform distribution over R_q , we can use this scheme a polynomial number of times with negligible probability that an adversary can guess \mathbf{s} .

To decrypt, do the following:

- (1) Compute $b' = \lfloor \langle \mathbf{c}, \mathbf{s} \rangle \rfloor_q$
- (2) Output $m = \lfloor b' \rfloor_2$

A Parallel and Scalable Processor for JSON Data

ABSTRACT

Increasing interest in JSON data has created a need for its efficient processing. Although JSON is a simple data exchange format, its querying is not always effective, especially in the case of large repositories of data. This work aims to integrate the JSONiq extension to the XQuery language specification into an existing query processor (Apache VXQuery) to enable it to query JSON data in parallel. VXQuery is built on top of Hyracks (a framework that generates parallel jobs) and Algebricks (a language-agnostic query algebra toolbox) and can process data on the fly, in contrast to other well-known systems which need to load data first. Thus, the extra cost of data loading is eliminated. In this paper, we implement three categories of rewrite rules which exploit the features of the above platforms to efficiently handle path expressions along with introducing intra-query parallelism. We evaluate our implementation using a large (803GB) dataset of sensor readings. Our results show that the proposed rewrite rules lead to efficient and scalable parallel processing of JSON data.

1 INTRODUCTION

The Internet of Things (IoT) has enabled physical devices, buildings, vehicles, smart phones and other items to communicate and exchange information in an unprecedented way. Sophisticated data interchange formats have made this possible by leveraging their simple designs to enable low overhead communication between different platforms. Initially developed to support efficient data exchange for web-based services, JSON has become one of the most widely used formats evolving beyond its original specification. It has emerged as an alternative to the XML format due to its simplicity and better performance [28]. It has been used frequently for data gathering [22], motion monitoring [20], and in data mining applications [24].

When it comes time to query a large repository of JSON data, it is imperative to have a scalable system to access and process the data in parallel. In the past there has been some work on building JSONiq add-on processors to enhance relational database systems, e.g. Zorba [2]. However, those systems are optimized for single-node processing.

More recently, parallel approaches to support JSON data have appeared in systems like MongoDB [10] and Spark [7]. Nevertheless, these systems prefer to first load the JSON data and transform them to their internal data model formats. On the other hand systems like Sinew [29] and Dremel [27] cannot query raw JSON data. They need a pre-processing phase to convert the input file into a readable binary for them (typically Parquet [3]). They can then load the data, transform it to their internal data model

and proceed with its further processing. The above efforts are examples of systems that can process JSON data by converting it to their data format, either automatically, during the loading phase, or manually, following the pre-processing phase. In contrast, our JSONiq processor can immediately process its JSON input data without any loading or pre-processing phases. Loading large data files is a significant burden for the overall system's execution time as our results will show in the experimental section. Although, for some data, the loading phase takes place only in the beginning of the whole processing, in most real-time applications, it can be a repetitive action; data files to be queried may not always be known in advance or they may be updated continuously.

Instead of building a JSONiq parallel query processor from scratch, given the similarities between JSON and XQuery, we decided to take advantage of Apache VXQuery [4, 17], an existing processor that was built for parallel and scalable XQuery processing. We chose to support the JSONiq extension to XQuery language [8] to provide the ability to process JSON data. XQuery and JSONiq have certain syntax conflicts that need to be resolved for a processor to support both of them, so we enhanced VXQuery with the *JSONiq extension* to the XQuery language, an alteration of the initial JSONiq language designed to resolve the aforementioned conflicts [9].

In extending Apache VXQuery, we introduce three categories of JSONiq rewrite rules (*path expression*, *pipelining*, and *group-by* rules) to enable parallelism via pipelining and to minimize the required memory footprint. A useful by-product of this work is that the proposed group-by rules turn out to apply to both XML and JSON data querying.

Through experimentation, we show that the VXQuery processor augmented with our JSONiq rewrite rules can indeed query JSON data without adding the overhead of the loading phase used by most of the state-of-the-art systems.

The rest of the paper is organized as follows: Section 2 presents the existing work on JSON query processing, while Section 3 outlines the architecture of Apache VXQuery. Section 4 introduces the specific optimizations applied to JSON queries and how they have been integrated into the current version of VXQuery. The experimental evaluation appears in Section 5. Section 6 concludes the paper and presents directions for future research.

2 RELATED WORK

Previous work on querying data interchange formats has primarily focused on XML data [26]. Nevertheless there has been considerable work for querying JSON data. One of the most popular JSONiq processors is Zorba [2]. This system is basically a virtual machine for query processing. It processes both XML and JSON data by using the XQuery and JSONiq languages respectively. However, it is not optimized to scale onto multiple nodes with multiple data files, which is the focus of our work. In

contrast, Apache VXQuery is a system that can be deployed on a multi-node cluster to exploit parallelism.

A few parallel approaches for JSON data querying have emerged as well. These systems can be divided into two categories. The first category includes SQL-like systems such as Jaql [14], Trill [18], Drill [6], Postgres-XL [11], MongoDB [10] and Spark [13], which can process raw JSON data. Specifically, they have been integrated with well-known JSON parsers like Jackson [1]. While the parser reads raw JSON data, it converts it to an internal (table-like) data model. Once the JSON file is in a tabular format, it can then be processed by queries. Our system can also read raw JSON data, but it has the advantage that it does not require data conversion to another format since it directly supports JSON’s data model. Queries can thus be processed on the fly as the JSON file is read. It is also worthwhile mentioning that Postgres-XL (a scalable extension to PostgreSQL [12]) has a limitation on how it exploits its parallelism feature. Specifically, while it scales on multiple nodes it is not designed to scale on multiple cores. On the other hand, our system can be multinode and multicore at the same time. In the experimental section we show how our system compares with two representatives from this category (MongoDB and Spark).

We note that AsterixDB [5], can process JSON data in two ways. It can either first load the file internally (like the systems above) or, it can access the file as external data without the need of loading it. However, in both cases and in contrast to our system, AsterixDB needs to convert the data to its internal ADM data model. In our experiments we compare VXQuery with both variations of AsterixDB.

Systems in the second category (e.g. Sinew [29], Argo [19] and Oracle’s system [25]) cannot process raw JSON data and thus need an additional pre-processing phase (hence an extra overhead than the systems above). During that phase, a JSON file is converted to a binary or Parquet ([3]) file that is then fed to the system for further transformation to its internal data model before query processing can start.

Systems like Spark and Argo process their data in-memory. Thus, their input data sizes are limited by a machine’s memory size. Recently, [23] presents an approach that pushes the filters of a given query down into the JSON parser (Mison). Using data-parallel algorithms, like SIMD vectorization and Bitwise Parallelism, along with speculation, data not relevant to the actual query is filtered out early. This approach has been added into Spark and improves its JSON performance. Our work also prunes irrelevant data, but does so by applying rewrite rules. Since the Mison code is not available yet, we could not compare with them in detail; we also need to note that Mison is just a parallel JSON parser for JSON data. In contrast, VXQuery is an integrated processor that can handle the querying of both JSON and XML data (regardless of how complex the query is).

As opposed to the aforementioned systems, our work builds a new JSONiq processor that leverages the architecture of an existing query engine and achieves high parallelism and scalability via the employment of rewrite rules.

3 APACHE VXQUERY

Apache VXQuery was built as a query processing engine for XML data implemented in Java. It is built on top of two other frameworks, namely the Hyracks platform and the Algebricks layer. Figure 1, also, shows AsterixDB [5], which uses the same infrastructure.

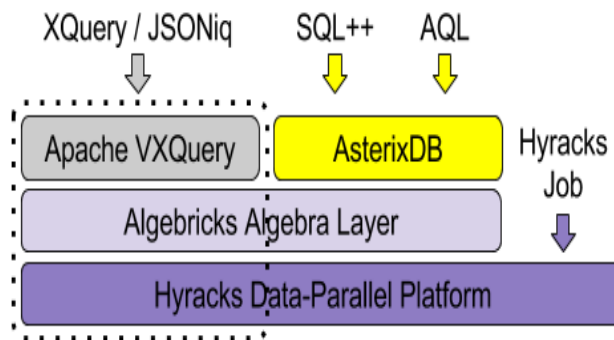

Figure 1: The VXQuery Architecture

3.1 Infrastructure

The first layer is *Hyracks* [16], which is an abstract framework responsible for executing dataflow jobs in parallel. The processor operating on top of Hyracks is responsible for providing the partitioning scheme while Hyracks decides how the resulting job will be distributed. Hyracks processes data in partitions of contiguous bytes, moving data in fixed-sized frames that contain physical records, and it defines interfaces that allow users of the platform to specify the data-type details for comparing, hashing, serializing and de-serializing data. Hyracks provides built-in base data types to support storing data on local partitions or when building higher level data types.

The next layer, *Algebricks* [15], takes as input a logical query plan and, via built-in optimization rules that it provides, converts it to a physical plan. Apart from the transformation, the rules are responsible for making the query plan more efficient. In order to achieve this efficiency, Algebricks allows the processor above (in this case Apache VXQuery) to provide its own language specific rewrite rules.

The final layer, *Apache VXQuery* [4, 17], supports a XQuery processor engine. To build a JSONiq processor, we used the JSONiq extension to XQuery specifications. Specifically, we focused mostly on implementing all the necessary modules to successfully parse and evaluate JSONiq queries. Additionally, several modules were implemented to enable JSON file parsing and support an internal in-memory representation of the corresponding JSON items.

The resulting JSONiq processor accepts as input the original query, in string form, and converts it to an abstract syntax tree (AST) through its query parser. Then, the AST is transformed with the help of VXQuery’s translator to a logical plan, which becomes the input to Algebricks.

As mentioned above, VXQuery uses Hyracks to schedule and run data parallel jobs. However, Hyracks is a data-agnostic platform, while VXQuery is language-specific. This creates a need for additional rewrite rules to exploit Hyracks’ parallel properties for JSONiq. If care is not taken, the memory footprint for processing large JSON files can be prohibitively high. This can make it impossible for systems with limited memory resources to efficiently support JSON data processing. In order to identify opportunities for parallelism as well as to reduce the runtime memory footprint, we need to examine in more depth the characteristics of the JSON format as well as the supported query types.

3.2 Hyracks Operators

We first proceed with a short description of the Hyracks logical operators that we will use in our query plans.

- **EMPTY-TUPLE-SOURCE:** outputs an empty tuple used by other operators to initiate result production.
- **DATASCAN:** takes as input a tuple and a data source and extends the input tuple to produce tuples for each item in the source.
- **ASSIGN:** executes a scalar expression on a tuple and adds the result as a new field in the tuple.
- **AGGREGATE:** executes an aggregate expression to create a result tuple from a stream of input tuples. The result is held until all tuples are processed and then returned in a single tuple.
- **UNNEST:** executes an unnesting expression for each tuple to create a stream of output tuples per input.
- **SUBPLAN:** executes a nested plan for each tuple input. This plan consists of an AGGREGATE and an UNNEST operator.
- **GROUP-BY:** executes an aggregate expression to produce a tuple for each set of items having the same grouping key.

Figure 2: XML vs JSON structure

It is imperative for understanding this work to describe the representation along with the navigation expressions of JSON items according to the JSONiq extension to the XQuery specification. A json-item can be either an array or an object, in contrast to an XML structure, which consists of multiple nodes as described in Figure 2. An array consists of an ordered list of items (members), while an object consists of a set of pairs. Each pair is represented by a key and a value. The following is the terminology used for JSONiq navigation expressions:

- **Value:** for an array it yields the value of a specified (by an index) array element, while for an object it yields the value of a specified (by a field name) key.
- **Keys-or-members:** for an array it outputs all of its elements, and for an object it outputs all of its keys.

4 JSON QUERY OPTIMIZATION

The JSONiq rewrite rules are divided into three categories: the Path Expression, Pipelining, and Group-by Rules. The first category removes some unused expressions and operators, as well as

streamlining the remaining path expressions. The second category reduces the memory needs of the pipeline. The last category focuses on the management of aggregation, which also contains the group-by feature (added to VXQuery in the XQuery 3.0 specification). For all our examples, we will consider the bookstore structure example depicted in Listing 1.

```
{
  "bookstore": {
    "book": [
      {
        "-category": "COOKING",
        "title": "Everyday Italian",
        "author": "Giada De Laurentiis",
        "year": "2005",
        "price": "30.00"
      },
      ...
    ]
  }
}
```

Listing 1: Bookstore JSON File

4.1 Path Expression Rules

The goal of the first category of rules is to enable the unnesting property. This means that instead of creating a sequence of all the targeted items and processing the whole sequence, we want to process each item separately as it is found. This rule opens up opportunities for pipelining since each item is passed to the next stage of processing as the previous step is completed.

```
json-doc("books.json")("bookstore")("book")()
```

Listing 2: Bookstore query

The example query in Listing 2 asks for all the books appearing in the given file. Specifically, it reads data from the JSON file ("books.json") and then, the *value* expression is applied twice, once for the bookstore object ("bookstore") and once for the book object ("book"). In this way, it is ensured that only the matching objects of the file will be stored in memory. The value of the book object is an array, so the *keys-or-members* expression (()) applied to it returns all of its items. To process this expression, we first store in a tuple all of the objects from the array and then we iterate over each one of them. The result that is distributed at the end is each book object separately.

```
DISTRIBUTE-RESULT($S9)
UNNEST($S9:iterate($S8))
ASSIGN($S8:(keys-or-members($S2)))
ASSIGN($S2:value(value(json-doc(promote(data("books.json"),
string),"bookstore"),"book"))
EMPTY-TUPLE-SOURCE
```

Figure 3: Original Query Plan

In more detail, we can describe the aforementioned process in terms of a logical query plan that is returned from VXQuery (Figure 3). It follows a bottom-up flow, so the first operator in the query plan is the EMPTY-TUPLE-SOURCE leaf operator. The empty tuple is extended by the following ASSIGN operator, which consists of a *promote* and a *data* expression to ensure that the json-doc argument is a string. Also, the two *value* expressions inside it verify that only the book array will be stored in the tuple.

The next two operators depict the two steps of the processing of the *keys-or-members* expression. The first operator is an ASSIGN, which evaluates the expression to extend its input tuple. Since this expression is applied to an array, the returned tuple includes all of the objects inside the array. Then, the UNNEST operator applies an iterate expression to the tuple and returns a stream of tuples including each object from the array.

The final step according to the query plan is the distribution of each object returned from the UNNEST. From the analysis above, we can observe that there are opportunities to make the logical plan more efficient. Specifically, we observe that there is no need for two processing steps of *keys-or-members*.

Originally, the tuple with all the book objects produced by the *keys-or-members* expression flows into the UNNEST operator whose iterate expression will return each object in a separate tuple. Instead, we can merge the UNNEST with the *keys-or-members* expression. That way, each book object is returned immediately when it is found.

Finally, to further clean up our query plan, we can remove the *promote* and *data* expressions included in the first ASSIGN operator. The fully optimized logical plan is depicted in Figure 4.

```
DISTRIBUTE-RESULT($$13 )
UNNEST($$13:keys-or-members($$2))
ASSIGN($$2:value(value(json-doc("books.xml"),"bookstore"),"book")
EMPTY-TUPLE-SOURCE
```

Figure 4: Updated Query Plan

The new and more efficient plan opens up opportunities for pipelining since when a matching book object is found, it is immediately returned and, at the same time, passed to the next stage of the process.

4.2 Pipelining Rules

This type of rule builds on top of the previous rule set and considers the use of the DATASCAN operator along with the way to access partitioned-parallel data. The sample query that we use is depicted in Listing 3.

```
collection("/books")("bookstore")("book")()
```

Listing 3: Bookstore Collection Query

According to the query plan in Figure 5, the ASSIGN operator takes as input data source a collection of JSON files, through the *collection* expression. Then, UNNEST *iterate* iterates over the collection and outputs each single file. The two value expressions integrated into the second ASSIGN output a tuple source filled with all the book objects produced by the whole collection. The last step of the query plan (created in the previous section) is implemented by the *keys-or-members* expression of the UNNEST operator, which outputs each single object separately.

The input tuple source generated by the *collection* expression corresponds to all the files inside the collection. This does not help the execution time of the query, since the result tuple can be huge. Fortunately, Algebricks offers its DATASCAN operator, which is able to iterate over the collection and forwards to the next operator each file separately. To accomplish this procedure, DATASCAN replaces both the ASSIGN *collection* and the UNNEST *iterate*.

```
DISTRIBUTE-RESULT($$13 )
UNNEST($$13:keys-or-members($$6))
ASSIGN($$6:value(value($$4,"bookstore"),"book"))
UNNEST($$4:iterate($$2))
ASSIGN(collection("/books"), $$2)
EMPTY-TUPLE-SOURCE
```

Figure 5: Query Plan for a Collection

```
DISTRIBUTE-RESULT($$13 )
UNNEST($$13:keys-or-members($$4))
ASSIGN($$4:value(value($$2,"bookstore"),"book"))
DATASCAN(collection("/books"), $$2)
EMPTY-TUPLE-SOURCE
```

Figure 6: Introduction of DATASCAN

By enabling Algebricks' DATASCAN, apart from pipeline improvement, we also achieve partitioned parallelism. In Apache VXQuery, data is partitioned among the cluster nodes. Each node has a unique set of JSON files stored under the same directory specified in the *collection* expression. The Algebricks' physical plan optimizer uses these partitioned data property details to distribute the query execution. Adding these properties allows Apache VXQuery to achieve partitioned-parallel execution without any user-level parallel programming.

To further improve pipelining, we can produce even smaller tuples. Specifically, we extend the DATASCAN operator with a second argument (here it is the book array). This argument defines the tuple that will be forwarded to the next operator.

In the updated query plan (Figure 6), the newly inserted DATASCAN is followed by an ASSIGN operator. Inside it, the two *value* expressions populate the tuple source with all the book objects of the file fetched from DATASCAN. We can merge the value expressions with DATASCAN by adding a second argument to it. As a result, the output tuple, which was previously filled with each file, is now set to only have its book objects (Figure 7).

```
DISTRIBUTE-RESULT($$13 )
UNNEST($$13:keys-or-members($$4))
DATASCAN(collection("/books"), $$4, ("bookstore")("book"))
EMPTY-TUPLE-SOURCE
```

Figure 7: Merge *value* with DATASCAN Operator

At this point, we note that by building on the previous rule set, both the query's efficiency and the memory footprint can be further improved. In the query plan in Figure 7, DATASCAN *collection* is followed by an UNNEST whose *keys-or-members* expression outputs a single tuple for each book object of the input sequence.

```
DISTRIBUTE-RESULT($$4 )
DATASCAN(collection("/books"), $$4, ("bookstore")("book"))
EMPTY-TUPLE-SOURCE
```

Figure 8: Merge *keys-or-members* with Datascan Operator

This sequence of operators gives us the ability to merge DATASCAN with *keys-or-members* by extending its second argument.

Figure 8 shows this action, whose result is the fetching of even smaller tuples to the next stage of processing. Specifically, instead of storing in DATASCAN's output tuple a sequence of all the book objects of each file in the collection, we store only one object at a time. Thus, query's execution time is improved and Hyracks' dataflow frame size restriction is satisfied.

```
for $x in collection("/books")("bookstore")
("book")()
group by $author:=$x("author")
return count($x("title"))
```

Listing 4: Bookstore Count Query

4.3 Group-by Rules

The last category of rules can be applied to both XML and JSON queries since the group-by feature is part of both syntaxes. Group-by can activate rules enabling parallelism in aggregation queries.

```
for $x in collection("/books")("bookstore")
("book")()
group by $author:=$x("author")
return count(for $j in $x return $j("title"))
```

Listing 5: Bookstore Count Query (2nd form)

The example query that we will use to show how our rules affect aggregation queries is in Listings 4 and 5. Both forms of the query read data from a collection with book files, group them by author, and then return the number of books written by each author.

```
DISTRIBUTE-RESULT($$20 )
UNNEST($$20:iterate($$19))
ASSIGN($$19:count(value($$18,"title")))
ASSIGN($$18:treat(item,$$16))
GROUP-BY($$17:0->$$14){
  AGGREGATE($$16:create_sequence($$13))
}
ASSIGN($$14:data(value($$13,"author")))
DATASCAN(collection("/books"), $$13, ("bookstore")("book")())
EMPTY-TUPLE-SOURCE
```

Figure 9: Query Plan with Count Function

In Figure 9, the DATASCAN *collection* passes a tuple, for one book object at a time, to ASSIGN. The latter applies the *value* expression to acquire the author's name for the specific object. GROUP-BY accepts the tuple with the author's name (group-by key) and then its inner focus is applied (AGGREGATE) so that all the objects whose author field have the same value will be put in the same sequence.

At this point, ASSIGN *treat* appears; this ensures that the input expression has the designated type. So, our rule searches for the type returned from the sequence created from the AGGREGATE operator. If it is of type *item* which is the *treat* type argument, the whole *treat* expression can be safely removed. As a result, the whole ASSIGN can now be removed since it is a redundant operator (Figure 10).

After the former removal, GROUP-BY is followed by an ASSIGN *count* which calculates the number of book titles (*value* expression) generated by AGGREGATE *sequence*. According to the JSONiq extension to XQuery, *value* can be applied only on a JSON object or array. However, in our case the query plan applies

```
DISTRIBUTE-RESULT($$20 )
UNNEST($$20:iterate($$19))
ASSIGN($$19:count(value($$16,"title")))
GROUP-BY($$17:0->$$14){
  AGGREGATE($$16:create_sequence($$13))
}
ASSIGN($$14:data(value($$13,"author")))
DATASCAN(collection("/books"), $$13, ("bookstore")("book")())
EMPTY-TUPLE-SOURCE
```

Figure 10: Query Plan without *treat* Expression

value to a sequence, since GROUP-BY aggregates all the records having the same group-by key in a sequence. Thus, ("title") is applied on a sequence. To overcome this conflict, we convert the ASSIGN to a SUBPLAN operator (Figure 11). SUBPLAN's inner focus introduces an UNNEST *iterate* which iterates over AGGREGATE *sequence* and produces a single tuple for each item in the sequence. The inner focus of SUBPLAN finishes with an AGGREGATE along with a count function which incrementally calculates the number of tuples that UNNEST feeds it with.

```
DISTRIBUTE-RESULT($$20 )
UNNEST($$20:iterate($$19))
SUBPLAN{
  AGGREGATE($$19:count(value($$18,"title")))
  UNNEST($$18:iterate($$16))
}
GROUP-BY($$17:0->$$14){
  AGGREGATE($$16:create_sequence($$13))
}
ASSIGN($$14:data(value($$13,"author")))
DATASCAN(collection("/books"), $$13, ("bookstore")("book")())
EMPTY-TUPLE-SOURCE
```

Figure 11: Convert scalar to aggregation expression

This conversion not only helps resolving the aforementioned conflict but it also converts the scalar count function to an aggregate one. This means that instead of calculating count on a whole sequence, we can incrementally calculate it as each item of the sequence is fetched.

In Figure 11, GROUP-BY still creates a sequence in its inner focus, which is the input to SUBPLAN UNNEST. Instead, we can push the AGGREGATE operator of the SUBPLAN down to the GROUP-BY operator by replacing it (Figure 12). That way, we exploit the benefits of the aforementioned conversion and have the count function computed at the same time that each group is formed (without creating any sequences). Thus, the new plan is not only smaller (more efficient) but also keeps the pipeline granularity introduced in both of the previous rule sets.

At this point, it is interesting to look at the second format of the query in Listing 5. The for loop inside the count function conveniently forms a SUBPLAN operator right above the GROUP-BY in the original logical plan. This is exactly the query plan described in Figure 11, which means that in this case we can immediately push the AGGREGATE down to GROUP-BY, without any further transformations.

```

DISTRIBUTE-RESULT($$20 )
UNNEST($$20:iterate($$16))
GROUP-BY($$17:0->$$14){
  AGGREGATE($$16:count(value($$13,"title")))
}
ASSIGN($$14:data(value($$13, "author"))
DATASCAN( collection("/books"), $$13, ("bookstore")("book")())
EMPTY-TUPLE-SOURCE

```

Figure 12: Updated Query Plan with Count Function

Now that the count function is converted into an aggregate function, there is another rule introduced in [17] that can be activated to further improve the overall query performance. This rule supports Algebricks' two-step aggregation scheme, which means that each partition can calculate locally the count function on its data. Then, a central node can compute the final result using the data gathered from each partition. Thus, partitioned computation is enabled, which improves parallelism effectiveness.

The final query plan, produced after the application of all the former rules, calculates the count function at the same time that each grouping sequence is built as opposed to first building it and then processing the aggregation function.

5 EXPERIMENTAL EVALUATION

We have tested our rewrite rules by integrating them into the latest version of Apache VXQuery [4]. Each node has two dual-core AMD Opteron(tm) processors, 8GB of memory, and two 1TB hard drives. For the multi-node experiments we built a cluster of up to nine nodes of identical configuration. We used a real dataset with sensor data and a variety of queries, described below in Sections 5.1 and 5.2 respectively. We repeated each query five times. The reported query time is an average of the five runs. We first consider single-node experiments and include measurements for execution time (before and after applying our rewrite rules) and for speed-up. For the multi-node experiments we measure response time and scale-up over different numbers of nodes. We, also, include comparisons with Spark SQL and MongoDB that show that the overhead of their loading phase is non-negligible. Finally, we compare with AsterixDB which has the same infrastructure as our system; in particular we compare with two approaches, one that sees the input as an external dataset (depicted in the figures as AsterixDB) and one that first loads the file internally (depicted as AsterixDB(load)).

5.1 Dataset

The data used in our experiments are publicly available from the National Oceanic and Atmospheric Administration (NOAA) [21]. The Daily Global Historical Climatology Network (GHCN-Daily) dataset was originally in dly format and was converted to its equivalent NOAA web service JSON representation.

Listing 6 shows an example JSON sensor file structure. All records are wrapped into a JSON item, specifically array, called "root". Each member of the "root" array is an object item which contains the object "metadata" and the array "results". The latter stores various measurements organized in individual objects. A specific measurement includes the date, the data type (a description of the measurement, with typical values being TMIN, TMAX, WIND etc.), the station id where the measurement was taken, and the actual measurement value. The "count" object

included into the "metadata" denotes the number of measurements objects in the accompanying "results" array. Typically a "results" array contains measurements from a given station for one month (i.e. typically 30 measurements). A sensor file contains only one "root" array which may consist of several "results" (measurements from the same or different stations) accompanied by their "metadata".

Sensor file sizes vary from 10MB to 2GB. Each node holds a collection of sensor files; the size of the collection varies from 100MB to 803GB. The collection size is varied throughout the experiments and is cited explicitly for each experiment. In our experiments, we assume that the data has already been partitioned among the existing nodes.

```

{
  "root": [
    {
      "metadata": {
        "count":31,
      },
      "results": [
        {
          "date": "20132512T00:00",
          "dataType": "TMIN",
          "station": "GSW123006",
          "value": 4
        },
        ...
      ]
    },
    {
      "metadata": {
        "count":29,
      },
      "results": [
        {
          "date": "20142512T00:00",
          "dataType": "WIND",
          "station": "GSW957859",
          "value": 30
        },
        ...
      ]
    },
    ...
  ]
}

```

Listing 6: Example JSON Sensor File Structure

5.2 Query Types

We evaluated our newly implemented rewrite rules by evaluating different types of queries including selection (Q0, Q0b), aggregation (Q1, Q1b) and join-aggregation queries (Q2). The query description follows.

```

for $r in collection("/sensors")("root")("results")()
let $datetime := dateTime(data($r("date")))
where year-from-dateTime($datetime) ge 2003
and month-from-dateTime($datetime) eq 12
and day-from-dateTime($datetime) eq 25
return $r

```

Listing 7: Selection Query (Q0)

```

for $r in collection("/sensors")("root")("results")("date")
let $datetime := dateTime(data($r))
where year-from-dateTime($datetime) ge 2003
and month-from-dateTime($datetime) eq 12
and day-from-dateTime($datetime) eq 25
return $r

```

Listing 8: Selection Query (Q0b)

Q0: In this query (Listing 8), the user asks for historical data from all the weather stations by selecting all December 25 weather measurement readings from 2003 on.

Q0b is a variation of *Q0* where the input path (1st line in Listing 8), is extended by a *value* expression ("date").

```
for $r in collection ("/sensors") ("root")()
("results")()
where $r("dataType") eq "TMIN"
group by $date:= $r("date")
return count($r("station"))
```

Listing 9: Aggregation Query (Q1)

```
for $r in collection ("/sensors") ("root")()
("results")()
where $r("dataType") eq "TMIN"
group by $date:= $r("date")
return count(for $i in $r return $i("station"))
```

Listing 10: Aggregation Query (Q1b)

Q1: This query (Listing 10), finds the number of stations that report the lowest temperature for each date. The grouping key is the date field of each object.

Q1b is a variation of *Q1* that has a different returned result structure.

Q2: This self-join query (Listing 11) joins two large collections, one that maintains the daily minimum temperature per station and one that contains the daily maximum temperature per station. The join is on the station id and date and finds the daily temperature difference per station and returns the average difference over all stations.

```
avg(
  for $r_min in collection("/sensors")("root")()
  ("results")()
  for $r_max in collection("/sensors")("root")()
  ("results")()
  where $r_min("station") eq $r_max("station")
  and $r_min("date") eq $r_max("date")
  and $r_min("dataType") eq "TMIN"
  and $r_max("dataType") eq "TMAX"
  return $r_max("value") - $r_min("value")
) div 10
```

Listing 11: Join-Aggregation Query (Q2)

5.3 Single Node Experiments

To explore the effects of the various rewrite rules we first consider a single node, one core environment (i.e. one partition) and progressively enable the different sets of rules. We start by considering just the *path expression rules*. Figure 13 shows the execution time for all five queries with and without these rules. For this experiment, we used a 400MB collection of sensor files (each of size 10MB). Note that for these experiments we used a relatively small collection size since without the JSONiq rules Hyracks would need to process the whole (possibly large) file thus slowing its performance. The application of the Path Expression Rules results to a clear improvement of the execution time for all queries. These rules decrease the buffer size between operators since large sequences of objects are avoided. Instead, each object is passed on to the next operator separately, resulting in faster query execution.

Using the same dataset and having enabled the Path Expression rules, we now examine the effect of adding the *Pipelining* rules (Figure 14). We observe that in all cases the pipelining rules provide a drastic improvement (note the logarithmic scale!),

Figure 13: Execution Time before and after Path Expression Rules

Figure 14: Execution Time (logscale) before and after the Pipelining Rules

speeding queries up by about two orders of magnitude. Applying these rules decreases the initial buffering requirement since we don't store the whole JSON document anymore, but just the matching objects. It is worth noting that the best performance is achieved by *Q0b*. *Q0b* stores in memory only the parts of the objects whose key field is "date". By focusing only on the "date", this gives the DATASCAN operator the opportunity to iterate over much smaller tuples than *Q0*. Clearly, the smaller the argument given to DATASCAN, the better for exploiting pipelining.

Figure 15: Execution Time before and after Group-by Rules

Having enabled both the path expression and the pipelining rules, we proceed considering the effect of adding the *Group-by* rules. The results are depicted in Figure 15. Clearly Q0, Q0b and Q2 are not affected since the Group-by rules do not apply. The Group-by rules improve the performance of both queries Q1 and Q1b. The improvement for both queries comes from the same rule, the rule that pushes the COUNT function inside the group-by. We note that the second Group-by rule, the one performing conversion, applies only to Q1; we do not enjoy an improvement from the conversion rule here because Q1b is already written in an optimized way. It is worth mentioning that the efficiency of the group-by rules depends on the cardinality of the groups created by the query. Clearly, the larger the groups, the better the observed improvement.

To study the effectiveness of all of the rewrite rules as the partition size increases, we ran an experiment where we varied the collection size from 100MB to 400MB. Figure 16 (again with a log scale) depicts the execution time for query Q1 both before and after applying all three sets of rewrite rules. We chose Q1 here because it is indeed affected by all of the rules. We can see that the system scales proportionally with the dataset size and that the application of the rewrite rules results in a huge query execution time improvement.

Figure 16: Execution Time (logscale) for Q1 before and after Rewrite Rules for different Data Sizes

From the above experiments, we can conclude that the Pipelining rules provide the most significant impact. It is also worth noting that the execution of the rewrite rules during query compilation adds a minimal overhead (just a few msec) to the overall query execution cost.

Single node Speed-up: To test the system's single node speed up, we used a dataset larger than our node's available memory space (8GB). Specifically, we used 88GB of JSON data, which we progressively divided from one up to eight partitions (our CPU has 4 cores and supports up to 8 hyperthreads). Each partition corresponds to a thread. The results are shown in Figure 17.

For up to 4 partitions and for almost all query categories, we achieve good speed-up since our observed execution time is reduced by a factor close to the number of threads that are being used. On the other hand, when using 8 hyperthreaded partitions we observe no performance improvements and in some cases a slightly worst execution time. This is because our processing is CPU bound (due to the JSON parsing), hence the two hyperthreads are effectively run in sequence (on a single core). In summary, we see the best results when we match the number of partitions to the number of cores.

Figure 17: Single Node Speed-up

Comparison with MongoDB and AsterixDB: When comparing our performance against MongoDB and AsterixDB we observed that the performance of these systems is affected by the structure of the input JSON file. For example, a file with the structure of Listing 6 will be perceived by MongoDB and AsterixDB as a single, large document. Since MongoDB and AsterixDB are optimized to work with smaller documents (MongoDB has in addition a document size limitation of 16MB), to make a fair comparison we examined their performance while varying the number of documents per file.

We first unwrapped all the JSON items inside "root" (Listing 6). This results to many individual documents per file, each document containing a "metadata" JSON object and its corresponding "results" JSON array (typically with 30 measurements). We further manipulated the number of documents per file by varying the number of member objects (measurements) inside the "results" array from 30 (one month of measurements per document) to 1 (one day/measurement per document).

Figure 18.a depicts the query time performance for query Q0b for VXQuery, MongoDB, AsterixDB and AsterixDB(load); the space used by each approach appears in Figure 18.b. The total size of the dataset is 88GB and we vary the measurements per JSON array.

In contrast to MongoDB and the AsterixDB approaches, we note that the performance of VXQuery is independent of the number of documents per file. MongoDB has better query time for larger documents (30 measurements per array). Since MongoDB performs compression per document, larger documents allow for better compression and thus query time performance. This can also be seen in figure 18.b, where the space requirements increase as the document becomes smaller (and thus less compression is possible). The space for both AsterixDB approaches and VXQuery is independent from the document size (which is to be expected as currently these systems do not use compression).

AsterixDB shows a different query performance behavior than MongoDB. Its best performance is achieved for smaller document sizes (one measurement per document). Since it shares the same infrastructure as VXQuery, the difference in its performance relative to VXQuery is due to the lack of the JSONiq Pipeline Rules. Without them, the system waits to first gather all the measurements in the array before it moves them to the next stage of processing. This holds for both AsterixDB and AsterixDB(load). Among the two approaches, the AsterixDB(load) approach has better query performance since it is optimized to work better for data that is already in its own data model. Interestingly, for the

Figure 18: (a) Execution Time and (b) Space Consumption for Different Measurement Sizes per Array

Measurements/Array	30	22	15	7	1
MongoDB	9000	11703	14443	17146	19876
AsterixDB (load)	24659	23987	24205	24547	24612

Table 1: Loading Time in sec for AsterixDB (load) and MongoDB for Different Record Sizes

smaller document sizes (where compression is limited), AsterixDB and MongoDB have similar query performance. For larger document sizes their query performance difference seems to be directly related to their data sizes. For example, with 30 measurements per document, MongoDB uses about 4.5 times less space due to compression and has about 4 times less query time than AsterixDB(load).

Table 1 depicts the loading times for MongoDB and AsterixDB(load) for different measurements/array (in contrast there is no loading time for AsterixDB and VXQuery). The different loading times can also be explained by the space consumed by MongoDB and AsterixDB(load) (Figure 18.b). Specifically, MongoDB needs less loading time due to its use of compression; as expected, its loading time increases as the number of measurements per array is decreased due to less compression.

Comparison with SparkSQL: We next compare with a well-known NoSQL system, SparkSQL. In this experiment we ran Q1 both on VXQuery with the JSONiq rewrite rules and on Spark SQL and we compared their execution times. We used a single node and one core as the setup for both systems. We varied the dataset sizes starting from 400MB up to 1GB. We could not run experiments with larger input files because Spark required more than the available memory space to load such larger datasets.

Table 2 shows the SparkSQL loading times for the datasets used in this experiment. Figure 19 shows the query times for query Q1 for the different data sizes. Note that the VXQuery bar shows the total execution time for each file (which includes the loading and query processing) while the SparkSQL bar corresponds to the query processing time only. VXQuery’s total execution time is slower than Spark’s query time for small files. The two systems show similar performance for 800MB files. However, as the collection size increases, Spark’s behavior starts to deteriorate. For the 1GB dataset our system’s overall performance is clearly faster. If one counts also for the file loading time of SparkSQL (the overhead added by loading and converting JSON data to a SQL-like format), the VXQuery performance is faster. While the overhead of the loading phase is not a significant burden for

Figure 19: Spark SQL vs VXQuery Execution Time for Query Q1 Using Different Data Sizes (MB)

Data Size (MB)	Loading Time (s)
400	6.3
800	15
1000	40

Table 2: Loading Time for Spark SQL

Data Size (MB)	Spark Memory (MB)	VXQuery Memory (MB)
400	5650	1690
800	6230	1750
1000	7953	1760

Table 3: Data size to system memory in MBs

SparkSQL when considering small inputs (400MB) it becomes an important limiting factor even for medium size files (800MB).

We also examined the memory allocated by both systems (Table 3). The results show that VXQuery stores only data relevant to the query in memory, as opposed to SparkSQL, which stores everything. For file sizes above 2GB, the memory needs of SparkSQL exceeded the node’s available 16GB, so it was unable to load the input data so as to query it.

5.4 Cluster Experiments

The goal of this section is to examine the cluster speed-up and scale-up achieved by VXQuery due to our JSONiq rewrite rules

Figure 20: VXQuery Cluster Speed-up for all Queries (803GB Dataset)

Figure 21: VXQuery Cluster Scale Up for all Queries (88GB per Node)

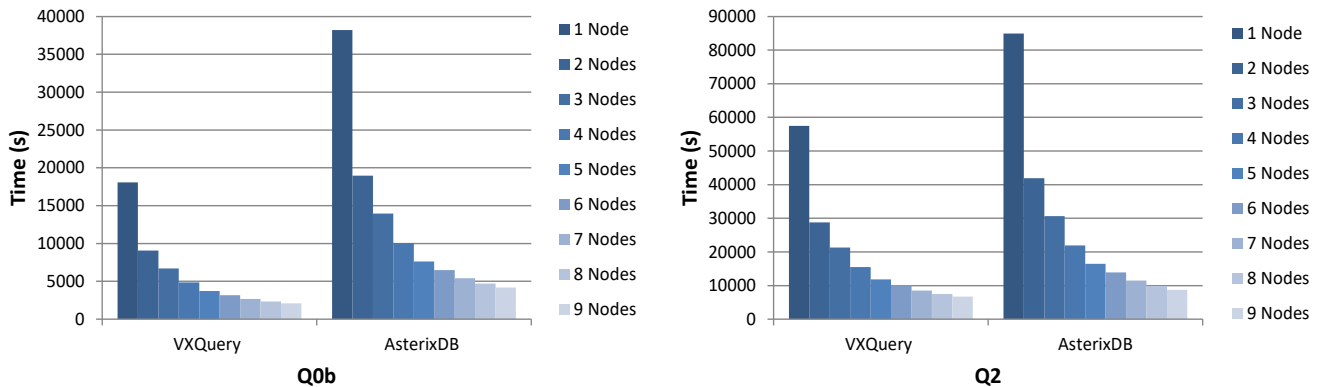

Figure 22: VXQuery vs AsterixDB: Cluster Speed-up for Q0b and Q2 (803GB Dataset)

and compare it with AsterixDB and MongoDB. For all the following experiments we used 4 partitions per node which achieves the best execution time as shown in the previous section.

To measure the *cluster speed-up* we started with a single node and extended our cluster by one node until it reached to 9 nodes. We used 803GB of JSON weather data which were evenly partitioned among the nodes used in each experiment. This dataset exceeds the available cluster memory. The results for this evaluation are shown in Figure 20. We note that in all the cases cluster speed-up is proportional to the number of nodes being used, without depending on the type of the query. We observe that the last query (Q2) takes the most time to execute. This is expected because Q2 is a self join query, which means that it has to process

twice the amount of data. On the other hand, for VXQuery, Q0b has the best response time due to its small input search path as described in previous sections.

To show the *scalability* achieved by VXQuery, we started with a dataset of size 88GB which exceeds one node's available memory (8GB). With each additional node added we add four partitions totaling 88GB (hence when using 9 nodes the whole collection is 803GB). The results appear in Figure 21. As it can be seen our system achieves very good scale-up performance; the query execution time remains roughly the same, which means that the additional data is processed in roughly the same amount of time.

Comparison with AsterixDB: In the cluster experiments, we compare against AsterixDB (i.e. without loading; each dataset

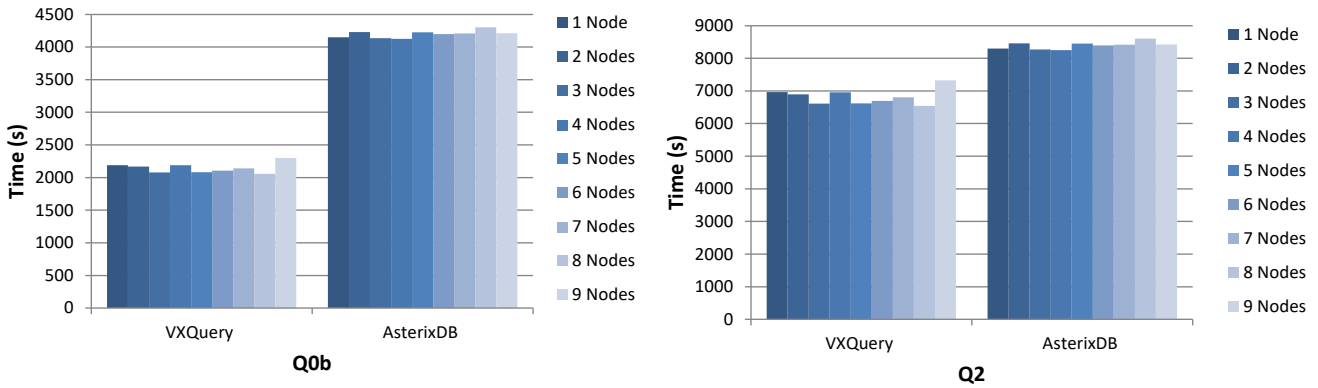

Figure 23: VXQuery vs AsterixDB: Cluster Scale-up for Q0b and Q2 (88GB per Node)

Figure 24: VXQuery vs MongoDB: Cluster Speed-up for Q0b and Q2 (803GB Dataset)

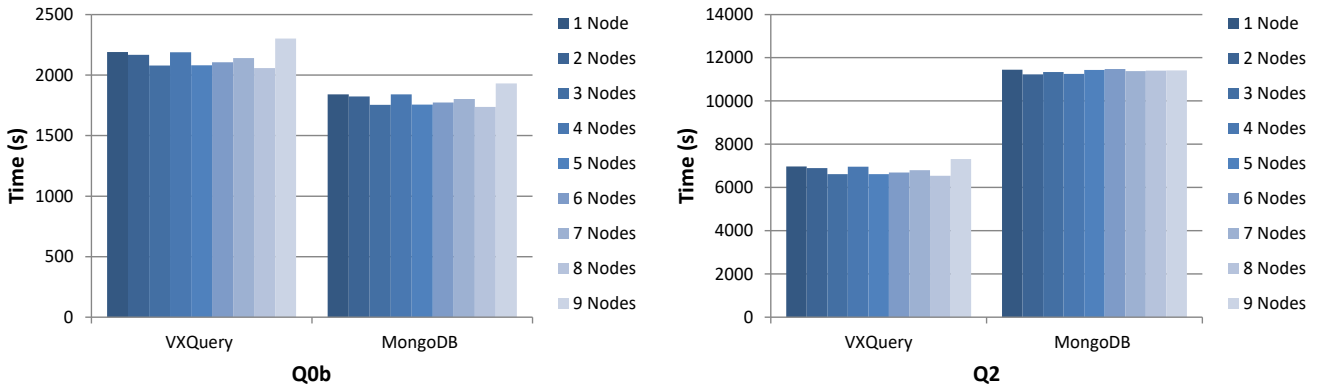

Figure 25: VXQuery vs MongoDB: Cluster Scale-up for Q0b and Q2 (88GB per Node)

is provided as an external data source). As seen in the single-node experiments, the best performance for AsterixDB is achieved when "results" consists of only one measurement; thus we use this structure for the following evaluation.

Following similar reasoning with the single-node comparison, we observe that VXQuery performs better both for speed up (Figure 22) and scale up (Figure 23), using queries Q0b and Q2 as representative examples.

Comparison with MongoDB: Similarly, we compare against the MongoDB configuration that achieved the best performance in the single-node experiments (i.e., "results" contains all monthly measurements). Overall, MongoDB has faster query time for selection queries than VXQuery (Figure 24 shows speedup for query

Q0b; the Q0 query performed similarly). Since MongoDB performs a compression during the loading phase of the dataset, the dataset stored in the database is much smaller giving an advantage to selection queries. However, VXQuery's execution time for query Q0b is still comparable since its small input search path gives the opportunity for the Pipeline rules to be exploited.

In contrast, VXQuery has a faster execution time than MongoDB on join queries (like Q2). For this self-join, MongoDB tries to put all the documents that share the same station and date in the same document; thus creating huge documents which exceed the 16MB document size limit causing it to fail. To overcome this problem, we perform an additional step before the actual join. We unwind the "results" array and we project only the

Data Size (GB)	Loading Time (sec)
88	9000
803	81000

Table 4: Loading Time for MongoDB

necessary fields. After that, we perform the actual join on the corresponding attributes (i.e. station, date of measurement).

On the other hand, in VXQuery there is no document size limitation, making VXQuery more efficient in handling large JSON items. Table 4 shows the MongoDB loading times per node. This adds a huge overhead to the performance of the overall system and it can be prohibitively large for real-time applications where the dataset may not be known in advance.

Comparison with SparkSQL: As mentioned in the single node experiments SparkSQL could not run experiments with larger input files because of the required memory space to load such larger datasets. Hence we omit multi-node experiments with SparkSQL, since the dataset size will be very small to indicate and difference in the execution time.

6 CONCLUSIONS AND FUTURE WORK

In this work we introduced two categories of rewrite rules (path expression and pipelining rules) based on the JSONiq extension to the XQuery specification. We also introduced a third rule category, group-by rules, that apply to both XML and JSON data. The rules enable new opportunities for parallelism by leveraging pipelining; they also reduce the amount of memory required as data is parsed from disk and passed up the pipeline. We integrated these rules into an existing system, the Apache VXQuery query engine. The resulting query engine is the first that can process queries in an efficient and scalable manner on both XML and JSON data. Through experimentation, we showed that these rules improve performance for various selection, join and aggregation queries. In particular, the pipelining rules improved performance by several orders of magnitude. The system was also shown both to speed-up and scale-up effectively. Moreover, when compared with other systems that can handle JSON data, VXQuery shows significant advantages. In particular, our system can directly process JSON data efficiently without the need to first load it and transform it to an internal data model.

We are currently working on supporting indexing over both types of data (XML and JSON). Indexing presents a significant challenge, as there is no simple way to decide the level at which an object could be indexed; indexing will further improve the system’s performance since the searched data volume will be significantly reduced. All of the code for our JSONiq extension is available through the Apache VXQuery site [4] and it will be included in the next Apache VXQuery release. Furthermore, we plan to add the proposed path and pipelining rules directly to AsterixDB given that it shares the same infrastructure (Algebricks and Hyracks) with VXQuery.

An Automated System for Internet Pharmacy Verification

Alberto Cordioli

Prometeia

alberto.cordioli@prometeia.com

Themis Palpanas

Paris Descartes University

themis@mi.parisdescartes.fr

ABSTRACT

In the past years, we have witnessed an explosion of web applications, and in particular of electronic commerce websites. This has led to unquestionable benefits for both producers and consumers of goods. On the other hand, however, untrusted companies have the opportunity to bypass checks and regulations imposed by relevant bodies. This problem is prevalent in the context of online commerce of pharmaceutical products, where it is essential that such products are safe, of good quality, and only used with a proper prescription. In this work, we study the problem of internet pharmacy verification. To this effect, we build a classifier, able to find patterns and predict the class of unseen data. Moreover, we devise algorithms that give a trust score to each pharmacy, in order to have a legitimacy indicator usable by human reviewers. We experimentally evaluate the proposed approach with real data coming from two different time periods. The results demonstrate the effectiveness of our approach, as well as the potential of using similar techniques for automatically checking regulation compliance in electronic commerce.

1 INTRODUCTION

The growth of web-related technologies, and in particular e-commerce, has offered companies the opportunity to increase their own business, selling directly their products and goods to customers within and across borders. Even though this has led to unquestionable benefits for customers, untrusted companies can also access the market and sell products, for which it is not always possible to assess the quality.

The above problem is even more prominent when we are dealing with pharmaceutical products. Online sale of counterfeit drugs has become an important problem, with studies by the World Health Organization (WHO) showing that in more than 50% of the cases, drugs sold by websites that conceal their physical address are counterfeit¹. The WHO argues that counterfeiting occurs both with branded and with generic products, and counterfeit drugs may include the correct ingredients but fake packaging, the wrong ingredients, insufficient active ingredients, or no active ingredients whatsoever². Evidently, counterfeit drugs represent an enormous public health challenge [26], and also a major illicit economic activity, with an estimated \$75 billion market for 2010³.

Moreover, the mere task of distinguishing a *legitimate* from an *illegitimate* online pharmacy is rather challenging. This is true for domain experts, and is often times impossible to do for simple users, especially since *illegitimate* pharmacies and drugs are designed to look like *legitimate* ones (including the packaging

of drugs, and the drugs themselves, which are usually identical to the original ones).

Figure 1 shows the front webpage of two online pharmacies, only one of which is *legitimate*. Evidently, a simple observation of the two webpages is not enough to reveal which one⁴. Hence, there is a pressing need for assessing the quality of pharmaceutical products sold online, and a major step in this direction is to assess the trustiness of online pharmacies, which is the focus of this study.

There are different factors that make a pharmacy *illegitimate*. In U.S.A. (as well as in many other countries), an online pharmacy must satisfy regulations and meet strict requirements. The requirements that are most frequently violated in the U.S. are, for example, the selling of products without prescriptions and the selling of drugs that are not “FDA-Approved”⁵ [21]. Evidently, checking these factors is not an easy task, especially for people that do not have any kind of competence and knowledge in this field, such as the normal consumers.

It is for this reason that specialized companies have made the verification of health-related websites their own business. LegitScript⁶, for example, offers an internet pharmacy verification service and collaborates with the major search engines (e.g., Google, Bing) in order to enforce policies against *illegitimate* online pharmacies, which can be as much as 90% of the total number of online pharmacies [21].

The process of classifying health-related websites into *legitimate* and *illegitimate* pharmacies is currently mostly *manual*, and requires a great investment of time and human resources. The increasingly large number of online pharmacies, and correspondingly large number of *illegitimate* online pharmacies, leads to the necessity of streamlining the review process with a system capable of automatically giving a trust score to online pharmacies. In this manner the system can assist the human reviewers, relieving them of some tedious and time-consuming tasks.

In this paper, we propose the first systematic approach to the aforementioned problem, using techniques that are based on both text and network features, and we describe a system capable of verifying internet pharmacies. We have made all our code publicly available⁷. Even though previous studies have discussed this problem (e.g., [3, 23, 28]), they did not provide algorithmic solutions for it.

The contributions we make in this paper are as follows.

- We provide the first systematic study for the problem of internet pharmacy verification and formalize two sub-problems: (a) classification of online pharmacies into *legitimate* and *illegitimate*; and (b) ranking online pharmacies according to a *legitimacy* score.
- We study and evaluate indicators that can distinguish between *legitimate* and *illegitimate* pharmacies. We propose

Figure 1: Examples of two online pharmacies.

novel features that are based on both the text of the online pharmacy website, and its network structure, and integrate these features in our models.

- We describe effective and efficient solutions for the classification and ranking problems. The proposed solutions can automate to a large extent the process of online pharmacy verification.
- We experimentally validate our methods with the two largest real datasets used in the literature, comprising of almost 2500 *illegitimate* pharmacies and 200 *legitimate* pharmacies, crawled in two different time periods. The results demonstrate the accuracy of our approach and its practical value, and showcase the potential of similar techniques in relevant problems in e-commerce.

The rest of this paper is organized as follows. In Section 2, we elaborate on existing work. In Section 3, we provide some background material that is necessary for the discussion that follows, and we formally define the two problems we solve. We describe our proposed solution in Sections 4 and 5. We present the experimental results in Section 6, and finally, we conclude in Section 7 with a brief summary and some thoughts on future work.

2 RELATED WORK

2.1 Pharmacy Verification

Previous works have discussed the problem of online pharmacy verification [22], and advocated the need for studying this problem from the regulation and public-health points of view [27, 28]. A study in the area of medicinal drug commerce has shown that consumers should be able to reduce their risk by relying on trusted lists compiled by credited agencies [3], and by using common sense when examining packaging and pills, while other studies have explored the problem of identifying controversial drugs, by monitoring consumer opinion [33, 34].

Nevertheless, the major problem is that it is not possible to assess the quality of a drug sold online, at least until it has been purchased. And even at that time, determining if such medicine is safe or not, requires several analyses and competences, often not held by the normal consumer. The most promising solution is the one of using official lists of trusted online pharmacies. Nevertheless, this is a daunting task to complete manually, because of the sheer number of online pharmacies and the rate with which they appear (or disappear).

Some studies have focused on the problem of identifying features and signals that distinguish *legitimate* and *illegitimate* online pharmacies [23, 27, 28]. In [23] the authors performed a comparative analysis of website trust features applied to the case of online pharmacies, which showed that proven *legitimate* pharmacies use more extensively verification seals and have more instances of health content than *illegitimate* pharmacies. On the other hand, *illegitimate* pharmacies have fewer store presence features than *legitimate* pharmacies. In [22] the authors try to understand the reasons for the success of unlicensed online pharmacies. They discover that instead of directly competing with licensed pharmacies, unlicensed pharmacies often sell drugs that licensed pharmacies do not, or cannot sell.

Additional studies [27, 28] demonstrate that the problem of online pharmacy verification should be studied at two different levels: from the regulation point of view and from the public health point of view. The very same conclusion has been outlined another study as well [27], where the authors perform a review of the scientific literature and a study of several scientific and institutional databases. They showed that the phenomenon is continuing to spread, and in order to enhance the benefits and minimize the risks, a 2-level approach could be adopted: first, from a policy point of view implementing international level laws, and second on an individual consumer point of view. Note that none of studies mentioned above propose algorithmic solutions for tackling the problem at hand.

CADRE [36] is a cloud-assisted drug recommendation system, which can recommend users with related drugs, according to their symptoms. The system clusters drugs into several groups according to the functional description information, and designs a basic personalized drug recommendation based on user collaborative filtering. While this system can help consumers find alternative drugs for their symptoms, it can not be used for identifying *illegitimate* drugs, or *illegitimate* online pharmacies.

In this study, we show that another direction is possible and effective. We claim that relevant bodies (e.g., LEAs and private agencies in health-care system) could use state-of-the-art data mining techniques in order to find, isolate, and eventually shut-down *illegitimate* online pharmacies. Our approach outlines a text classification process and a network trust algorithm in order to assess the *legitimacy* of internet pharmacies.

2.2 Text Classification and Network Trust Algorithms

Our problem is reminiscent to spam detection [5]. Even though the problems of internet pharmacy verification and web spam detection exhibit some similarities, they are very different in the definition of what is considered *legitimate*. In our case, we might require very specific knowledge in order to differentiate between *legitimate* and *illegitimate* examples. Moreover, the final scope of the two systems are different. In [5] the authors aim to improve search engines algorithms, while in this work the final users are domain-specific analysts working in the field of online pharmacy verification.

Text Classification (TC) is defined as the process, in which a document is automatically classified in one or more categories (classes) [1, 31]. In this process, a set of labeled data is used to train a classifier, which recognize patterns among instances of the same class. These patterns are then used to build a model able to classify unlabeled instances. TC have been used in many contexts, including language identification [6], message filtering (i.e., spam filtering) [2, 19, 25], hierarchical categorization of web pages [7, 11], and others. Recent studies have surveyed text classification algorithms [1], and also studied the behavior of classifiers in the presence of label noise [14, 24].

In the specific context of web content, the classification of web content in one or more classes has been studied by many researchers. In [17], the author analyzes the nature of web content and metadata in relation to requirements for text features, and presents a system for automatically classifying websites into industrial categories. The work presented in [11] explores the use of a hierarchical structure for classifying a large, heterogeneous collection of web content.

In [13], the authors compare three different text representation techniques, based on (character) N-Gram Graphs, the Term Vector model, the Character N-Grams model, and the N-Gram Graphs model, with respect to three different categories of documents: curated, semi-curated and raw documents. They show that each category calls for different classification settings with respect to the representation model; moreover they show that N-Gram Graphs model achieves higher performances on each of the three different categories analyzed. This is a versatile technique that we use in our work, and that we further discuss in the following sections.

Assessing the trustiness in a network of hosts or websites has become very important in the web context, where the number of web spam pages increases by the minute. In order to address this problem, some search engines have adopted trust algorithms to reduce the rank of such pages in query results. TrustRank [15] is a link analysis technique for semi-automatically separating useful webpages from spam. Starting from a seed of reputable web pages, TrustRank uses the underlying network structure to discover other pages that are likely to be legitimate.

In [20] the authors provide a variation of TrustRank algorithm, called Anti-TrustRank, where non-reputable web pages are selected as initial seed. A different algorithm, which is able to decrease the number of downloads of inauthentic files in a peer-to-peer file-sharing network, is presented in [18].

An important characteristic of our domain is that the two classes - *legitimate* and *illegitimate*- are strongly imbalanced: the number of *legitimate* examples represents only a small percentage of the total. The effect of skewed distribution has been studied in many aspects. In [35] the authors analyzed the effect

of class distribution on classifier learning and showed that the naturally occurring class distribution is often not the best choice for learning. In [10, 29, 32] the effects of dataset distribution have been studied for two very well known classifiers: C4.5 and SVM. In our work, we compare the results obtained by training classifiers with the natural distribution and with resampling (both undersampling and oversampling).

3 PRELIMINARIES AND PROBLEM DEFINITION

In this section, we recap some concepts and techniques needed for the rest of the paper, and formally define the problems we solve.

3.1 Preliminaries

We first define the concept of an online pharmacy, and we point out the differences between *legitimate* and *illegitimate* online pharmacies. This is important, since the term *illegitimacy* may have different interpretations depending on the contexts.

An online pharmacy is a website that offers medical products for sale. In this context there are different levels of *illegitimacy* for a pharmacy, and such levels depend on certain features that, if present, contribute to make that pharmacy *illegitimate*. We can group *illegitimate* pharmacies in three big categories:

- online pharmacies that do not adhere to accepted standards of medicine and/or pharmacy practice, including standards of safety;
- online pharmacies that violate, appear to violate, encourage violation of, or are not in compliance with applicable national or regional laws or regulations;
- online pharmacies that engage in fraudulent or deceptive business practices.

The first two categories are self explanatory. They include pharmacies that represent a threat for the people’s health, as they sell drugs that are not approved, or they are not in compliance with national or regional regulations. The third category is a more general class that includes those websites that scam people, stealing their data, or money (obviously, these websites are not only health-related). These three categories are not mutually exclusive, and a *illegitimate* pharmacy may belong to more than one, which is actually true for the majority of them.

Signals that make a pharmacy more likely to be *illegitimate* include concealing its physical address, being isolated from major trusted websites, as well having fewer store presence features, and fewer health-related text content than *legitimate* pharmacies [3, 28].

3.2 Problem Statement

We now formalize the problems that we solve in this study: first, classification of online pharmacies in *illegitimate* and *legitimate*; and second, ranking of online pharmacies according to their *legitimacy*.

We denote with \mathcal{P} the set of all the pharmacy websites. Let’s call \mathcal{P}^+ and \mathcal{P}^- the *legitimate* and the *illegitimate* pharmacies, respectively, in \mathcal{P} . We also suppose to know the class of a subset of pharmacies $\mathcal{P}_0 \subseteq \mathcal{P}$, i.e., there exists an *oracle function* O that for all the $p \in \mathcal{P}_0$:

$$O(p) = \begin{cases} 1 & \text{if } p \in \mathcal{P}^+ \\ 0 & \text{if } p \in \mathcal{P}^- \end{cases} \quad (1)$$

Assuming that a human reviewer can evaluate if a website is *legitimate* or not, we can think of the oracle function O as an evaluation performed by a human reviewer. However, oracle invocations are expensive and we cannot call O for each pharmacy in \mathcal{P} , so we aim to find another function, T , such that for some model Π :

$$T(p) = \begin{cases} 1 & \text{if } \Pi \models p \in \mathcal{P}^+ \\ 0 & \text{if } \Pi \models p \in \mathcal{P}^- \end{cases} \quad (2)$$

We recall that the formal notion $\Pi \models p \in \mathcal{P}^+$ means that Π entails $p \in \mathcal{P}^+$, where Π is a model derived and built from the training set \mathcal{P}_0 with some learning algorithm.

Note that there exist infinite T derived by infinite Π , but we are interested in the one that maximizes some evaluation measure (e.g., number of correctly classified instances, recall, precision). We can now formalize the classification problem:

PROBLEM 1 (ONLINE PHARMACY CLASSIFICATION (OPC)). *Given a set of pharmacies \mathcal{P} divided in two classes \mathcal{P}^+ and \mathcal{P}^- , a set of “known” pharmacies $\mathcal{P}_0 \subseteq \mathcal{P}$, and an evaluation measure φ , we seek a model Π_i such that $\forall p \in \mathcal{P}$, $T_i(p)$ maximizes φ .*

The second problem we are trying to solve is a ranking problem. We want to give a trust score to each pharmacy, which we could then use to produce an ordered list. More formally, we want to define a *totally ordered set*, where for each pair of pharmacies $p_1, p_2 \in \mathcal{P}$ it holds that $score(p_1) \leq score(p_2)$ or $score(p_2) \leq score(p_1)$. The score for each pharmacy is computed by combining different models.

PROBLEM 2 (ONLINE PHARMACY RANKING (OPR)). *Given a set of pharmacies \mathcal{P} divided in two classes \mathcal{P}^+ and \mathcal{P}^- , a set of “known” pharmacies $\mathcal{P}_0 \subseteq \mathcal{P}$, and a list of models Π_1, \dots, Π_k , we seek a totally ordered set $\langle \mathcal{P}, \leq \rangle$ such that, for each pair of elements $p_1, p_2 \in \mathcal{P}$, if $score(p_1) \leq score(p_2)$, then p_1 is “less legitimate” than p_2 .*

We expect that the ordered list naturally divides the pharmacies \mathcal{P} in two subsets (i.e., *legitimate* and *illegitimate* pharmacies), with all the elements of one subset at the top of this list, and all the elements of the other subset at the bottom. Without loss of generality, in the following we will focus on a *legitimacy* relation, which builds a list with *legitimate* examples at the top and *illegitimate* ones at the bottom.

In the following sections, we discuss how we solve the two problems formalized above, namely the classification and the ranking problem.

4 ONLINE PHARMACY CLASSIFICATION

Our classification algorithm is based on features that are relevant to both the text contained in the website of the online pharmacy and the web network structure around it.

4.1 Text Analysis

In order to reduce the dimensionality of the problem, it is common practice in Text Classification (TC) to use *preprocessing* and *summarization*.

Preprocessing: In the preprocessing step we remove the stop words found in the documents. In this way the most common words, which could adversely affect classification accuracy, are removed. To do so we rely on Apache Lucene⁸ version 3.4.0. We also decided to not use stemming, as the text contains a lot

⁸<http://lucene.apache.org/>

of technical words and trademarks, and this technique causes undesirable side-effects.

Summarization: The process of transforming a set of web pages into a unique summary is called *summarization*. For each pharmacy, we merge the text content of all the pages crawled into a single document. This step produces documents that include a large number of terms; documents comprising of 160,000 terms are not unusual. In our experiments, we evaluate the performance of the classifier models when we use the entire content of the document (all terms), as well as subsets of it. During this phase, we generate subsamples of the summary document considering a limited number of terms by randomly selecting 100, 250, 1000 and 2000 terms.

We are now ready to describe the core steps of our classification approach. Considering pharmacy websites as documents, and the two classes, *legitimate* and *illegitimate*, as mutually exclusive, we map our problem into the TC problem. We first convert each document (i.e., the text contained in an online pharmacy website) in a format suitable for the classification phase. We study two different such models, the Term Vector model [30], and the N-Gram Graphs model [12], both outlined below. Then, we use TC to classify unseen data relying on models built using the subset of labeled data \mathcal{P}_0 . We employ different learning algorithms to build a two-class classifier, including Naïve Bayesian Multinomial (NBM), Support Vector Machine (SVM), and the C4.5 decision tree learning algorithm.

4.1.1 Term Vector Model :

The Term Vector model is the most widely used text representation model in information retrieval, due to its high level of performance and scalability [30]. The model works as follows: given a set of documents \mathcal{D} , each document $d \in \mathcal{D}$ is represented as a vector of words $v_d = (v_1, v_2, \dots, v_{|\mathcal{W}|})$, where \mathcal{W} is the set of all the distinct words in \mathcal{D} . Each position v_i with $1 < i < |\mathcal{W}|$ in the vector represents the presence, or the absence, of word w_i in document d .

There are many variants to represent d_i values, but the most popular is the TF-IDF approach, which takes into account the number of occurrences of a term in a document (term frequency), and its overall frequencies in the whole set of documents \mathcal{D} (inverse document frequency).

4.1.2 N-Gram Graphs :

The N-Gram Graph is a graph $\mathcal{G}(V, E)$ which has character n-grams as its vertices, while the edges connecting the n-grams indicate proximity of the corresponding vertex N-Grams [12]. The weights on the edges represent how much the two N-Gram are related (one way of setting these weights is by counting how many times two N-Grams co-occur within a sliding window in the text). The advantage of N-Gram Graphs is that they conserve the order of the characters' appearance in the original text, and hence are more stable than the standard Character N-Gram Model. The three measures characterizing an N-Gram Graph are: (i) the minimum n-gram rank L_{min} , (ii) the maximum n-gram rank L_{max} , and (iii) the minimum neighborhood distance D_{win} . In our experiments, we use $L_{min} = L_{max} = D_{win} = 4$ [13].

In order to use N-Gram Graphs, we first transform each document d in a N-Gram Graph (refer to Figure 2). For each class c , we build an N-Gram Graph derived from merging the individual graphs in c , and we compute the similarities between each document d and the class graph. We then use the following similarity measures, namely, Containment Similarity (CS), Size Similarity

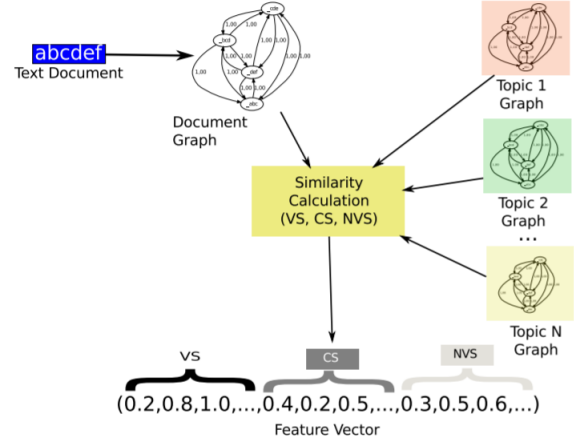

Figure 2: An overview of the classification process using N-Gram Graphs [13].

(SS), and Value Similarity (VS) in order to build a classifier able to predict the class of unseen data.

Containment Similarity (CS) expresses the proportion of edges of a graph G_i that are shared with a graph G_j .

$$CS(G_i, G_j) = \frac{\sum_{e \in G_i} \mu(e, G_j)}{\min(|G_i|, |G_j|)}$$

where e is an edge, and $\mu(e, G_i) = 1$ if, and only if $e \in G_i$. The cardinality $|G_i|$ here is intended as the number of edges of the graph G_i .

The ratio of sizes between two graphs is measured by the Size Similarity (SS):

$$SS(G_i, G_j) = \frac{\min(|G_i|, |G_j|)}{\max(|G_i|, |G_j|)}$$

We recall that with $|G_i|$ we indicate the number of edges in graph G_i

Value Similarity (VS) represents how many of the edges contained in G_i are contained in G_j , considering also the weight of such edges.

$$VS(G_i, G_j) = \frac{\sum_{e \in G_i} \frac{\min(w_e^i, w_e^j)}{\max(w_e^i, w_e^j)}}{\max(|G_i|, |G_j|)}$$

where w_e^i is the weight of edge e in the graph G_i .

A combination of VS and SS gives another useful measure, called Normalized Value Similarity (NVS):

$$NVS(G_i, G_j) = \frac{VS(G_i, G_j)}{SS(G_i, G_j)}$$

4.2 Network Analysis

Apart from the text features described above that we use for the classification of online pharmacies, we additionally use features derived from the web network in which they are embedded. More specifically, we are interested in the links an online pharmacy web page has with other web pages: the web pages that this pharmacy points to, and the web pages that point to this pharmacy.

To this effect, we use features extracted from the TrustRank algorithm [15]. In TrustRank, the network is represented as a graph $\mathcal{G}(V, E)$, where the set of nodes V are websites (or more generally web pages) and the links between pages, represented by the set E , are drawn as directed edges. The algorithm computes a

(a) Initial state of a network made of "good" (white) and "bad" (black) nodes. (b) The network after the execution of the TrustRank algorithm, with different levels of "trustiness".

Figure 3: Illustration of the TrustRank algorithm.

Algorithm 1 Creates the network graph $\mathcal{G}(V, E)$

GRAPH-CREATION(\mathcal{P} : set of pharmacies)

```

1:  $V \leftarrow \emptyset$ 
2:  $E \leftarrow \emptyset$ 
3: for all Pharmacy  $p \in \mathcal{P}$  do
4:    $V \leftarrow V \cup p$ 
5:    $\mathcal{L} \leftarrow \text{outboundLinks}(p)$ 
6:   for all Link  $u \in \mathcal{L}$  do
7:      $V \leftarrow V \cup \text{endpoint}(u)$ 
8:      $E \leftarrow E \cup \{u\}$ 
9:   end for
10: end for

```

trust score for each node in the graph, based on the premise that "good" pages rarely point to "bad" ones (this property is also called *approximate isolation of good pages*). More specifically, TrustRank starts by selecting a seed of "known" pages, and gives a trust score of 1 to good pages and 0 to all others. After normalizing the values, the trust is propagated at each step until convergence. This process is illustrated in Figures 3a and 3b.

In order to run our version of TrustRank, we first need to construct the graph (refer to Algorithm 1), on which the algorithm will be applied.

Recall that the set \mathcal{P} contains both labeled and unlabeled examples. The *outboundLinks()* function (line 5) accepts the URL of an online pharmacy as input, and returns all the outbound links for this website, namely, all links that point to external domains⁹. The *endpoint()* function (line 7), returns the final destination of a link, extracting the second level domain.

For example, assume that *outboundLinks(p)* for some website p returns the following set of links: "http://www.medicalnewstoday.com/articles/238663.php", and "http://www.fda.gov/forconsumers/consumerupdates/ucm149202.htm". Then, the function *endpoint()* applied on each one of these URLs will return: "medicalnewstoday.com", and "fda.gov", respectively.

This step is important because it allows us to significantly prune the feature space, which in this case is represented by URLs. Please also note that this step will not affect the quality as we can assume all the pages belonging to the same domain having the same trustiness.

In a second step we have to assign an initial trust score to each node in the graph. In our graph we have 4 types of nodes:

- (1) *legitimate* nodes in \mathcal{P}_0 ; we denote this set with \mathcal{P}_0^+

⁹In other contexts outbound links are sometimes called *external links*, or *outcoming links*.

- (2) *illegitimate* nodes in \mathcal{P}_0 ; we denote this set with \mathcal{P}_0^-
- (3) unknown pharmacy nodes in $\mathcal{P} \setminus \mathcal{P}_0$
- (4) non-pharmacy nodes pointed to by nodes in \mathcal{P}

Note that the last category includes all the websites extracted from pharmacy links with functions *outboundLinks()* and *endpoint()*. Following our previous example, these are "medicalnewstoday.com" and "fda.gov".

During the initialization phase of TrustRank, we assign to all nodes in \mathcal{P}_0 the value returned by the oracle function, O , when invoked on these nodes. Hence, after the initialization, the known *legitimate* nodes (the first category of the list) have a trust score of 1, while all the other nodes have a value of 0. Finally, we can run TrustRank and train a classifier using the output values of corresponding nodes in \mathcal{P}_0 .

5 ONLINE PHARMACY RANKING

Our goal here is, given a pharmacy, to calculate a value that indicates the degree by which this pharmacy is *legitimate* or *illegitimate*. Having these values for all pharmacies will allow us to compute the *totally ordered set* sought in Problem 2. We assume that the list is ranked in decreasing order of *legitimacy* (if $p_1 \leq p_2$ then p_1 is "less *legitimate*" than p_2). We propose a cumulative model that combines the models built with text and network:

$$\text{rank}(p) = \text{textRank}(p) + \text{networkRank}(p).$$

When we use the Term Vector model with TF-IDF to represent documents, the *textRank* of a pharmacy p is computed as the membership probability of this instance p to the *legitimate* class, as estimated by a classifier solving Problem 1. For example, in the case of the Naïve Bayesian Multinomial classifier, the probability of a document d being in class c is computed as:

$$P(c | d) \propto P(c) \prod_{1 \leq k \leq n_d} P(t_k | c),$$

where $P(c)$ is the prior probability of class c , and $P(t_k | c)$ is the conditional probability of term t_k occurring in a document of class c . If the classifier is non-probabilistic, like for example SVM, we give to *textRank* a value of 1 if the instance is classified as *legitimate* and 0 if it is classified as *illegitimate*, which is the same as the output of function T .

On the other hand, when we use the N-Gram Graphs representation model, we compute *textRank()* using a different formula: rather than considering the output of the classifier, we sum up the graph similarity measures according to this formula:

$$\begin{aligned} \text{textRank}(p) = & CS_{\text{legitimate}}(p) + (1 - CS_{\text{illegitimate}}(p)) \\ & + SS_{\text{legitimate}}(p) + (1 - SS_{\text{illegitimate}}(p)) \\ & + VS_{\text{legitimate}}(p) + (1 - VS_{\text{illegitimate}}(p)) \\ & + NVS_{\text{legitimate}}(p) + (1 - NVS_{\text{illegitimate}}(p)) \quad (3) \end{aligned}$$

The abbreviations CS, SS, VS and NVS denote containment, size, value and normalized value similarities for the class in subscript, described in Section 4.1.

The function *networkRank()* simply returns the TrustRank value computed with the algorithms presented in Section 4.2.

6 EXPERIMENTAL EVALUATION

We now evaluate the proposed approach using real data provided by an American company, who is a leader in internet pharmacy verification. We will call this company *PharmaVerComp*. The pharmacies used in our study have been manually labeled as

	Dataset 1 Date 1	Dataset 2 Date 2 (6 months later)
# Examples	1459 (100%)	1442 (100%)
# Legitimate Examples	167 (12%)	167 (12%)
# Illegitimate Examples	1292 (88%)	1275 (88%)

Table 1: Datasets

legitimate or *illegitimate* by personnel of this company. Therefore, the dataset is consistent and error free.

All our code is publicly available at: <https://sites.google.com/view/acolfplg/home>.

6.1 Experimental Setup

At the time of this study, PharmaVerComp monitored almost 200,000 health-related websites, out of which about 42,000 are active internet pharmacies. Only 0.5% of them are legitimate, while 96.7% are not legitimate. The remaining 2.8% are pharmacies defined as potentially legitimate. This class is represented by pharmacies that do not fully adhere to the PharmaVerComp policies, but are probably not *illegitimate*. In this database, the examples are manually labeled by experts in the sector (i.e., human reviewers), and constitutes our ground truth.

We worked on two different instances of this database, generated with a six months difference, which were provided by PharmaVerComp. The summary statistics of these two instances are provided in Table 1. The intersection between the *illegitimate* instances of Dataset 1 and Dataset 2 is empty, i.e., in Dataset 2 we have 1275 different *illegitimate* domains. The two datasets contain the same *legitimate* instances, but crawled in different periods of time. We used crawler4j¹⁰ in order to crawl each one of the domains in the two datasets, without depth limit, but for a maximum of 200 pages. In our analysis we use Dataset 1 as *base* dataset to test our algorithms, while we use Dataset 2 to inspect how our models evolve over time, i.e., how models built on “old” data behave in dealing with “new” data.

We observe that the two classes in both datasets are strongly imbalanced. In order to cope with this situation, we can use *undersampling*, which modifies the frequencies of the two classes by randomly removing examples belonging to the majority class in the training set, until the minority class reaches the same percentage as the majority class. The other technique we used is *SMOTE* [9]. SMOTE is an oversampling technique in which the minority class is oversampled by creating “synthetic” examples. Examples are created operating in “feature space” rather than in “data space”, the opposite of what happens in oversampling with replacement. In our experiments we trained our classifiers using the natural class distribution as well as the ones generated using these two sampling techniques. Then, for each classifier, we took the one which offered the best results.

6.2 Evaluation Measures

In the following, we call “positive” the *legitimate* class, and “negative” the *illegitimate* class. With the notions TN , TP , FN , FP we denote respectively the number of true negatives, true positives, false negatives and false positive. Based on those, the evaluation measures we use are the following.

Overall Accuracy. Overall accuracy is the general correctness of the classifier and it is calculated as the sum of correct classified

instances divided by the total number of instances:

$$Acc = \frac{(TP + TN)}{(TP + TN + FP + FN)}.$$

Note that in the case of imbalanced classes this indicator does not provide a very good evaluation measure. In fact, given the actual distribution of our dataset (12% *legitimate*, 88% *illegitimate*), a simple strategy of guessing the majority class would have an accuracy of 88%, but, of course, such a kind of classifier does not help us to distinguish between *illegitimate* and *legitimate* pharmacies.

Precision. Precision is a measure of the accuracy provided for a specific class. It is defined as the number of correct classified instances for a specific class divided by the total number of instances for that class. For example, the precision for the *legitimate* class is computed as:

$$Precision_{legitimate} = \frac{TP}{TP + FP}.$$

Recall. Recall measures how many examples of one class are classified correctly. The recall of the *legitimate* class is computed as:

$$Recall_{legitimate} = \frac{TP}{TP + FN}.$$

Due to the imbalance of the two classes, we expect a good classifier to have a high *illegitimate* precision and an high *legitimate* recall. This would mean that the classifier is able to correctly identify the *legitimate* examples.

Area Under ROC Curve. The ROC curve is drawn by plotting the *False Positive Rate* ($FPR = \frac{FP}{TN+FP}$) against the *True Positive Rate* ($TPR = \frac{TP}{TP+FN}$) of the classifier, at various threshold settings. The ideal point on this curve would be on the top left corner, meaning that all the positive examples are classified correctly, and no negative examples are classified as positive. The area under ROC curve is a useful measure, especially in the case of imbalanced datasets.

Pairwise Orderedness. For what concern the second problem, we rely on a measure generally adopted in ranking problems, *pairwise orderedness*, which is an indicator of the number of “violations” of the ordered property in a list. First of all we define a function I as follows:

$$I(p, q) = \begin{cases} 1 & \text{if } rank(p) \geq rank(q) \text{ and } O(p) < O(q) \\ 1 & \text{if } rank(p) \leq rank(q) \text{ and } O(p) > O(q) \\ 0 & \text{otherwise} \end{cases}$$

This function give 1 if and only if a *illegitimate* pharmacy receives an equal or higher score than a *legitimate* pharmacy. Then, we evaluate our ranking computing the fraction of the pairs for which there is not such a violation:

$$pairord(\mathcal{X}) = \frac{|\mathcal{X}| - \sum_{(p,q) \in \mathcal{X}} I(p, q)}{|\mathcal{X}|},$$

where \mathcal{X} is the set of all the pairs of pharmacies (p, q) , $p \neq q$, in the set $\mathcal{P} \setminus \mathcal{P}_0$. If *pairord* is equal to 1 there are no violations in the pairs and we have all the *legitimate* pharmacies at the top of the list and all the *illegitimate* ones at the bottom.

6.3 Classification Results

We ran experiments on Dataset 1 in order to test the methods described in Sections 4.1 and 4.2. In particular, we trained different classifiers with several combinations of text and network features. Below we present the results of the text and network

¹⁰<https://github.com/yasserg/crawler4j>

classification, and ensemble classification, where we combine both.

For all results, we computed the corresponding confidence interval, which indicates the reliability of the results. We used a confidence level of $100(1 - \alpha)\%$ with $\alpha = 0.05$ (i.e., confidence level 95%). In all cases, the confidence intervals for our classifiers are very small (less than 1%): this means that the classifiers are stable, with the results of each fold being very close to the mean.

6.3.1 Text Classification. :

Text classifiers were trained with different text representation techniques on different subsets of the data. We employed 3-fold cross validation, where two folds were used for training and the third for testing. In the case of N-Gram Graphs, we randomly selected half of the training instances to build the class graph [13]. Hence, we compared these class graphs with all our instances (training and test). The N-Gram Graphs library we used to build the graphs and compute similarities is JInsect¹¹, while for the implementations of the classifiers we relied on Weka [16].

Table 2 lists the abbreviations concerning the classifiers and the sampling techniques employed in our experiments. We performed various tests with all combinations among classifiers and sampling techniques. However, due to space requirements, for each classifier we present only the sampling technique that performed best.

The overall accuracy with the TF-IDF representation are reported in Table 3. In all cases, accuracy is above 88%, with the best performers reaching 99%. However, as we can observe in Table 4, the J48 classifier has low *legitimate* recall for small subsamples of data. (As we already explained in Section 6.2, overall accuracy is not enough to properly evaluate a classifier in an imbalanced classes context.)

Increasing the number of words considered in the subsample generally results in better performance. SVM is the classifier that performs the best in terms of overall accuracy. Also for what concerns *legitimate* precision and *illegitimate* recall, the best performer is SVM (refer to Tables 4 and 5). It is interesting to note the inverse trend of NBM, whose efficacy decreases, especially in *legitimate* precision, as we consider larger term subsets. As expected, *illegitimate* precision is generally high, with all values above 93%. This derives directly by the imbalance of the two classes. In fact, since we have much less *legitimate* than *illegitimate* examples, if the classifier put some *legitimate* instances in the wrong class, this does not heavily affect the recall of the *illegitimate* class.

The AUC ROC curve, which is more robust to the case of imbalanced classes, is shown in Table 6. NBM is the winner in all cases considered. We note that SVM, which offers good results in terms of *legitimate* precision and *illegitimate* recall, does not have high AUC ROC values, especially for small subsets of terms. Another observation is that the choice of the sampling technique makes almost no difference for NBM and SVM. Instead, for J48, the sampling technique leads to substantial variations in performance. In particular, SMOTE is the sampling technique that offered the best results. Similar observations have also been documented in previous studies [8, 10].

We performed the same experiments using N-Gram Graphs, in order to compare the two text representation techniques. For N-Gram Graphs we do not use sampling, because of the nature of this representation.

Abbreviation	Description
NBM	Naïve Bayesian Multinomial
NB	Naïve Bayesian
SVM	Support Vector Machines
J48	Java implementation of C4.5 algorithm
MLP	Multilayer perceptron (Artificial Neural Networks)
NO	No sampling technique used
SUB	Subsampling
SMOTE	Oversampling with SMOTE algorithm

Table 10: N-Gram Graphs - Area Under ROC Curve

The overall accuracies are shown in Table 7. MLP (Artificial Neural Networks) is the classifier that offers the best accuracy results. MLP is also the winner when we consider *legitimate* recall and *illegitimate* precision, as well as the AUC ROC, though similarly to the TF-IDF case, SVM gives better results for *illegitimate* recall and *legitimate* precision (see Tables 8 and 9). Note that J48 is the second best classifier.

When we compare the results obtained by the two text representation techniques, we realize that they perform very close to one another. Nevertheless, TF-IDF has a small edge when compared to N-Gram Graphs, since it leads to slightly better *legitimate* recall and AUC ROC values for “small” documents, which are easier to handle.

The conclusion of these experiments is that the use of text classification in the process of internet pharmacy verification leads to good results, independently of the text representation technique used. The reason for such good performance resides on the fact that online *legitimate* and *illegitimate* pharmacies behave very differently when selling products.

Taking a close look at the most frequent terms used by *illegitimate* websites, we noticed that words like “viagra”, “cialis” and “no prescription” appear more frequently compared to *legitimate* pharmacies, which usually target a more broad and educated audience. Therefore, our classifiers built on top of the text representations of the pharmacy websites (using TF-IDF, and N-Gram Graphs) are in general able to recognize these differences and correctly predict the class of new instances.

6.3.2 Network Classification. :

In Table 11, we report the ten most linked-to websites by *legitimate* and *illegitimate* pharmacies. We observe that the most linked-to websites we find in the *legitimate* list are the two major social networks, Facebook and Twitter. This is in accordance with a previous study, which claims that *illegitimate* online pharmacies have fewer store presence features than *legitimate* pharmacies [23].

We can also find in the *legitimate* list many government websites that are not present in its *illegitimate* counterpart. For example, fda.gov, which is an agency responsible for protecting and promoting public health, is the third most linked-to website among the *legitimate* examples, while it is not even present in the *illegitimate* list. This is also the case for other government websites, like the National Institute of Health (nih.gov), and the Centers for Disease Control and Prevention (cdc.gov).

	<i>legitimate</i> precision	<i>legitimate</i> recall	<i>illegitimate</i> precision	<i>illegitimate</i> recall
NB	0.904	0.732	0.966	0.990

Table 13: Network - precision and recall

On the other hand, we note that the two most linked-to websites in the *illegitimate* list are not directly related to the health sector (wikipedia.org and wordpress.org). Furthermore, in the *illegitimate* list there are some websites that are themselves classified as *illegitimate* pharmacies (e.g., rxwinners.com)¹² This fact is supported by many studies, which report networks of *illegitimate* pharmacies connected together in an affiliated way, where there is a central website and multiple other sites link to it¹³.

For the network experiments, we used the same settings as for the text classification. The dataset is divided into 3 folds (2 train, 1 test) and each experiment is repeated three times, changing the folds, according to cross-validation. Note that the two folds used for training represent the initial seed \mathcal{P}_0 . In the set of graph nodes V , we assigned 1 to those nodes that represent *legitimate* pharmacies in \mathcal{P}_0^+ , 0 to the others. We use the scores computed by TrustRank algorithm to train and test the classifiers, and the Naïve Bayes as the base classifier.

The overall accuracy and the AUC ROC are summarized in Table 12. The overall accuracy is around 96%, that is fairly close to the case of text classification, but for what concerns the AUC ROC curve the result is significantly worse. This is reflected also to *legitimate* recall, shown in Table 13, which is around 0.73, while for the other measures the method exhibits quite good results.

Given these results, we conclude that network analysis offers good performance in terms of *illegitimate* precision and recall, and could be used to assess the *legitimacy* of a pharmacy, even though it does not reach the level of confidence provided by the text analysis method.

6.3.3 Ensemble Classification. :

In order to enhance our results, we also combine the two analyses techniques, building a single model that embodies the characteristics of both the text and the network. In order to implement

¹²*illegitimate* status verified via the LegitScript public interface (<http://www.legitscript.com>).

¹³<http://legitscript.com/research>

	J48	SMOTE	0.994
N-Gram Graph			0.998

Table 15: Ranking using TF-IDF and N-Gram Graphs

this approach, we relied on “Ensemble Selection” [4], which is a method for constructing ensembles from libraries of models. We used an implementation of “Ensemble Selection” available in Weka. According to the process explained in [4], the library of models was trained, building a new model with standard parameters.

The results we obtained are presented in Table 14, comparing ensemble selection with the two best single models on text and network. For simplicity we report only the results considering subsamples of 1000 words; the other cases exhibit very similar results.

We note that ensemble selection increases the overall accuracy, *legitimate* precision and *illegitimate* recall when compared to the other classifiers. This results in a higher AUC ROC value, as well, which means that our ensemble classifier is the preferred method for this task.

6.4 Ranking Results

In Table 15, we summarize the ranking results for both the TF-IDF and the N-Gram Graph representations. As we expected, the results reflect the trend observed in the classification results. The best ranking is the one that is computed with the SVM classifier. Also the other classifier results follow the patterns highlighted in Section 6.3, with SVM and NBM performing better than J48.

As part of the ranking analysis, we performed an analysis of the *legitimate* and *illegitimate* outliers, i.e., the *illegitimate* examples that appear high in our ranking, and the *legitimate* examples that obtained poor score and appear at the bottom of the list. Performing a manual analysis on such examples gives us the possibility to check which *illegitimate* pharmacies are able to fool our system. Moreover, these insights could be very useful in helping *legitimate* pharmacies to better market themselves.

We extracted a subset of the *legitimate* and *illegitimate* outliers, and provided those to PharmaVerComp, in order to obtain feedback about their characteristics. The domain experts pointed out that *illegitimate* outliers, are in general not part of any *illegitimate* networks¹⁴. On the other hand the *legitimate* outliers are the pharmacies that offer new prescriptions, while the majority of them simply give the possibility to refill existing prescriptions.

6.5 Model Evolution over Time

As previously mentioned, we also want to test the behavior and robustness of our models over time. Given the good performance obtained with Dataset 1, we are now interested in evaluating how

¹⁴We recall that *illegitimate* examples are very likely to belong to *illegitimate* networks (see Section 6.3.2).

		Old-Old		New-New		Old-New

J48	SMOTE	0.71	0.76	0.67	0.79	0.66	0.51

Table 17: TF-IDF - Model over Time - *legitimate* Precision

much our models are affected by time. In particular, we want to answer the following two questions:

- (1) Will models computed on the new dataset (Dataset 2) get the same performance as the models computed on the old dataset (Dataset 1)?
- (2) Are models trained with the old data still valid on the new data?

The answer to the first question will give us the opportunity to evaluate the robustness of the model. The answer to the second question, will evaluate the validity of the proposed models over time, and test whether it is necessary to train the models often, or not.

In the following analysis, we only consider the classification part of the proposed approach. Note that ranking models are derived directly from the classifiers. We report here the performance for the two most meaningful classification measures for our problem, that is, AUC ROC and *legitimate* precision.

As we have seen, the first one offers a good overall indication of how well our classification process works, while the second measure is very sensible due to the small number of *legitimate* examples. Moreover, we focus on results for the Term Vector with TF-IDF weights and subsets of 250 and 1000 words.

6.5.1 New model with new data. :

In order to answer the first question posed above, we ran the same experiments conducted in Section 6.3, using Dataset 2. The results are used to verify if our models are effective even when applied to a new test dataset, despite the fact that *illegitimate* pharmacies appear in and disappear from the web at a relatively high rate.

We report the results in Tables 16 and 17. To do the comparison we report also the results obtained with the old dataset, namely, Dataset 1. In particular, we indicate with “Old-Old” the results obtained when computing and testing models on Dataset 1, and with “New-New” the results obtained by building and testing models on Dataset 2. We observe that the two models achieve almost the same performance for both measures. The conclusion of this analysis is that our approach is stable in analyzing different datasets that follow the natural distribution of instance classes.

6.5.2 Old model with new data. :

The answer to the second question will help us understand whether or not we need to adapt our models to pharmacy behavior changes. In particular, we expect that pharmacies change their text content and their relationship with other websites over

time. This may affect our approach, which is strongly based on these two factors.

We tested models computed on old dataset, i.e., Dataset 1, on the new Dataset 2. Recall that these two datasets were crawled with a difference of six months. In this period of time, online pharmacies may have changed their characteristics, especially the *illegitimate* pharmacies, since they may be closed by the inspection authorities.

The results of this analysis are presented in Tables 16 and 17 (column Old-New). We can observe that there is a small reduction in *legitimate* precision is evident, while the AUC ROC value remains almost the same.

The conclusion of this experiment is that our model is fairly robust over time. However, it has some problems related to the *legitimate* accuracy measure. In turn, this means that re-training and maintenance of the model is necessary to ensure good quality of results, though, it is not necessary that this re-training takes place very often.

7 CONCLUSIONS AND FUTURE WORK

In this paper, we proposed solutions for the problem of automatic internet pharmacy verification, which is becoming an increasingly relevant and important problem, gaining attention from both the public and the private sectors.

We formalized two different problems: first, a binary classification problem, where we define two classes, *legitimate* and *illegitimate*, and we classify the online pharmacies in one of them; and second, a ranking problem, where we seek a *totally ordered set* that defines a ranking among pharmacies. We then described solutions for both these problems, based on features that are relevant to the text and the network structure of online pharmacies. These are the first solutions that have been proposed in the literature in order to address the internet pharmacy verification problem.

We experimentally validated the effectiveness of our approach using two real datasets from two different time periods. The experiments demonstrate that the proposed algorithms can very accurately perform the classification and ranking tasks, and that the models we use are fairly robust over time. Our results confirm that our system could be effectively employed in the process of internet pharmacy verification, as well as in other similar tasks, offering considerable assistance to the human analysts dealing with such real-world problems.

As part of future work, we intend to extend our algorithms across two dimensions: (a) include in our network analysis non pharmacy websites that point to pharmacies, as well as consider websites at distances greater than one to our working set, and (b) study and evaluate classification schemes with combined (network and text), or additional features. In both cases, the aim will be to employ a richer input, and therefore to improve the performance of the algorithms.

Moreover, we plan to apply the proposed techniques to other domains of electronic commerce, where it will be possible to create publicly available datasets that can serve for making further progress in this area.

ABSTRACT

Applications need to analyze the past state of their data to provide auditing and other forms of fact checking. Retrospective snapshot systems that support computations over data store snapshots, allow applications using simple data stores like Berkeley DB or SQLite, to provide past state analysis in a convenient way. Current snapshot systems however, offer no satisfactory support for computations that analyze multiple snapshots. We have developed a Retrospective Query Language (RQL), a simple declarative extension to SQL that allows to specify and run multi-snapshot computations conveniently in a snapshot system, using a small number of simple mechanisms defined in terms of relational constructs familiar to programmers. We describe RQL mechanisms, explain how they translate into SQL computations in a snapshot system, and show how to express a number of common analysis patterns with illustrative examples. We also describe how we implemented RQL in a simple way utilizing SQLite UDF framework in a Berkeley DB data store using Retro page-level incremental snapshot system. Multi-snapshot computations running over page-level incremental snapshots bring up interesting performance issues that have not been studied before. We present the first study defining a performance envelope for multi-snapshot computations over page-level incremental snapshots.

1 INTRODUCTION

To provide auditing and other forms of claim checking more and more applications need to answer questions, often formulated after the fact, about the past states of their data. To free applications from the burden of managing past states on their own, data management systems need to run ad-hoc computations over past states of the objects they store.

Computations over past states have been long supported by temporal databases, used by applications in specialized domains but not used by general applications because of cost and performance penalty for in-production operation. More recently, cheap storage and interest in using past state analytics for in-production operation led to development of systems that integrate past state analytics in a database [7, 11, 13], and all major vendors today offer products providing OLTP and OLAP processing in a single system [16]. These products however are not a good match for Internet applications that store their data in simple key value stores such as Berkeley DB (BDB) [15] or SQLite [8] and need past state analysis for on-line historical claim checking or auditing. Today however, even applications using key value stores can support past state analysis using snapshot systems that support retro-spection, the ability of a data store to run queries over consistent snapshots of application past state as if they were the current state [22]. Retrospection makes it easy for programmers to provide expressive past state analysis since it allows to implement ad-hoc queries as general programs in the application language

using the application code base and then run these programs on the snapshots of interest. For example, Retro [21], a snapshot system of BDB, allows to analyze the state of BDB SQLite applications at a particular point in time simply by running SQLite queries over the corresponding BDB snapshot.

As convenient as it is to analyze a single point in time using a snapshot system, many analyses concern multiple data points. Retro and other snapshot systems come short when it comes to analyzing multiple snapshots. A programmer needs to write a C script that manually identifies snapshots of interest, queries each snapshot separately, manually collects the results, and then processes the results. This approach is cumbersome, error prone and onerous for a SQL programmer who needs to learn a new language. The programmer would much prefer to specify the computation in a declarative manner using the language of the application.

To help with programming the desired computation logic for multiple snapshot analysis, we have developed a Retrospective Query Language (RQL), a simple declarative extension to SQL that allows to specify and run multi-snapshot computations without the need to use a low-level script. RQL mechanisms combine in a modular way high-level relational constructs to express general SQL computations over arbitrary sets of past BDB SQLite application snapshots. The constructs specify in SQL the set of snapshots that identify the past states of interest, the computations over each snapshot, and the computations that process the results.

We describe RQL mechanisms and explain how each high-level mechanism translates into a SQL computation over multiple snapshots in the Retro snapshot system. We also show how to express a number of common analysis patterns with illustrative examples. We then describe how we implemented RQL in a simple way using SQLite UDF.

RQL programs bring to light important performance considerations that arise when programs compute over multiple snapshots. For one, RQL mechanisms allow to specify computations over arbitrary size sets of snapshots. The number of snapshots stored by a snapshot system such as Retro, only limited by available storage, can be very high given today's low storage costs. Each snapshot includes the entire state of the database. RQL program therefore can compute over potentially very large amounts of data. A programmer needs to know how much CPU, memory and I/O resources his program requires, especially in today's utility computing environments. Furthermore, an important performance consideration in the design of snapshot systems like Retro is to avoid interfering with the data store performance so that snapshots can be created at required frequency without blocking or disrupting in-production application performance. Retro snapshot system achieves this by using a low-cost copy-on-write technique that creates an incremental page-level snapshot representation with a compact snapshot index [22, 23]. Such representation is known to be slower to compute with but the slowdown is considered to be an acceptable trade-off to preserve in-production performance. The reason a computation runs slower over a snapshot and incurs higher resource costs compared to

the current database state is that the snapshot state needs to be assembled on-the-fly from the incremental representation. Inherently however, with a snapshot representation created using copy-on-write, consecutive snapshots share large parts of their state. An RQL program that iterates computations over multiple consecutive snapshots can therefore reduce its costs and improve performance by assembling such a shared state only once. The performance of programs computing over multiple *page-level copy-on-write* snapshots however has not been studied before.

To this end, we implemented RQL in SQLite BDB using Retro snapshot system and conducted an experimental study that characterizes the performance envelope of RQL programs. The goal of the study is to explain the performance in a way that is easy to understand by the programmer. Since the programmer specifies RQL mechanisms as a modular composition of relational constructs in SQLite, we relate the performance of RQL program to the performance of its SQL components, a cost that should be familiar to the programmer. Our experiments use workloads derived from the standard TPC-H benchmark to evaluate RQL performance so that even though our system is different from other past state systems, its performance is explained using a standard workload.

In summary, the paper makes the following contributions:

- RQL, a SQLite extension that allows to express computations over multiple snapshots in a convenient way in the language of the application. Our focus here is SQL extension but we believe a similar approach can be used for BDB applications in other languages since the BDB/Retro system is language-independent.
- An implementation of RQL system using SQLite UDF.
- A performance study of RQL programs including the first analysis explaining the performance of computations running over multiple page-level copy-on-write snapshots. While the performance results reported in our study are specific to our system, our performance analysis is more general and applies to other page-level copy-on-write snapshot systems.

The rest of the paper is organized as follows. Section 2 describes the RQL mechanisms, Section 3 outlines the salient points of RQL implementation using SQLite UDF, Section 4 briefly outlines the basic structure of the copy-on-write snapshot system Retro, providing the background for our performance analysis, Section 5 describes the experimental study, Section 6 considers the related work, Section 7 concludes.

2 RQL LANGUAGE

In this section we present RQL, the programming language for specifying SQL computations over sets of snapshots of past states in a data store. Our departure point is a transactional key value store with an integrated snapshot system that allows a SQL application to take snapshots of its state and subsequently run a SQL computation over a snapshot. Specifically, we assume the Retro snapshot system integrated with the BDB SQLite [21]. We first explain the snapshot computation model provided by Retro, and the concrete language constructs used by SQL programmers to create snapshots and to specify a program that runs over a snapshot.

Retro extends BDB/SQLite with a language construct that allows to declare a snapshot as part of normal transaction commit using the *BEGIN*; and *COMMIT WITH SNAPSHOT*; commands. The declaration command creates a transactionally consistent

Figure 2: SnapIds table

persistent snapshot that includes the state of the entire database (e.g., tables, indexes, system catalogs). The snapshot reflects the modifications committed by the declaring transaction T, and all the transactions committed before T. The declaration permanently associates with the snapshot a unique snapshot identifier that names the snapshot. The identifier and a current timestamp are entered in a table with name *SnapIds*. Although Retro uses integer sequence numbers as snapshot identifiers internally, a programmer can associate meaningful snapshot names with the identifiers.

A query can run on a snapshot at any point following the snapshot declaration. To run a SQL program, such as "SELECT ..." over previously declared snapshot with identifier *sid*, the programmer simply specifies "SELECT AS OF *sid* ...". SQL queries and update transactions that do not declare snapshots remain unchanged by Retro.

Consider an example SQL application using a *LoggedIn* table that stores the users who are logged in a system, along with the time and the country from which each user has logged in. Whenever a user logs out, he is deleted from the table. Figure 3 shows a SQL program containing three consecutive snapshot declaration commands, (lines 1-2, lines 3-5, and lines 6-8), a snapshot query command that runs on the snapshot *sid* 1 (line 9), and the same query that runs on the current database state (line 10). Figure 1 shows the table state in three declared snapshots, and Figure 2 shows the *SnapIds* table. Note, that the state of *LoggedIn* table in the snapshot 2 declared in lines 3-5 does not include *UserA* since a snapshot reflects updates of the declaring transaction.

Retro makes it easy to analyze a single snapshot but has no support for analysis concerning multiple snapshots. In order to provide this functionality we propose RQL, a simple language for specifying computations over a set of Retro snapshots.

```

Declare snapshot S1
1. BEGIN;
2. COMMIT WITH SNAPSHOT;

Update table and declare snapshot S2
3. BEGIN;
4. DELETE FROM LoggedIn WHERE l_userid = 'UserA';
5. COMMIT WITH SNAPSHOT;

Update table and declare snapshot S3
6. BEGIN;
7. INSERT INTO LoggedIn (l_userid, l_time, l_country)
   VALUES ('UserD', '2008-11-11 10:08:04', 'UK');
8. COMMIT WITH SNAPSHOT;

Retrospective query
9. SELECT AS OF 1 * FROM LoggedIn;

Query on current state
10. SELECT * FROM LoggedIn;

```

Figure 3: Retro SQL example

RQL queries specify computations using a small set of basic computational mechanisms that compose relational constructs familiar to a SQL programmer. A computation defined by an RQL query iterates over a set of snapshots, runs a SQL query on each snapshot, collects results of the query and performs on the results different combining computations determined by the specific mechanism used.

In specifying the set of snapshots to iterate over, and the snapshot query to be executed in each iteration, RQL uses two auxiliary constructs, a *snapshot table* that holds all the declared snapshot identifiers and timestamps, referred to as *SnapIds*, and a function *current_snapshot* that provides the identifier of the snapshot used in the iteration where the current computation is performed.

The RQL mechanisms *Collate Data*, *Aggregate Data In Variable*, *Aggregate Data In Table* and *Collate Date Into Intervals* are best described operationally by explaining the SQL computation each one performs.

2.1 Collate Data

The RQL mechanism *Collate Data* collects records from multiple snapshots into a table.

```
CollateData(Qs, Qq, T)
```

Collate Data requires three parameters, the queries *Qs*, *Qq* and table name *T*. Query *Qs* returns a single column containing snapshot identifiers selected from the snapshot table *SnapIds*. The *Qs* output represent the snapshot set (interval) the programmer is interested in. Query *Qq* is applied to every snapshot in the snapshot interval. *T* is the name of the table into which we collate the results of every *Qq*.

For the first snapshot identifier *Sx* returned by the *Qs*, the mechanism issues "CREATE TABLE *T* AS *Qq*" within the snapshot *Sx*. For all the subsequent *Sy* returned by *Qs*, "INSERT INTO *T* *Qq*" is issued, within snapshot *Sy*.

The following example collects all the user_ids and the snapshot identifier of the snapshot they appear in.

```
CollateData("SELECT snap_id FROM SnapIds",
```

```
"SELECT DISTINCT l_userid, current_snapshot()
FROM LoggedIn", "Result")
```

Collate Data along with the snapshot table *SnapIds* and the *current_snapshot()* function provide a general language for implementing any kind of computation by issuing SQL queries on the Collate Data output. However, Collate Data can have a large footprint in terms of the memory required to hold its result, especially when the *Qs* set and *Qq* result set are large.

The two aggregation mechanisms we present next, allow to reduce the memory footprint for RQL computations that need to aggregate results over snapshots.

2.2 Aggregate Data In Variable

The first aggregation mechanism *Aggregate Data In Variable* applies an aggregate function on a single element across multiple snapshots.

```
AggregateDataInVariable(Qs, Qq, T, AggFunc)
```

In addition to the queries *Qs*, *Qq* and table name *T*, it requires an aggregate function as a parameter and it expects from *Qq* to return a single row and a single column. For the first snapshot identifier *Sx* returned by *Qs*, we execute *Qq* on snapshot *Sx* and save the single value in a variable *V1*. For all subsequent identifiers *Sy* returned by *Qs*, we issue *Qq* on snapshot *Sy*, save the single value in a variable *V2* and update *V1* as *AggFunc(V1, V2)*. Finally, we store the result in the table *T*.

The following example shows how we can count the number of snapshots in which a tuple appears. For example, we want to count the number of snapshots in which user *UserB* is logged in.

```
AggregateDataInVariable("SELECT snap_id FROM SnapIds",
"SELECT DISTINCT 1 FROM LoggedIn
WHERE l_userid = 'UserB', "Result", "sum")
```

In the next example, we want to find the first occurrence of the same user.

```
AggregateDataInVariable("SELECT snap_id FROM SnapIds",
"SELECT DISTINCT current_snapshot() FROM LoggedIn
WHERE l_userid = 'UserB' ", "Result", "min")
```

2.3 Aggregate Data In Table

The mechanism *Aggregate Data In Table* provides the ability to apply aggregate functions on records of multiple columns across snapshots.

```
AggregateDataInTable(Qs, Qq, T, ListOfColFuncPairs)
```

The additional required parameter is a list of pairs of column names and aggregate functions.

For the first snapshot identifier *Sx* returned by *Qs*, we create a table *T* and insert the *Qq* output. For all the subsequent identifiers *Sy* returned by *Qs* we issue the query *Qq* and for each record in its output we search in table *T* to find a tuple with the same values in columns not included in the *ListOfColFuncPairs*. If such a record exists we perform the required computation on the values in columns of *ListOfColFuncPairs*, otherwise we insert into *T* the record returned by *Qq*. Note, the *Aggregate Data In Table* queries can be considered as across time *GROUP BY* queries where the grouping columns are the columns of the *Qq* output not appearing in the *ListOfColFuncPairs*. So, for the aggregation across snapshots to be well defined, *Qq* should never return two records that coincide on all the values in the grouping columns.

The following example shows how we can find the first time that each user has logged in.

Figure 4: General structure of RQL computations

```
AggregateDataInTable("SELECT snap_id FROM SnapIds",
"SELECT DISTINCT l_userid, l_time FROM LoggedIn",
"Result", "(l_time,min)")
```

The next example shows how we can compute, for each country, what is the maximum number of users who are simultaneously logged in, from that country.

```
AggregateDataInTable("SELECT snap_id FROM SnapIds",
"SELECT l_country, COUNT(*) AS c FROM LoggedIn
GROUP BY l_country", "Result", "(c,max)")
```

In order for *Aggregate Data in Variable* and *Aggregate Data in Table* to work as described, we require the aggregate function to satisfy certain mathematical properties. Formally, the aggregate function must be definable by an abelian monoid (X, op, e) where X is the domain of values, op is an associative and commutative binary operation and e is the identity element. Most SQL aggregate functions e.g. min, max, count and sum, satisfy the requirement but some, e.g. average, and aggregations over distinct elements e.g. count distinct or sum distinct do not. Because average is widely used in SQL, our aggregation mechanisms implement a simple extension that support average as a special case. Aggregations over distinct elements can use the *Collate Data* mechanism to return a column containing the elements and then use SQL to perform the needed aggregation. Of course, such approach may not reduce the memory footprint of the result computation.

2.4 Collate Data Into Intervals

The mechanism *Collate Data Into Intervals* creates an alternative, potentially more compact snapshot data representation that resembles the traditional record lifetime representation used by temporal databases, and could be used by applications that expect this kind of representation. When the snapshots are taken frequently, it is likely that the same record appears in many consecutive snapshots. The mechanism collects records from multiple snapshots into intervals which indicate the lifetime of the records. This is achieved by creating two attributes in our result table and storing the *start_snapshot* and the *end_snapshot* for each record's lifetime.

```
CollateDataIntoIntervals(Qs, Qq, T)
```

Collate Data Into Intervals requires the same parameters as *Collate Data*. For the first snapshot identifier S_x returned by the Q_s , we create the table T and insert the records returned by Q_q with *start_snapshot* and *end_snapshot* for each record set to S_x . For all the subsequent S_y returned by Q_s we issue the query Q_q and for each record in its output we search in table T to find a tuple with the same values in all columns except the *start_snapshot* and *end_snapshot*. If a tuple exists and if its *end_snapshot* value is the same as the snapshot identifier of the previous iteration we update the *end_snapshot* to S_y , otherwise we insert a new tuple with *start_snapshot* and *end_snapshot* set to S_y .

The following example calculates the interval during which each user was logged in.

```
CollateDataIntoIntervals("SELECT snap_id FROM SnapIds",
"SELECT l_userid FROM LoggedIn", "Result")
```

Figure 4 provides the general structure of our RQL computations. The *Aggregation* part is bypassed in case of *Collate Data*.

3 IMPLEMENTATION

An RQL computation iterates (loops) over the snapshots in the snapshot set defined by the parameter query Q_s , and for each snapshot it executes a "loop body" that invokes the query Q_q on this snapshot, processing its results in a way specific to each mechanism. This section explains how we implement this computation in SQLite/BDB Retro system using SQLite UDF. We highlight the salient points of the implementation, including the cross snapshot iteration with constructs *current_snapshot()* and *SnapIds*, and the processing of snapshot query results.

We create the SQL program for RQL computation by composing the Q_s and Q_q query programs using the callback infrastructure provided by SQLite UDF. The infrastructure allows to interpose a UDF callback function on a SELECT statement so that the callback is invoked for each element of a set returned by the SELECT.

We define the "loop body" of our computation in a UDF callback function, providing for each mechanism a mechanism-specific callback, and iterate over snapshots by interposing the "loop body" callback on the SELECT statement for Q_s .

The following SQLite statement shows the general syntax used by our implementation for an RQL mechanism.

```
SELECT rql_udf (snap_id, Qq, T, ...)
FROM SnapIds WHERE ...;
```

By issuing this statement to SQLite, we achieve the iteration over the snapshot identifiers in the table *SnapIds* returned by the SELECT (i.e. Q_s), where for each returned snapshot identifier, SQLite invokes the "loop body" defined by the UDF callback *rql_udf*. Figure 5 shows the general structure of the resulting computation.

The UDF argument *snap_id* is filled at runtime by SQLite with values returned by Q_s in each iteration, the other parameters, including the string defining the Q_q query, the table name T , and additional parameters needed for the aggregation mechanisms are specified by the programmer.

Inside the "loop body" UDF, we treat the parameter *snap_id* as "loop index". The "loop body" UDF uses Retro to run the query Q_q on snapshot *snap_id* in every iteration it gets invoked.

To run on a snapshot *snap_id*, Retro requires a query to be in the form of "SELECT AS OF *snap_id* ...". Furthermore, the SQL program Q_q may include the function *current_snapshot()*, explained in Section 2, that denotes the snapshot identifier of the current iteration. Therefore, as a first step, our "loop body" UDF rewrites the Q_q , binding it to the value of "loop index" *snap_id*.

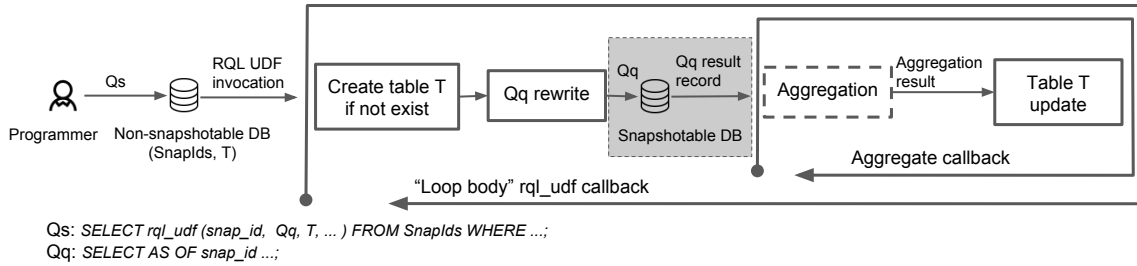

Figure 5: Implementation structure of RQL computations

The rewriting involves adding the "AS OF snap_id" extension, and replacing every occurrence of `current_snapshot()` function with the value of `snap_id`.

For example, for the iteration with `snap_id` value of `Si`, the following Qq query typed by the programmer:

```
SELECT DISTINCT current_snapshot() FROM LoggedIn
WHERE l_userid = 'UserB';
```

will be rewritten by the RQL UDF to take the following form:

```
SELECT AS OF Si DISTINCT Si FROM LoggedIn
WHERE l_userid = 'UserB';
```

After Qq is rewritten, the UDF issues it to SQLite, invoking the `sqlite3_exec` function from the SQLite API. The "loop body" UDF then proceeds to process the results across snapshots in a mechanism-specific manner, as shown in Figure 5. Note the shaded area depicts the Qq computation run by Retro within a single snapshot.

Consider an example *Collate Data* query specified below:

```
SELECT CollateData(snap_id,
"SELECT DISTINCT l_userid, current_snapshot() AS sid
FROM LoggedIn", "Result") FROM SnapIds;
```

Since the mechanism does not perform any computation besides Qq, its "loop body" UDF only utilizes the SQLite API. That is, *Collate Data* UDF callback executes SQL statements using the `sqlite3_exec` function to insert Qq results into the result table T.

The UDF callbacks that implement our aggregate mechanisms are more involved since they need to implement aggregation. Consider an example of *Aggregate Data in Variable* specified as follows:

```
SELECT AggregateDataInVariable(snap_id,
"SELECT DISTINCT current_snapshot() AS sid
FROM LoggedIn WHERE l_userid = 'UserB' ",
"Result", "min") FROM SnapIds;
```

In the first iteration, its "loop body" UDF creates a table `Result` with attribute `sid`. It then rewrites Qq and invokes the `sqlite3_exec` function from the SQLite API to run the Qq. One of the arguments of `sqlite3_exec` is a callback function which gets invoked for every tuple returned by the Qq, providing access to the returned tuple. In this callback function we implement the aggregate computation for *Aggregate Data In Variable*, directly following the specification in the previous section.

Consider next an example of *Aggregate Data in Table* specified as follows.

```
SELECT AggregateDataInTable(snap_id,
"SELECT l_country, COUNT(*) AS c FROM LoggedIn
GROUP BY l_country", "Result", "(c,max)") FROM SnapIds;
```

Here the first "loop body" iteration creates the table `Result` with attributes `l_country` and `c`. It then rewrites and issues Qq and for

every tuple returned by the Qq a callback function is invoked that inserts the tuple in the table `Result`. At the end of the first "loop body" iteration we also create an index on `Result` using as key the values in non-aggregating columns, in this case `l_country`. In subsequent iterations, for every record returned by the Qq, in the callback function we utilize the index to search in table `Result`. If a tuple with the same values in non-aggregating columns is present, we apply the aggregate functions on the columns specified in the `ListOfColFuncPairs` and update the record in the result table accordingly, otherwise we insert a new tuple.

We have also experimented with alternative *Aggregate Data in Table* implementation using a sort-merge based algorithm that turned out to be costlier.

For brevity, we omit the implementation details of *Collate Data Into Intervals*. It is implemented similarly to *Aggregate Data in Table* but instead of applying an aggregate function we check whether we need to update the record's lifetime or insert a new tuple in the result table.

Note that RQL mechanisms by default create the result table T as temporary non-snapshotable table. However, it can be created as persistent if the programmer decides otherwise.

We now briefly consider the construct *Snapids*. It is currently implemented at application level to support user friendly snapshot names. Also, it is stored in a separate SQLite database than application data because it is a non-snapshotable persistent table (whereas the rest of the data are snapshotable). Every time the application declares a snapshot and gets back the snapshot identifier, it inserts the identifier in the `SnapIds` along with a timestamp and any application meaningful information the programmer needs to later refer to the snapshot. The update operations on `SnapIds` table are transactional. Note, that concurrent updates to `SnapIds` table and RQL queries do not block each other since Retro runs snapshot queries as read-only snapshot transactions taking advantage of MVCC concurrency control in BDB, as we explain in section 4. Nevertheless, updating `Snapids` in a transaction adds overhead so we are currently working on an internal implementation to reduce this overhead.

4 RETRO SNAPSHOT SYSTEM

We briefly describe Retro, the snapshot system used in RQL. Our goal is to explain how the cost of snapshot query is impacted by the method of incremental page-level snapshot creation and indexing, and the different update workloads. The complete description of Retro system can be found in [21–23].

Retro snapshot system is implemented as a small set of modular extensions to the Berkeley DB transactional storage manager. The extensions interpose on transaction *commit*, *page flush*, *page fetch and recovery* operations. The implementation at the storage manager level allows to create transactionally consistent,

recoverable snapshots efficiently, without blocking application transactions, by exploiting the BDB MVCC concurrency control and recovery mechanisms [22].

The snapshot system interface supports two operations, *snapshot declaration* and *snapshot query*, that can be exposed to applications in a language-specific way. Section 2 presented the SQL interface. A Retro snapshot is a set of immutable logical data pages that reflect the entire consistent database state, including the catalog and indexes, at snapshot declaration point. This allows to run on a snapshot any database query q that could run in the database at the snapshot declaration point. The snapshots are captured using a page-level copy-on-write technique (COW) that copies out and saves snapshot pages incrementally as transactions commit modifications to pages, following a snapshot declaration. At transaction commit time, Retro identifies any page P that is modified for the first time following the declaration of a snapshot S and copies out the pre-modification state (pre-state) of P . The pre-state corresponds to the state of P as-of snapshot S . If this modification of P is also the first since an earlier declared snapshot S' , the pre-state is shared by S' .

Retro accumulates the copied-out pre-states in memory and writes them to an on-disk log-structured snapshot archive called *Pagelog* when the database flushes updates. The pre-states are indexed at low cost by simply recording a mapping that associates a snapshot page P with its *Pagelog* location. Retro writes the mappings to an on-disk log-structured list called *Maplog* [23]. When a snapshot S is needed, an efficient scan of *Maplog* allows to construct a snapshot page table $SPT(S)$ that maps every page P in snapshot S to its location in *Pagelog*. The scan length is $n \log(n)$ where n is the number of pages in the snapshot, independent of snapshot history length [23].

To run a query q on a snapshot S Retro interposes on the database page *fetch* operation. When q requests a page P , Retro looks up page location in $SPT(S)$ and fetches P from *Pagelog*, the same way q would fetch P from the database if it was running on the current database state.

Retro caches snapshot pages in a buffer cache along with the database pages and needs extra cache memory to hold the snapshot pages when running snapshot queries. While we expect the database pages to reside in memory given today's large memories, we do not expect snapshot pages to fully reside in memory because with long snapshot histories *Pagelog* can grow very large, limited only by the available disk space. For this reason, even with a large snapshot cache, when a query runs on a snapshot that has not been accessed recently, we expect the snapshot page cache hit rate to be low. The *I/O* cost of a snapshot query therefore depends on the number of pages it fetches from *Pagelog* when the page is not present in the cache.

Retro allows to run snapshot queries concurrently with current state queries and update transactions. It relies on the BDB concurrency control scheme MVCC to avoid snapshot queries from interfering with updates. Consider a snapshot query q that runs over snapshot S following the snapshot declaration. At this point the snapshot shares all its pages with the database. Consider a page P requested by q and a concurrent transaction T that modifies page P . Retro runs q as a read-only MVCC transaction relying on MVCC to provide q with the unmodified pre-state of P to the end of q , without interfering with T .

We now consider the amount of *Pagelog I/O* needed by a snapshot query. Consider a set of update transactions T_1, \dots, T_n that updates every page in the database following the declaration of snapshot S . We call such transaction set an overwrite cycle

of S . After the overwrite cycle of S completes, the entire state of S and all the snapshots declared before S , is copied out into *Pagelog*. A snapshot declared a long time ago is likely to have a complete overwrite cycle so a query running over old snapshots fetches all its pages not present in a cache from *Pagelog*. On the other hand, consider a snapshot S that has been declared recently. Some of the pages of the database likely have not been modified since snapshot S declaration, so its overwrite cycle is incomplete. If a page P has not been modified since snapshot S declaration, S shares P with the database. A snapshot query running on S and requesting a shared page P will fetch P from the database. Therefore, we expect a query running on recent snapshots to have less *Pagelog I/O*.

Finally, consider two snapshots S_1 and S_2 declared consecutively, and the set of update transactions T_1, \dots, T_k committed between S_1 and S_2 . Note that snapshot S_1 and S_2 share all their pages except those pages modified by T_1, \dots, T_k . Let $shared(S_1, S_2)$ be the set of pages shared by S_1 and S_2 , and $diff(S_1, S_2)$ be the set of pages that are not shared by S_1 and S_2 . Consider a snapshot query q running consecutively over two old snapshots S_1 and S_2 using a cache large enough to hold all the snapshot pages requested by q . If snapshots S_1 and S_2 have not been accessed for a long time, all pages of S_1 will need to be fetched from *Pagelog* but any page P in $shared(S_1, S_2)$ needs to be fetched from *Pagelog* only once since P will be in the cache after q runs on S_1 . On the other hand, any page Q in $diff(S_1, S_2)$ requested by q running on S_2 likely will need to be fetched from *Pagelog*. The size of $diff(S_1, S_2)$ will therefore determine the cache miss rate for q running on S_2 . The size of $diff(S_1, S_2)$ is determined by the transaction update workload, i.e. by how many pages the transactions modify, and by the frequency of snapshot declarations, i.e. how many transaction apart are the declarations S_1 and S_2 . If transactions modify many pages and snapshot declaration are infrequent, $diff(S_1, S_2)$ will be large, but if transactions modify few pages and snapshot declarations are frequent, $diff(S_1, S_2)$ will be small and S_1 and S_2 will share most of the pages.

5 PERFORMANCE EVALUATION

This section presents an experimental study that characterizes the performance of RQL computations. We aim to explain RQL performance in terms that are familiar to a SQL programmer. Since the programmer specifies an RQL query r by providing SQL programs Q_s, Q_q and the aggregation functions, we consider how the performance characteristics of these SQL programs impact the performance of r .

To explain the performance of RQL we need to characterize the costs of a computation that iterates over snapshots. The performance of a snapshot computation that runs over a stand-alone single snapshot has already been studied [21]. However, as we explain in Section 4 because of snapshot page sharing, a snapshot computation that runs as one of the RQL iterations can have a different performance than a snapshot computation that runs on a stand-alone snapshot. Our study evaluates the benefit of page sharing for different transaction update workloads and explains how the benefit of sharing depends on the properties of the snapshot set Q_s , and whether the snapshot computation Q_q is *I/O* or computation intensive. Our experiments also analyze the memory requirements of different RQL mechanism and quantify the memory benefits of the aggregation mechanisms.

Our experiments run our implementation of RQL in the Retro snapshot system integrated with BDB SQLite version 5.3.21.

Parameters	Notations	Description
Update Workload	UW15 UW30	Delete and insert 15K orders and their lineitem records per snapshot Delete and insert 30K orders and their lineitem records per snapshot
Query Qs	Qs_N	Query that determines the snapshot interval length N
Query Qq	Qq_io Qq_cpu Qq_collate Qq_agg Qq_int	SELECT COUNT(*) FROM orders WHERE o_orderstatus = 'O' ; SELECT SUM(l_extendedprice) AS revenue FROM lineitem, part WHERE p_partkey = l_partkey and p_type = 'STANDARD POLISHED TIN'; SELECT o_orderkey FROM orders WHERE o_orderdate < '[DATE]'; SELECT o_custkey, COUNT(*) AS cn, AVG(o_totalprice) AS av FROM orders GROUP BY o_custkey; SELECT o_orderkey, o_custkey FROM orders;
RQL UDF		CollateData (Qs, Qq, T) AggregateDataInVariable (Qs, Qq, T, AggFunc) AggregateDataInTable (Qs, Qq, T, ListOfColFuncPairs) CollateDataIntoIntervals (Qs, Qq, T)
Aggregate function		MIN, MAX, SUM, COUNT, AVG

Table 1: Parameters and notations

The hardware platform consists of 2 hexa-core Intel Xeon CPU clocked at 2.50 GHz with Hyper-Threading enabled, 2 Intel 400 GB SATA SSD and 64 GB of RAM. The operating system is Red Hat Enterprise Linux Server release 6.8 (Santiago), x86_64 and the file system is formatted with ext4.

RQL performance depends on the database update workload, the in-snapshot query workload, and the type of RQL computation that combines the results of the snapshot queries. We expect the in-snapshot queries to include both *native* queries the application runs in the current state, e.g. when performing auditing, and *ad-hoc* queries formulated after the fact, e.g. when performing fact checking. The native queries are more likely to have native indexes captured in the snapshot. The ad-hoc queries may need to create the indexes at RQL execution time. Our experiments use both native and ad-hoc queries.

The database we use for our experiments is a TPC-H database. TPC-H [6] is a standard decision support benchmark consisting of tables designed to be business relevant and the database schema includes tables with information about Customers, Orders, Lineitems, etc. We create the database by using the TPC-H *dbgen* tool to produce the initial state of the database with size of 1.4 GB (the default size) without additional indices. The size increases accordingly when indices are included.

In order to create a snapshot history, we utilize the TPC-H refresh functions which produce a set of order identifiers for deletion and a set of order records along with Lineitem records associated with the orders for insertion. Our update workload program receives as input the TPC-H refresh function output, updates the database by deleting and inserting a certain number of Orders and their Lineitem records and creates snapshots. Between two consecutive snapshot declarations a constant number of orders and their associated records are inserted and deleted making it easier to interpret the performance results and memory requirements.

We consider two update workloads that delete and insert different amount of data, as defined in Table 1. These update workloads generate different $diff(S1, S2)$, the amounts of non-shared data between two consecutive snapshots $S1$ and $S2$, and affect how frequently the database gets overwritten, i.e. the length of the

snapshot overwrite cycle. The UW30 overwrites the database every 50 snapshots while the UW15 overwrites every 100 snapshots, so the $diff(S1, S2)$ in UW30 is double the size of UW15.

We assume the current state database is memory resident, and the snapshot pages are stored in Pagelog on the SSD. We achieve the expected snapshot cache behavior by assuming the snapshot page cache is empty at the start of an RQL query, and assume the cache can hold the snapshot pages requested by a single RQL query, except when discussing memory costs.

For our experiments, we define custom queries that stress different RQL costs in both native and ad-hoc queries. Table 1 reports all the queries used throughout our performance evaluation. We explain the characteristics of each query when describing the experiments that use them. The reason we don't provide any experimental results using TPC-H queries is because their complexity makes them CPU intensive and does not allow us to stress and focus on a single RQL cost each time.

5.1 I/O intensive queries: Impact of snapshot sharing

Our first set of experiments considers the impact of snapshot sharing on the *I/O* costs of an RQL query for old and recent snapshots.

We first consider old snapshots. When all the snapshots included in the set defined by Qs are old, the first iteration fetches from the Pagelog disk all the pages it needs and is likely to fetch the highest number of pages compared to the subsequent iterations. We refer to the first iteration as *cold*, and to the subsequent iterations as *hot*. Note, the number of pages fetched by a cold iteration is identical to a stand-alone snapshot query and is determined by the code of Qq . The maximum number of pages potentially fetched by the subsequent *hot* iterations depends on two factors, the $diff(S1, S2)$ in the update workload explained in Section 4 and how far apart are the snapshots in the hot iterations, determined by the number of snapshots skipped in the Qs query. In the extreme case, if Qs defines a skip that exceeds the snapshot overwrite cycle length, the performance of a hot iteration will be no different than a performance of a cold iteration. We refer to an RQL query run where all iterations are cold

Figure 6: Ratio C with old snapshots: impact of sharing between snapshots.

as *all – cold*. In general, we expect sharing to improve the RQL query performance compared to *all – cold* but the amount of improvement depends on the snapshot interval length since for short intervals the performance of cold iteration may dominate.

The combined impact of sharing can be succinctly captured using a ratio C of latency of an RQL query r with a given Qq and Qs , to the latency of an *all – cold* run with the same number of snapshots.

Figure 6 shows the ratio C as the number of snapshots in the interval increases, for update workloads with different amount of sharing, UW30 and UW15 and different distance between consecutive iterations. To isolate the impact of sharing on total *I/O* costs we use a computationally light RQL Aggregate Data in Variable query with an *I/O* intensive and computationally light Qq_{io} . At each RQL iteration, Qq scans the table Orders and returns the number of open orders for the current snapshot and the RQL query computes the average number of open orders per snapshot.

Since all snapshots are old, the cost of the *all – cold* run remains constant. Sharing increases as we move from update workload UW30 to UW15 and when the number of skipped snapshots drops from 10 to 1. The ratio C drops with increased sharing reflecting the RQL query latency decrease compared to *all – cold* run. Overall, C is high for short intervals since sharing makes little difference as the cost of the first cold iteration dominates the RQL query latency. For sufficiently long intervals however (more than 20 snapshots) C converges to a constant as the cost of the cold iteration stops being the dominant cost, and the RQL query latency is fully determined by sharing. The first two bars in Figure 8 break down the cost of the cold and hot iteration for UW30 showing the impact of sharing on the absolute *I/O* costs in the hot and cold iterations in this workload.

We next consider recent snapshots. When the set of snapshots defined by Qs includes recent snapshots, the number of pages fetched from *Pagelog* in a given snapshot iteration is impacted by an additional factor, namely by the number of pages the snapshot shares with the current state of the database since page shared with the current state is fetched from the main memory, as explained in Section 4. Therefore, the number of pages fetched by a snapshot iteration decreases as snapshot gets closer to the end of our snapshot history and snapshots share more pages with the current state.

Figure 7: Ratio C with recent snapshots: impact of sharing with current state.

The ratio C , defined as ratio of measured RQL query cost to the cost of *all – cold* run, can be used to explain the additional impact of sharing pages with the current state database. Due to the database overlap, the cost of the cold iteration depends on the starting point of the interval. Therefore, the cost of *all – cold* run for two intervals with the same number snapshots drops when interval starts at a more recent snapshot. Figure 7 shows the ratio $C(x)$ for fixed size interval of consecutive snapshots (skip 1) starting at snapshot x , for intervals that include recent snapshots. We show two update workloads UW30 and UW15 exhibiting different inter-snapshot sharing $diff(S1, S2)$.

Assuming *Slast* is the most recent declared snapshot, and *OverwriteCycle* is the overwrite cycle length for a given update workload UW , the interval starting at snapshot $Slast - OverwriteCycle - 20$ is the earliest interval to include a snapshot sharing pages with the database. *OverwriteCycle* is 100 in case of UW15 and 50 in case of UW30. We consider therefore intervals starting at $x = Slast - 100 - 20$ and later for UW15, and $x = Slast - 50 - 20$ and later for UW30.

For intervals starting with an old snapshot x , $C(x)$ drops as x becomes more recent since the measured RQL cost decreases but the cost of *all – cold* run remains constant. For intervals starting with a recent snapshot x , $C(x)$ increases since the cost of *all – cold* run decreases and converges to the measured RQL cost, as both cost drop as intervals become more recent.

In absolute terms, RQL cost decreases sharply as we move to more recent intervals as shown in Figure 8, where an iteration on a more recent snapshot *Slast-25* performs significantly better than on older *Slast-50* (UW30).

Where cold iteration cost can be a dominant factor for old snapshot intervals since it can fetch substantial number of pages from *Pagelog*, this is not so for recent intervals where cold iteration fetches a substantial number of pages from the database so the dominating factor for intervals of recent snapshot is the sharing with the current state of the database.

5.2 CPU intensive queries

We expect snapshot page sharing to have less impact on CPU intensive RQL queries.

We consider two kinds of CPU intensive RQL queries. In one case, an RQL query issues a computationally heavy Qq so that SQL query execution time is the dominant cost, in the other case

Figure 8: Single iterations cost for the RQL query `AggregateDataInVariable(Qs_50, Qq_io, T, AVG)` with update workload UW30.

Figure 10: Single iteration cost for `CollateData(Qs_50, Qq_collate, T)` with varying Qq output size with UW30.

Figure 9: Single iteration cost for the RQL query `AggregateDataInVariable(Qs_50, Qq_cpu, T, AVG)` with update workload UW30.

RQL defines a Qq with a large output size. In the latter case the RQL UDF becomes the dominant cost.

For computationally intensive Qq, especially with join operations, if there is no native index in the snapshot, SQLite creates covering indices to assist the query evaluation. An experiment reported in Figure 9 shows that index creation always dominates RQL cost. Our experiment uses `AggregateDataInVariable` to avoid introducing significant RQL UDF cost and `Qq_cpu`. The Qq performs a join operation on tables `Part` and `Lineitem` and returns the revenue of the orders that include an item of a certain type. SQLite decides the building of a covering index on table `Lineitem` as part of the query execution plan. Note, unlike for I/O intensive queries, here the cost difference between a cold and hot iteration is less since I/O cost is small part of total Qq execution cost.

The Qq will not always be an *ad-hoc* query in the database workload and may have a native index built by the programmer. We evaluate the cost of the same RQL query where a native index is available in the snapshot. As shown in Figure 9 the I/O cost due

to index creation drops but instead the SPT build cost increase since an index increases the size of the database and the PageLog.

Our last experiment considers Qq that returns as a result a large number of records. This increases RQL UDF cost since SQLite UDFs invokes a callback function to perform operations for every record returned by the Qq. These operations are either insert operations in case of `Collate Data` or aggregations in case of `Aggregate Data` in Table.

Figure 10 shows the RQL performance where the CPU cost is dominated by the cost of UDF for `Collate Data` with a computationally light Qq query (`Qq_collate` in Table 1). The query scans the table `Orders` and returns the orders with order date less than a certain date. It has a single predicate which we vary to control the query output size. As in earlier CPU intensive queries, sharing has minimal impact on RQL cost.

5.3 Memory costs

The memory requirements of an RQL computation include two parts, the memory to hold the snapshot pages requested by Qq iterations, and the memory needed for result computation and to hold the result table T. Since Qq iterates over snapshots sequentially, the first part is independent of snapshot set size, and is essentially the memory needed to run Qq over a single snapshot, which includes the snapshot pages holding the working set of Qq plus the snapshot metadata structures such as `Maplog` and `SPT(S)`. The memory costs of single snapshot computation have been studied before [21]. Here we consider the memory costs of RQL mechanism result computation for different mechanisms.

RQL can support general computations over snapshots using `Collate Data` and running SQL computations over the results. However, such a method could incur high memory cost when Qs requires to compute over large number of snapshots. Memory cost can be reduced for RQL computations that perform aggregations on records across snapshots by using RQL aggregation mechanisms.

Consider the case where given the table `Orders` of TPC-H the user wants to find out, for each customer, what is maximum number of orders placed in a single snapshot by the customer and their average total price. This can be accomplished by running a single `Aggregate Data` in Table.

```
AggregateDataInTable(Qs_50, Qq_agg, T, (MAX, cn))
```

Figure 11: Comparison of RQL queries that producing the same result using Aggregate Data in Table and Collate Data for different number of aggregations.

The same result can be produced using Collate Data by first collecting how many orders each customer has placed in every snapshot in the given snapshot interval along with their average total price.

```
CollateData(Qs_50, Qq_agg, T)
```

A single SQL query can then compute the final result.

```
SELECT o_custkey, MAX(cn), av FROM T;
```

In Figure 11, the first two bars compare the performance of the two approaches for Qs that iterates over 50 snapshots. The RQL UDF cost dominates the RQL cost because the query’s output is approximately 1M of records for every snapshot. The Collate Data performs slightly better than Aggregate Data in Table.

However, Aggregate Data in Table has a significantly smaller memory footprint. Where Collate Data result table is more than 1GB, the Aggregate Data in Table result table is less than 100MB. Aggregate Data in Table achieves the memory footprint reduction for only 6% overhead in total execution time. Importantly, the memory footprint of Aggregate Data in Table is independent of Qs since we don’t expect the result table to grow significantly after each iteration, whereas Collate Data inserts the entire Qq output at each iteration.

The reason why Aggregate Data in Table is costlier than Collate Data can be explained in Figure 12 which shows single cold and hot iteration of the two RQL queries issuing the same Qq_agg. The first cold iteration is more expensive in case of Aggregate Data in Table even though they insert exactly the same number of records in the result table, because the Aggregate Data in Table creates an index on its result table. In addition, the insert operations in Collate Data is slightly cheaper than in Aggregate Data in Table because the result table of Collate Data does not have a primary key. Maintaining a primary key on a table introduces overhead to the insert operations. The reason why hot iteration is more expensive in case of Aggregate Data in Table is because we overall perform more operations. The Qq query returns approximately 1M records so, Collate Data in a single iteration executes 1M insert operations. Aggregate Data in Table on the other hand executes 1M select operation on the result table and a number of inserts or updates given the aggregation it performs. In this experiment is perform approximately 22K inserts or updates.

Figure 12: Single iteration cost for the RQL queries CollateData(Qs_50, Qq_agg) and AggregateDataInTable(Qs_50, Qq_agg, (MAX,cn)) and update workload UW30.

Figure 13: Single iteration cost for Aggregate Data in Table for different aggregate function

Since the Aggregate Data in Table is able to aggregate on multiple columns Figure 11 also evaluates the cost of additional aggregation. The second aggregation calculates the maximum among averages of the total price using the following Aggregate Data in Table query:

```
AggregateDataInTable(Qs_50, Qq_agg, (MAX,cn): (MAX,av))
```

And the extra query required by the Collate Date will be:

```
SELECT o_custkey, MAX(cn), MAX(av) FROM collate_result;
```

As we can see adding extra aggregation does introduce significant overhead.

For some aggregate functions like SUM and COUNT the Aggregate Data in Table have to update its result table for every record returned by the Qq. For these aggregations, we expect the hot iterations to have increased cost. Figure 13 compares Aggregate Data in Table RQL queries that apply different aggregate functions, MAX and SUM on the results of the Qq_agg. The cold iterations perform the same because they do the same initial insert operations and index creation. The hot iterations do the same number of search operations on the result table but in case of SUM they will do significantly more updates, 1M versus 22K in case of MAX.

Next, we briefly consider the Collate Data Into Intervals mechanism, comparing it to Collate Data. We focus on the memory costs since the non-memory costs of Collate Data Into Intervals closely resemble Aggregate Data In Table.

The result table size of Collate Data Into Intervals depends on the size of Q_q , and the lifetimes of records, i.e. the number of updated and deleted records between consecutive snapshots. The mechanism also needs memory to store the index. The result table size of Collate Data only depends on the size of Q_q . Our experiment uses a Q_s that defines an interval of 50 consecutive snapshots, a Q_q that returns 1.5 millions records in each snapshot (Q_q_int in Table 1), and four different update workloads UW7.5, UW15, UW30, and UW60 that respectively modify between consecutive snapshots 7,500, 15,000, 30,000, and 60,000 order records.

For Collate Data mechanism, the result table has 75M records of total size more than 3GB. For Collate Data Into Intervals, the result table has respectively 1.86M records (89 MB), 2.3M records (105MB), 2.97M records (138 MB) and 4.4M records (204 MB) for UW7.5, UW15, UW30 and UW60 update workloads. For each workload, the mechanism requires about 50% additional memory to hold the index during the computation. Interestingly, with our workloads, increasing the number of modified records between snapshots does not increase the result table size proportionally. Overall the experiment shows Collate Data Into Intervals can substantially reduce memory costs, confirming the known space saving properties of record lifetime based snapshot representation compared to naive page-level representation [24].

6 RELATED WORK

Computations over past state have been investigated in depth by a rich body of work on temporal databases [17, 27]. The most common data model adopted by the temporal databases is the extension of the relational data model with time-stamps that record lifetimes of record values via attributes indicating the start and end time [17]. The temporal dimensions can vary depending on whether a database supports the *transaction time* or the *valid time*, or both (bi-temporal databases). Temporal databases have not been widely adopted by general applications because of poor performance during normal in-production operation [10] and portability concerns.

One of the first commercial databases to support historical data management was Oracle Flashback [18] which allows to store all the modifications in a compressed format using the undo tablespace without affecting application portability. IBM provides support for bi-temporal tables in DB2 [19] by allowing the declaration of additional attributes in temporal tables to indicate the time dimension. Both Flashback and DB2 provide time travel operation to a single point in the past but offer no support for temporal computations over multiple past points which is the main focus for our work. Teradata [1] supports bi-temporal tables by extending the tables with columns representing the time domain and supports a set of temporal computations called temporal aggregations [30]. These computations scan the values which participate in the aggregation at the logical level, to determine how they have changed between different timestamps, and then compute the aggregation on the values changes.

In contrast to the logical record level approaches to past state management, RQL computations run in a snapshot system that manages the past state using a different low-level page-based approach where snapshots expose to application the entire past

state of the database, and portions of the state required by the snapshot computation are assembled on demand from the low-level representation. Using the snapshot system RQL provides multi-snapshot computations to applications in a seamless manner as we have explained. Moreover, in terms of expressive power, these computations can compute anything a record-level past state system can compute assuming snapshots capture all updates to the database. In particular, our Collate Data Into Intervals mechanism can create the same time-stamped representation used by the temporal databases. A potential downside of the snapshot system approach is that snapshot representation is less compact than logical record level representation and adds space overhead. However, prior work has shown that a snapshot system can reduce the space overhead substantially without impacting normal in-production application performance, using an adaptive low-level page-diff approach [24], that offers a convenient trade-off between more compact snapshot representation and a higher cost of snapshot reconstruction.

Temporal aggregations apply aggregate functions on relations that evolves over time, e.g. the average salary of an employee over the past certain years. Efficient methods for computing temporal aggregations have been the subject of numerous studies in temporal database research. The implementation of temporal aggregations is challenging in the logical temporal models because in order to aggregate along the time dimension a temporal computation may need to assemble the consistent state of multiple records at each time. Many of the proposed techniques in the literature accelerate this process using sophisticated data-structures that impose a variety of constraints to achieve efficiency. An early work by Kline and Snodgrass uses a non-indexed approach based on a data structure called Aggregation Tree [12]. The approach requires the entire structure to be memory resident, and has a worst case complexity of $O(n^2)$ when the tree is unbalanced. The complexity can be improved in special cases of ordered data. SB-Tree [28] and MVS-Tree [29] relax the in-memory limitation by introducing disk-based indexes for temporal aggregations. The approach limits the type of aggregate functions if data deletion is expected to SUM, COUNT and AVG. Moreover, the index size can be larger than the database. The TMDA [3] and Timeline Index [9] do not limit the aggregation functions. TMDA however does not support time travel queries. The Timeline Index is an in-memory system that requires large amount of memory to perform well. In contrast, RQL relies on state reconstruction at a lower level, and since each Retro snapshot includes the entire state of the database, RQL computations can aggregate over consistent state seamlessly without restricting types of aggregation and without requiring special temporal indexes. Nevertheless, auxiliary temporal data-structures can potentially be beneficial for repeated RQL computations and we consider this future work.

Similarly to temporal aggregations, temporal join is another challenging computation for temporal databases due to the need to identify all the versions of the join candidates that overlap in the time domain. Like with aggregation, in a snapshot system temporal join poses no addition challenge because the join candidates that overlap in time exist in the same snapshots and the temporal join is executed as if they were in current state.

Several temporal query languages have been adopted by temporal systems. The most notables are the TSQL2 [26] and TQuel [25] which extend SQL and Quel languages respectively. Some of the TSQL2 temporal properties have been adopted in SQL:2011 standard and the Teradata database. T4SQL [5] and TENORS [4] are more recent languages designed based on the time-stamping data

model. These languages are not suitable for our snapshot based system because of the different data model. Our SQL UDF based query language is fully compatible with SQL and does not require any change to the current ISO standard version. Languages designed for streaming data management such as CQL [2], resemble temporal computations since stream tuples include timestamps but since they are specialized for computations subject to real-time performance requirements they offer less expressive power compared to the temporal languages and RQL.

Although, RQL computations are most closely related to temporal databases, the snapshot system RQL extends is also similar to versioning systems with linear branching. These systems manage historical data by creating versions of the dataset somewhat similarly to the way Retro uses compact diff-based snapshot [24]. Array data versioning system [20] supports time travel queries and uses a SELECT primitive similar to ours to collect data from multiple versions. Decibel [14] is a branching system for relational datasets and supports time travel queries and multi-version aggregation. Our snapshot system does not support non-linear branching so many of the computation primitives and methods they explore are not applicable to RQL.

A snapshot system called Hyper [11] utilizes hardware-assisted memory snapshots to implement a hybrid OLTP and OLAP relational database system. OLTP and OLAP queries can run in parallel, in separate processes. The analytical queries access transaction consistent snapshots of the current state which are discarded after the queries are evaluated. Hyper does not consider a language for snapshot computations.

7 CONCLUSION

Auditing and other forms of claim checking require applications to compute over multiple past states of their data. The current systems supporting past state computations cannot be easily used by general applications using simple data stores. These applications however can easily use a snapshot system but current snapshots systems do not provide convenient support for multi-snapshot computations. Trying to bridge this gap, we proposed RQL, a retrospective query language that allows programmers to specify multi-snapshot computations in a snapshot system. Our language, implemented as a SQL extension using SQL UDF callbacks in SQLite BDB with Retro snapshot system, provides programmers a convenient way to express computations using the language of the application. Our experimental study evaluates the performance of RQL computations and explains how RQL program parameters, the SQL programs Qq and Qs interact with the page-level copy-on-write snapshot representation. This is the first study explaining the performance of programs running on multiple page-level copy-on-write snapshots. Our future work includes performance optimizations for RQL programs exploring how computations can be shared across multiple snapshots and whether parallelization can be applied.

ABSTRACT

The correlated exploitation of heterogeneous data sources offering very large archival and streaming data is important to increase the accuracy of computations when analysing and predicting future states of moving entities. Aiming to significantly advance the capacities of systems to improve safety and effectiveness of critical operations involving a large number of moving entities in large geographical areas, this paper describes progress achieved towards time critical big data analytics solutions to user-defined challenges in the air-traffic management and maritime domains. Besides, this paper presents further research challenges concerning data integration and management, predictive analytics for trajectory and events forecasting, and visual analytics.

1 INTRODUCTION

Aerial and maritime transportation have significant role and impact on the global economy and our everyday lives. The improvements along the last decades of these transportation means in terms of management, planning, security, information to operators and end-users has been driven by location-based information. The ever-increasing volume of data emphasizes the need for advanced methods supporting real-time detection and prediction of events and trajectories, together with advanced visual analytic methods, over multiple heterogeneous, voluminous, fluctuating, and noisy data streams of moving entities.

These transportation domains aim at fostering collaborative decision-making environments, involving all the stakeholders in the process as this is expected to provide direct and positive consequences in terms safety, efficiency and economy in both, aerial and maritime domains. For instance, by having a better understanding of the air navigation data (historical data of flight plans, sector configurations and weather), the number of published regulations (e.g. delays imposed to flights entering congested areas), which limit the number of flights planned to enter an airspace or aerodrome to match traffic demand to available capacity, could be more accurately forecasted and thus the adherence to scheduled trajectories improved, reducing delays and operational costs.

Tracking and analysis of vessels' behaviour at sea are also important challenges for enhancing the safety and efficiency of many maritime operations [10]: preventing ship accidents by monitoring vessels' activity represents substantial financial savings for shipping companies (e.g., oil spill clean-up) and averts irrevocable damages to maritime ecosystems (e.g., fishery closure).

The current Air Traffic Management (ATM) is nowadays changing its point of view from a time-based operations concept to a Trajectory-Based Operations (TBO) one, which means a better exchange, maintenance and use of the aircraft trajectories. Similarly, real-time tracking and forecasting of trajectories of ships from port-to-port, worldwide, together with route prediction and early recognition of maritime events, are essential to improve safety of operations at sea. More accurate and richer information on trajectories and related events is expected to increase the abilities to predict trajectories and forecast events, anticipate the behaviour of any moving entity, improve situational awareness, and consequently the decision-making process in both ATM and maritime domains.

Due to the complexity of these transportation systems, as well as due to factors contributing to increased uncertainty and lack of accuracy in the mobility data, the current techniques for predicting trajectories are limited to a short-term horizon, while the event detection and forecasting abilities are limited. The development of methodologies exploiting the amount of data from heterogeneous data sources, managing the possible lack of veracity for (actual, historical and planned) trajectories and other contextual aspects (e.g. airspace sector configurations, regulations and policies, sea protected areas, weather patterns), is expected to overcome some of the limitations of existing systems.

The objective of this paper is to describe progress achieved towards big data analytics solutions concerning moving entities in the air-traffic management and maritime domains, and to present related research challenges on data integration and management, predictive analytics for trajectory and events forecasting, and visual analytics. Challenges, methods and techniques developed in this paper originate from the datAcron project (<http://www.datacron-project.eu/>) whose aim is to provide advances for Big Data Analytics for Time Critical Mobility Forecasting.

The rest of the paper is organised as follows. Section 2 introduces the challenges from both domains from an end-user perspective. Section 3 presents the overall datAcron architecture. Section 4 presents the data management components and the datAcron ontology, while Section 5 presents the location and trajectory predictors. Section 6 presents the events detection and forecasting components, and Section 7 the online and offline visual analytics components. All sections present experimental results, providing evidence of the progress achieved towards time critical (i.e. real time) data processing and mobility analytics tasks. Finally, Section 8 draws the conclusions.

2 USER-DEFINED CHALLENGES IN THE ATM AND MARITIME DOMAINS

Efficiency in the air-traffic management system requires minimizing costs for both the airspace users (mainly airlines) and the operators (namely, Air Navigation Service Providers, ANSP's). In general, one key enabler for reducing costs is the predictability of the system. In particular, from the point of view of the ANSP, maintaining the balance between the demand (i.e., the number of users trying to use limited resources like airports, airspace sectors, etc.) and the capacity (i.e., the number of users which can safely use the mentioned resources) is one of the main challenges. For an airline, flying according to the plan, avoiding delays or extra fuel consumption represents the ideal to achieve daily operations. A trajectory based operation approach enables to plan which resources of the air-traffic management system will be used by each flight (airports, airways, sectors, etc.), define the achievable schedules, as well as the implied costs, increasing efficiency.

Big data technology, which can exploit very large historical and streaming data sources for positioning, contextual aspects and weather, presents opportunities to boost current predictability capacities that are based mainly on complex theoretical models of the different components of the air-traffic management system.

Surveillance is an ever-increasing data source since new technologies are deployed (like ADS-B) which allow to collect data more widely (space based ADS-B promises global coverage) and more frequently. Weather data, identically, each time is offered with more resolution, both geographical and temporal. Contextual data, like flight plans, waypoints, or airways is increasing, linked to the traffic growth, year after year. While each data set is big, correlating and jointly exploiting all of them together is what makes big data technology necessary. The aircraft trajectory must be understood not only as the 4D collection of points: It should also include events relevant for the traffic management and the airline operations. So, predicting the aircraft trajectory implies predicting these events too, and vice versa. The amount of information involved in this trajectory prediction process requires advanced visual analytics aids in order to understand the patterns of the predicted trajectories and events, inspect the exact reasons for deviating from plans towards either making adjustments to the actual system, or tune trajectory and event detection and prediction methods for more accurate results.

Accurate predictions of trajectories will further advance adherence to flight plans (i.e., intended trajectories) reducing many factors of uncertainty, allowing stakeholders to do better planning of the operations, reducing risk of disruptions. Our maritime scenarios [13] aim to address operational concerns regarding fishing activities, highlighting the need for continuous, timely (i.e.

real time) tracking of fishing vessels and surrounding traffic, as well as the need for offline data analytics.

Security in fishing addresses the need to detect and foresee collisions between ships, potentially optimizing rendezvous between rescuing ships in proximity of a vessel in danger and emergency services. Collision avoidance is a typical situation to be addressed: To prevent collision of fishing vessels with other ships we need to predict which other vessels (such as cargos, tankers, ferries) will cross the areas where the fishing vessels are fishing, sending a warning to the vessels identified for possible collision, taking also appropriate action as specified by COLREGs¹. To advance decision making in these cases the potential risk assessment should be as accurate as possible. Such a development could also be used on board to enhance situational awareness, when it is anticipated that a vessel will be required to "give way" to a fishing vessel.

Additionally, we need to detect vessels in distress, and further detect vessels in their vicinity to optimise rescuing operations. Analytics for detecting fishing patterns that are robust to noise and lack of veracity in data, as well as accurate trajectory prediction algorithms, are fundamental to support effectively those operational requirements.

Sustainable development maritime scenarios supporting the monitoring of fishing activities' impact, including the illegal ones, is of immense importance. In particular, towards the protection of areas from fishing we address the issue of Illegal Unreported Unregulated (IUU) fishing, which is a global threat to the preservation of maritime ecosystems and could potentially undermine the sustainable development in large areas of the world that depend on maritime resources. Beside the introduction of maritime protected areas where protected species live and where navigation is prohibited, fishing seasons are regulated and fishing activities are forbidden in certain periods of the year, depending on the area and on the type of catch. Towards these objectives we need to predict and detect vessels entering, exiting, sailing, spending time or fishing in geographical zones.

Given the above cases in both domains, real-time integration of disparate data sources enabling scalability for massive amounts of dynamic data is an existing challenge, which is very closely connected to the maritime domain, as well as to the ATM domain. Table 1 presents the main data sources exploited in datAcron².

A series of specific challenges concerning processing and managing data from these sources are as follows: (a) scalable, automatic, real-time processing, semantic annotation and linking of data towards coherent views on integrated cross-streaming (data-in-motion) and archival (data-at-rest) data; (b) incremental integration of data, allowing advanced management and query-answering of spatio-temporal data; (c) efficient distributed management and querying of integrated spatio-temporal data.

Revolving around the notion of trajectories and further making advances towards trajectories and events' detection and prediction, both domains present the following challenges: (a) real-time reconstruction of entities' trajectories, supported by real-time processing and analysis of streams of data; (b) algorithms for the prediction of anticipated trajectories at different time scale; (c) algorithms for complex event recognition and prediction in real-time.

Nevertheless, Visual Analytics (VA) [33] creates opportunities for a synergy between human analysts and computers by providing appropriate visual interfaces to all facets of analytical reasoning, from data exploration, pattern discovery and outlier identification, to prediction validation. It therefore facilitates the inclusion of the human domain expert’s tacit knowledge and his capabilities for reasoning and intuition into the decision process, which are of fundamental importance in surveillance activities. The most important VA research challenges for both domains are as follows: (a) interactive pattern extraction considering archival and streaming data, supporting the validation of early alerts obtained by the analysis tools; (b) building situation overview and situation monitoring, capable of providing the overall operational picture of mobility at desired scales and levels of detail, both in spatial and temporal dimensions.

3 THE DATAACRON SYSTEM ARCHITECTURE FOR TIME CRITICAL MOBILITY FORECASTING

Critical mobility operations require integrating data that stems from a wide variety of diverse data sources, both archival and streaming, having all big data characteristics. During data acquisition, various tasks need to be performed, including data cleaning, compression, transformation to a common representation model, and data integration. Besides real-time operations that must be supported with minimum latency requirements, there exists a need for offline analysis of the integrated data in order to discover patterns and extract useful knowledge.

To address these challenging requirements, the datAcron system architecture, depicted in Figure 1, has been devised as a Big Data architecture for processing both real-time and archival data. While it bears similarities with the Lambda architecture [19], since it encompasses both a real-time and a batch processing layer, these layers for different purposes (e.g. online trajectory/events forecasting vs offline trajectory clustering and visual analytics over archival data).

Figure 1: The datAcron system architecture.

In the real-time layer, streaming surveillance data describing the positions of moving entities, collected from terrestrial and satellite receivers are fed into the system, while several operations are performed: Statistics (min/max/avg) are computed over properties, such as speed and acceleration, in an online fashion; online data cleaning of erroneous data, as well as trajectory reconstruction and compression are performed. The goal is to provide only the data that is needed for analytics tasks: This is mainly done by generating synopses of trajectories, which are annotated towards the construction of “meaningful” trajectories. Thus, the generated trajectory synopses are transformed to RDF (Resource Description Framework) form, according to the datAcron ontology, thereby facilitating the expression of links with data originating from other sources. To this end, spatio-temporal link discovery is performed resulting in semantically enriched trajectories. Further online analysis of enriched trajectories aims at: (a) deriving predictions of the future location of a moving object, and (b) complex event recognition and forecasting. Finally, real-time visualizations support human interaction with the datAcron system.

In the batch layer, the enriched trajectories as well as data from other sources transformed in RDF are collected for persistent storage, in order to support offline data analytics. Due to the immense data volume, parallel data processing is performed over RDF data stored in a distributed way. On top of the distributed RDF store, higher-level data analysis tasks run, in order to perform trajectory analysis (clustering, sequential pattern mining) and towards building models for complex event recognition and forecasting using machine learning techniques. Last, but not least, visual analytics provide the ability to discover hidden knowledge and patterns, by means of interaction with a domain expert or a data analyst, further improving situation awareness, as well.

Below, we describe the main components of the architecture.

In-situ processing components. In-situ processing allows computation as close to the sources as possible, thus reducing communication and latency. In datAcron, we apply in-situ processing on the streaming surveillance data, as it is ingested in the system. This supports computing statistical measures of moving entities’ properties (such as speed and acceleration) and executing low-level event detection, annotating positions of moving entities with information regarding entry/exit to/from geographical areas of interest. In addition to that, trajectory compression aims to retain only a small set of positions of moving entities, also called *critical points*, without sacrificing the accuracy of the representation significantly.

Data manager. The data manager is responsible for providing a common representation of all data sources by integrating and linking data in a knowledge graph, and for query processing over that graph. To support linking of data from different

sources in a common representation format, we opt for RDF. First, any incoming data (no matter whether streaming or archival) is lifted to RDF, by means of RDF generators. The obtained representation is based on the datAcron ontology [28] (also in: http://ai-group.ds.unipi.gr/datacron_ontology) supporting the exploitation of semantically enriched information. Data interlinking is achieved via a spatio-temporal link discovery framework, which is designed to operate on streaming data sources, apart from archival. Finally, the integrated spatio-temporal RDF data is stored in a distributed way, supporting spatio-temporal RDF query answering by means of a parallel processing engine for RDF data, offering batch processing and analysis, with notable difference to existing solutions (see [1] for a recent survey).

Trajectory detection and prediction. This component predicts the future location of moving entities in real-time, exploiting enriched trajectories offered by the data manager. The trajectory prediction component complements the future location predictor, while offline trajectory analytics (not in the scope of this article) over distributed RDF data are delivered by the corresponding component.

Complex event recognition and forecasting. This component targets the need to detect and forecast complex events related to the movement of moving entities. To detect and forecast events in a timely fashion, a novel technique using Pattern Markov Chains is proposed for continuous narrative assimilation on data streams. In addition to that, machine learning methods are applied to build prediction models, while an offline *complex event analyser* operates on the historical data and discovers patterns of events to be predicted. The latter are not within the scope of this article.

Visual analytics. The aim is to support exploratory and interactive analysis of data, in order to enable the task of human interpretation, which is necessary in the case of Big Data. Visual analytics does not represent a single, specific analysis technique but rather a methodological approach to gain insight into large, complex, noisy and often conflicting data, to develop and test hypotheses, and to build and understand complex analytical models. The key aspect is the collaborative work between the computer and the human analyst, whereby the human expert imparts background knowledge about the current analysis task's context and reasoning in the overall analytical process.

For the implementation of the overall architecture, the big data technologies employed include a blend of state-of-the-art solutions that are used in production environments successfully. Stream processing components have been developed in Apache Flink, harnessing the scalability and low latency offered. Solutions that rely on micro-batching, such as Spark Streaming, do not match with the required complex stream processing and low latency requirements targeted by our work. Instead, for batch processing and analysis, we have selected Apache Spark which is a more mature project than Flink, having a larger ecosystem, and bigger user base, while also achieving scalability, high performance, and exploiting in-memory processing. The stream-based communication between components is achieved by means of Apache Kafka.

4 DATA PROCESSING AND MANAGEMENT

Aiming to build solutions towards managing data that are connected via, and contribute to enriched views of trajectories upon which ATM and maritime challenges focus, we revisit the notion of semantic trajectory and built on it towards integrating the

Figure 2: The main concepts and relations of the ontology.

wealth of information available in heterogeneous data sources in both domains in a representation where trajectories are the main entities: The datAcron ontology (http://ai-group.ds.unipi.gr/datacron_ontology) has been designed to provide a common model for all data sources in both domains towards supporting analysis tasks. Its development has been driven by ontologies related to our objectives (e.g. DUL, SimpleFeature, NASA Sweet and SSN) as well as schemas and specifications regarding data sources from both domains. To a greater extent than other models for representing trajectories, this ontology provides the means for specifying trajectories at varying levels of spatio-temporal analysis: Trajectories can be seen as temporal sequences of moving entities' positions derived from raw data, as raw data aggregations signifying meaningful events providing a synoptic view of raw trajectories (generalizing on the stops and moves model [31], according to the types of critical points), as temporal sequences of meaningful trajectory segments (each revealing specific behaviour, event, goal, activity etc.), or as mere geometries. Representations at any such level of analysis are linked to each other, as well as to related information and events. Beyond answering spatio-temporal SPARQL queries concerning trajectories along with information regarding aspects that affect and are affected by the mobility of moving entities, this ontology supports generic data transformations for adapting available data to the analysis goals, or to specific requirements of analysis tasks. This is done by converting movement data from one form to another, to support different task foci: movers, spatial, events, space, and time. Details are provided in [28].

According to the ontology specifications, as illustrated in Figure 2, a Trajectory can be segmented to TrajectoryParts, each including other segments and/or semantic nodes. Each semantic node may be associated with a specific raw position or a temporally ordered sequence of raw positions of a moving object. Trajectories and trajectory parts can be associated with any relevant information, as well as with events (*dul:Event*). Although events may happen independently from the trajectory, we focus on those happening on the trajectory itself (e.g. a "turn" or a "gap of communication") and on those concerning moving entity state (e.g. vessel in a protected or in a bad-weather area). The detailed patterns for specifying structured trajectories and occurring events are presented in [28].

4.1 Data processing

The *low-level event detection* component is aiming at enriching the raw-data generated by the moving entities with basic derived attributes that serve as input for higher-level processing. A major

consideration is to achieve that enrichment with low-latency, preferably by processing streaming data close to data source (in-situ): This provides a number of inherent advantages, such as decreased communication delays, savings in communication, and reduced overhead in sub-sequent evaluation steps.

The detection of low-level events refers to generating metadata on incoming raw data for detection of erroneous data, ensuring data quality, and enriching the data stream with contextual information for further analysis. For supporting the data quality assessment, described in Section 7, attributes of min/max, median/average of properties (e.g. speed, acceleration etc.) are generated on a per trajectory basis. In addition to that, raw position data are enriched with low-level events of entering or leaving of moving entities from one area to another one, by processing the real-time stream of moving entity positions.

The *Synopses Generation* detects important *mobility events* along trajectories represented as *critical points*: This task has to be carried out in a timely fashion against the streaming positional updates received from a large number of moving entities. Instead of retaining every incoming position for each object, the *Synopses Generator* module drops any predictable positions along trajectory segments of “normal” motion characteristics, since most vessels and aircrafts usually follow almost straight, predictable routes at open sea and in the air, respectively. By doing so we may only retain positions that signify changes in actual motion patterns. We opt to avoid costly trajectory simplification algorithms like [18, 21] operating in batch fashion, online techniques employing sliding windows [20] or safe area bounds for choosing samples [21], as well as more complex, error-bounded methods [16, 17]. Instead, emanating from the novel trajectory summarization framework introduced in [25, 27], specifically for online maritime surveillance, but significantly enhanced with additional noise filters and also extended for the needs of the aviation domain, the *Synopses Generator* applies single-pass heuristics for achieving succinct, lightweight representation of trajectories. We prescribe that each trajectory can be approximately reconstructed from judiciously chosen critical points of the following types:

- *Stop* indicates that an entity remains stationary (i.e., not moving) by checking whether its instantaneous speed is lower than a threshold over a period of time.
- *Slow motion* means that an entity consistently moves at low speed over a period of time (below a given threshold).
- *Change in Heading*: Once there is an angle difference in heading greater than a given threshold with respect to the mean velocity vector (computed over the most recent course), the current location should be emitted as critical.
- *Speed change*: Such critical points are issued once the rate of change for speed exceeds a given threshold with respect to its mean speed over a recent time interval.
- *Communication gaps* occur when an entity has not emitted a message over a time period, e.g., the past 10 minutes.
- *Change in Altitude* may be detected for aircrafts by checking their rate of climb (or descent), i.e., the vertical speed of the aircraft (in feet/sec) when ascending (respectively, descending). Once, this value exceeds a given threshold, a critical point should be issued in the synopsis.
- *Takeoff* is the latest position of an aircraft while on the ground: The next position has altitude above ground.
- *Landing* for flying aircrafts is the first reported location when they touch the ground.

This module can achieve dramatic compression over the raw streaming data with tolerable error in the resulting approximation. At lower or moderate input arrival rates, data reduction is quite large (around 80% with respect to the input data volume), but in case of very frequent position reports, compression ratio can even reach 99% without harming the quality of the derived trajectory synopses (typically, straight movements with constant speed).

Empirical results [25] indicate that such critical points can be emitted in real-time keeping in pace with the incoming raw streaming data. As a next step, we plan to address the case of cross-stream processing, i.e., correlating surveillance data from multiple sources in order to provide a coherent trajectory representation.

4.2 Data management

To convert the data from different sources into the common RDF model and integrate them in a knowledge graph, we designed and implemented a generic RDF generation framework, which can be instantiated to any of the given (streaming or archival) data sources. Due to the syntactic and semantic heterogeneity of data sources exploited in datAcron, and given that sizes vary from a few thousands (e.g. aircraft or vessel registries), to practically infinite streams of data (e.g. reported positions of moving entities), we need an efficient method that can easily be integrated to widely used SPARQL workflows, to rule all the data sources, and that will also be easily adapted to changes on both the ontology and the sources, while the output will be easily verified. The proposed method stands on two main components: (a) The *data connector*, which is responsible to connect to a data source and accept the data provided. It is capable of applying basic data cleaning operations, computing and converting values, applying simple filters, or extracting information regarding the incoming entries, e.g. extracting the Well-Known-Text representation of a given geometry in a Shapefile. (b) The *triple generator*, which is responsible to convert all the data coming through the data connector, into meaningful triples w.r.t. the datAcron ontology. Triple generators exploit graph templates and variables vectors. The variables vectors enable transparent reference to datasource fields, while they enable the RDF generation method to refer to data not explicitly available in the source, but generated during the generation process. The graph template, on the other hand, uses these variables into triple patterns; i.e. in triples where any of the subject or object can be either a variable or a function with variables as arguments. Such an example of data conversion into triples by exploiting a graph template made of triple patterns, is provided in Figure 3.

By doing so, and in contrast to other RDF generators, the proposed method needs no further knowledge of a specific vocabulary (e.g. compared to RML [11]), and it can be used by anyone who can write simple SPARQL queries. It requires no underlying SPARQL engine, and it inherently supports parallelisation and streaming data sources (compared to SPARQL-Generate [15] and GeoTriples [14]).

This RDF generation method manages to transform 10,500 input records to RDF per second. For some sources, this number may be smaller due to complicated geometries. Overall, the average time per triple generated is approximately 0.04 seconds, given that the frequency of position reporting per aircraft/vessel is at least 2 seconds.

Triples produced by the RDF generators are directed to the *datAcron link discovery* component: This detects spatio-temporal and proximity relations such as “within” and “nearby” relations between stationary and/or moving entities. It is noteworthy that there is not much work on the challenging topic of spatio-temporal link discovery nor on link discovery over streaming data sets. State of the art approaches such as [23], [30], [29] focus on spatial relations in static archival data sets only. In particular RADON [29] employs optimizations that can be only applied if the data sets are a-priori accessible as a whole, which cannot be assumed for streaming data sets. Our work addresses explicitly proximity and spatio-temporal relations in both archival and streaming datasources.

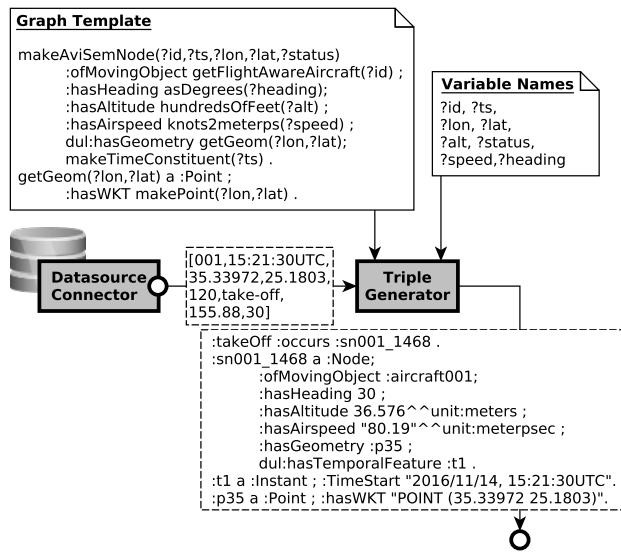

Figure 3: Triple Generation example.

The implemented component continuously applies SPARQL queries on each RDF graph fragment produced by an RDF generator, to filter only those triples relevant to the computation of a relation r . It applies a blocking method to organize entities (either being moving or stationary entities), and a refinement function to evaluate pairs of entities in any block.

Aiming to discover spatio-temporal relations among entities, existing methods use an equi-grid which organizes entities by space partitioning. The temporal dimension is not partitioned: given a temporal distance threshold, we can safely clean up data that are out of temporal scope, i.e. entities that will never satisfy the temporal constraints of the relations. To effectively prune candidate pairs of entities, the proposed method computes the *mask* of cell: This is the complement of the union of those spatial areas that correspond to entities in a cell and intersect with the cell area. Figure 4 depicts examples, where the green regions illustrate the mask of cells generated from 8,599 Natura2000 and fishing regions around Europe.

Thus, for each new entity we identify the enclosing cell, and then we evaluate that entity against the spatial mask of the cell. If it is found to be in the mask, we do not need to further evaluate any candidate pair with entities in that cell. In addition to masks, the link discovery component uses a book-keeping process for cleaning the grid, towards identifying proximity relations among entities when dealing with streamed data.

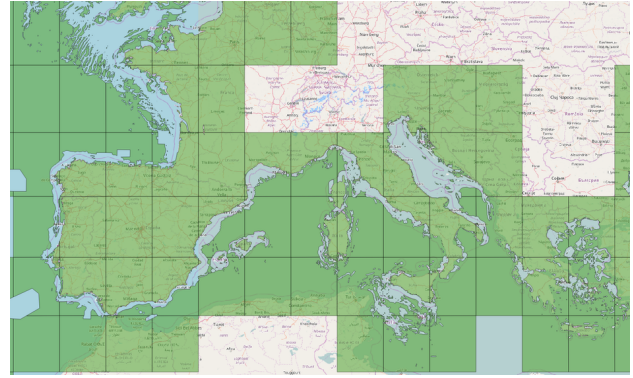

Figure 4: Equi-grid with masks for stationary areas.

We have evaluated the performance of the Link Discovery method with and without cell masks on a data set of 4,765,647 critical points, against a data set of 8,599 regions generating 381,262 `dul:within` and 9,122 `geosparql:nearTo` relations. The method without masks achieves linking 23.09 entities per second, while activation of the mask boosts the throughput to 123.51 entities per second. Preliminary results concerning `geosparql:nearTo` relations among critical points, as well as critical points and 3,865 ports, have shown a throughput of 328.53 entities per second, producing 2,536,967 relations. Challenges lying ahead for link discovery, include both, the identification of more complex spatio-temporal relations in real-time streaming data, and improving performance and scalability. The latter can be achieved by the refinement of blocking schemes for achieving better load-balancing for tasks’ parallelization, as well as by the use of advanced techniques for reducing the number of comparisons in the cells.

As far as the *Knowledge Graph Store* is concerned, even though there exist several solutions for distributed RDF processing (see [1] for a survey), a notable difference is that we deal with mobility data that have a strong spatio-temporal flavour and typical queries also contain spatio-temporal constraints. A typical distributed RDF processing engine cannot process efficiently spatio-temporal constraints, as such constraints would have to be enforced in a post-processing step to obtain the final result, at the cost of having computed a much larger set of candidate results. Motivated by this limitation, we designed a solution for scalable processing of spatio-temporal RDF data. The system contains a distributed storage layer, and a batch processing layer developed in Apache Spark. In the storage layer, we use a custom dictionary encoding technique for representing spatio-temporal entities. Our encoding technique allows representing an approximation of the position of any moving entity using a unique integer identifier, which corresponds to the spatio-temporal cell where the entity is located. We support different storage layouts, including “one-triples-table”, vertical partitioning, and property tables. Also, for the file layout we exploit Parquet, which provides a columnar layout and achieves compression. The RDF triples are stored in HDFS, while the dictionary needs to be stored in main memory for efficient access, so we opt for REDIS which fits our needs, although other NoSQL key-value stores may also comprise solutions (e.g., Aerospike, etc.) In the processing layer, we have developed different implementations of basic operators (such as filtering and join) that can be used to generate different physical execution plans from a given logical plan. Moreover, the spatio-temporal encoding is used during query processing,

by filtering triples that do not match with the spatio-temporal query constraints. This happens in parallel to filtering RDF triples, matching with the RDF graph patterns specified in the query [24].

Experimental results [24] performed over more than 269M RDF triples from surveillance, weather, and contextual data sources show that we can improve query processing time for star join queries with spatio-temporal constraints when using our techniques.

5 TRAJECTORY PREDICTION

The prediction of a trajectory evolution can be seen either (a) as a Future Location Prediction (FLP), or (b) as a Trajectory Prediction (TP) problem. In FLP, the task is to predict the next k points in the trajectory, a process that is inherently dynamic and continuously adaptive, exploiting measured (reactive mode) or predicted (proactive mode) error as feedback. On the other hand, TP aims to produce a “best guess” of the complete trajectory in the maximum likelihood sense. The two tasks are interconnected and applied in parallel, with FLP (TP) being the short-term online (full-length offline, respectively) predictor. Generally, there are two main approaches in addressing these prediction tasks:

(a) The *Kinetic approach*, which describes the forces and momentums that describe the motion of the moving entity in terms of physical laws. The kinetic approach can produce accurate predictions, but requires high-intensity processing, due to detailed simulation. Moreover, predictions, being sensitive to changes in many of the (stochastic) parameters involved, are quickly deviating, as the temporal window expands. In the aviation domain, the kinetic approach uses extremely accurate aircraft performance models, such as BADA (Base Of Aircraft Data), combined with localized weather forecasts. Similar kinetic approaches are used in various forms, e.g. for dead reckoning in navigation modules, in the maritime domain.

(b) The *Kinematic approach*, which considers only the temporal evolution of the model’s parameters as time series and exploits the causalities discovered. In practice, this includes data-driven methods that exploit enriched trajectories as training sets for FLP and TP purposes. In other words, the model “learns” the kinetic behaviour of the moving entity by processing historical information of its own trajectory in case of FLP or of an entire group of “similar” trajectories in case of TP.

In contrast, the data-driven FLP and TP targeted in datAcron rely exclusively on reference points of actual trajectories, enriched with features (e.g. weather conditions, operational constraints, etc.) that affect trajectories.

The current state-of-the-art in data-driven approaches for FLP and TP range from standard signal processing to advanced regression learners. In FLP, standard regression methods, as well as motion-type modelling have been applied primarily in the short-term time frame [32]. Since TP includes complete trajectories, a number of supervised and unsupervised methods have been applied in the context of classification: Grouping together “similar” trajectories and predicting new ones based on these groupings for “similar” input conditions, e.g. for the same departure/destination, same weather conditions, etc. [34]. The current state-of-the-art approaches do not address the range of options from short to long term predictions in its entirety, nor exploit the full enrichment of the data points as constraints to optimize the training. Additionally, the volume and velocity of the data are considered of less or even no importance compared to the spatio-temporal prediction accuracy.

Recursive Motion Functions (RMF) for FLP: Mobility patterns over short-term time frames are often studied in the sense of online predictive analytics, i.e., involving small set of positions as “recent history” and strict constraints with regard to storage and processing resources. Tao et al. [32] propose Spatio-Temporal Prediction trees as an indexing scheme supporting predictive queries and incorporating a general framework that computes different *non-linear motion patterns* to capture movements of arbitrary characteristics. In this context, the Recursive Motion Function (RMF) approach enables the computation of different types of movement (such as linear, polynomial, circular, etc) by exploiting the recent past of an object’s position sequence and adapting the prediction model according to its specific characteristics. According to our knowledge RMF is the most prominent candidate for addressing the online FLP task and under big data specifications. RMF captures the motion dynamics of an entity in a differential recursive formula by combining the most recent data points per f (system parameter) and is most effective when the acceleration components are zero, constant or at least exhibiting slow drifts: It results to very low prediction accuracy when it is applied in any of our domains.

The proposed RMF* method includes significant modifications and enhancements of the base RMF algorithm producing in real time the next k forward positions, using minimal storage and processing resources. It exploits dynamic motion pattern matching interchangeably with linear-only modes of operation. RMF* incorporates the advantages of linear extrapolation for the steady parts of the flights, while at the same time exploits additional information regarding any shift in the motion type provided by critical points produced by the synopses generation task, before activating the full pattern-matching mode. This means that the algorithm continuously checks for drifts to non-linear phases, i.e., the beginning of turn and/or altitude change, activating the proper differential approximation method accordingly, including sections of circular, ellipsoid, parabolic, hyperbolic or general quadratic trajectory.

RMF* can achieve very accurate predictions for the FLP task, as the data effectively capture the dynamics of the trajectory. Since FLP is very difficult for the take offs and landings, the experimental evaluation of the proposed RMF* is primarily focused on the aviation domain and specifically on these non-linear phases. Results provided in Figure 5(a) are based on complete flights between two airports (Barcelona-Madrid) and present average 2-D spatial error (longitude, latitude) of roughly 1-1.2 km for a look-ahead time frame of up to a minute, with a sampling rate of 8 secs, and 8 look ahead steps, i.e., roughly a 1-minute look-ahead time window (mean \approx 1000m, stdev \approx 500m, skewed towards zero).

The proposed RMF* algorithm is under fine-tuning of the pattern-matching module, with special attention in identifying and modelling a set of motion patterns, or “primitives”, separately for the aviation and for the maritime domains, so that the module can promptly and correctly identify the best choice when in non-linear mode.

Hybrid Clustering/HMM method for TP purposes: In order to address the TP task, there is a trend of using stochastic models for discovering and retrieving patterns from past history. Additionally, there is a need to address the task in the scale of big data. To address this challenge towards long term trajectory predictions our proposal is to partition historic trajectories into subsets, train separate predictive models for each one of them and then use these models for individual predictions, provided that the ability to select the correct model exists.

Figure 5: (Left) RMSE* prediction accuracy over various look-ahead time frames. (Right) Accuracy estimations for the per-waypoint deviation (m) from flight plan (cluster size=255) with the hybrid clustering/HMM method.

Clustering is the most popular approach for unsupervised learning, ranging from simple k nearest neighbour (k -NN) grouping, to multi-level hierarchical restructuring of the input data and using an arbitrary well-defined distance function as similarity metric. The advantages of a clustering approach include computing “cohesive” clusters of trajectories that are of smaller scale than the original set, while a distance function that exploits any data linked to enriched trajectories can be used. The SemT-OPTICS algorithm [26] is such an approach, where the similarity between two trajectory points is decomposed in two parts: The one regarding their spatio-temporal similarity and another for the enriching data, adopting an appropriate variant of Edit distance with Real Penalty (ERP) [9].

The Hidden Markov Model (HMM) approach is widely used in modelling and predicting time series, including spatio-temporal mobility patterns. The HMM approach models the evolution of an entity’s motion by a set of states and transitions between them, each one accompanied by a probability that is typically extracted by analyzing historic data. Additionally, the deviations between “intended trajectories” (e.g. flight plans in the ATM domain) and actual routes are modelled as HMM observations or *emissions*, in order to construct a probabilistic model for trajectories. We designed HMMs in a way that exploits reference points in conjunction to the enriching information. This is in contrast to approaches exploiting raw trajectory data [7, 8].

Based on these, we devised a novel Hybrid Clustering/HMM approach [12] to address the TP task, following a two-stage rationale: Clustering at the first stage of processing and training HMMs for each cluster, using only the reference points of the *medoid* of each cluster. The rationale behind this modelling approach is to be able to predict deviations from flight plans optimally, based on all the information available, including local weather (per waypoint), aircraft size, seasonal factors (time, weekday), etc. The current experiments on real aviation data (Spain, April 2016) show that deviations from flight plans can be predicted with a combined 3-D spatial accuracy of 183–736m (RMSE), in terms of half-width confidence interval for mean deviation between intended (flight plan) and actual route flown, averaged over the entire sequence of reference points for all clusters and statistically significant at $\alpha=0.05$. Results are shown in Figure 5 for one such cluster in the Madrid/Barcelona flights. Additionally, this approach exhibits at least an order of magnitude better accuracy in terms of absolute cross-track error compared to the current state-of-the-art “blind” HMM for TP, while at the same time it exhibits two to three orders of magnitude less processing

Figure 6: (Left) DFA and (Right) the corresponding Markov Chain.

and storage resources, due to the combined scaling-down of data due to clustering and to the use of reference points.

The proposed Hybrid Clustering/HMM approach is still under optimization. For the clustering stage, the challenge is to customize the similarity metrics properly and separately for the aviation and the maritime domains. For the HMM stage, the main challenge is to capture the statistics of the per-waypoint deviations for entire clusters of trajectories. Especially for the maritime domain, the reference points must be defined more dynamically (e.g. via detected critical points) since there are no equivalents to flight plans available. Hence, more specialized probabilistic distributions are tested for modelling the combination of distance-related Gaussian error distributions per-dimension. This typically involves exhaustive cross-validation experiments for prediction accuracy, rather than estimation of confidence intervals; e.g. via t-Student significance tests. Finally, segmented-trajectory models are also investigated, for very large training data sets.

6 COMPLEX EVENTS DETECTION AND FORECASTING

Given a stream of low-level events and a set of patterns defining spatial and temporal relations between low-level events, operational constraints and contextual information, we need to detect, in a timely manner, when these relations are satisfied. Whenever these relations are satisfied, we say that a high-level (or complex) event has been detected. Besides event detection, which contributes to increasing situation awareness, given the importance of predictability in both domains, we additionally address the problem of forecasting the occurrence of complex events.

Specifically, given the input stream of low-level events generated by the components described in Section 4.2, let us consider the case where a maritime analyst is interested in isolating parts of a vessel’s trajectory during which a vessel changes its direction by 180 degrees: These could indicate fishing activity. We could formally define this complex event as a temporal sequence of Change In Heading events where the first and last events in the sequence have opposite headings (headings difference is close to 180 degrees). This HeadingReversal pattern could be given to the event detection and forecasting module.

Whereas there exist multiple event detection systems, at different levels of maturity, very few of them address the issue of forecasting ([22] is one of the few cases). Moreover, being able to predict complex events which are defined by patterns that are not simple sequences of input events, poses significant challenges. Our event detection and forecasting module advances the state-of-the-art by moving beyond sequential patterns. It has the ability to predict complex events that are defined in the form of regular expressions, where the low-level events may be related through *sequence*, *disjunction* or *iteration*. In addition, by employing a

Figure 7: (Left) DFA and (Right) waiting-time distributions.

rigorous probabilistic framework, it can handle input streams that are generated by higher-order Markov processes (see [2] for a detailed description).

As a first step, event patterns in the form of regular expressions are converted to Deterministic Finite Automata (DFA). A detection occurs every time the DFA reaches one of its final states. As an example, see Figure 6 which depicts the DFA constructed for the simple sequential expression $R=acc$ (one event of type a followed by two events of type c) where the set of events that may be encountered are $\Sigma=\{a, b, c\}$.

For the task of forecasting, we need to build a probabilistic model for (the behaviour of) the DFA. We achieve this by converting the DFA to a Markov chain. If we assume that the input events are independent and identically distributed (i.i.d.), then it can be shown that we can directly map the states of the DFA to states of a Markov chain and the transitions of the DFA to transitions of the Markov chain. The probability of each transition would then be equal to the occurrence probability of the event that triggers the corresponding transition of the DFA. However, if we relax the assumption of i.i.d. events, then a more complex transformation is required, in which case the transition probabilities equal the conditional probabilities of the events. An example, see Figure 6 which shows the Markov chain derived from the indicated DFA, if we assume that the input events are generated by a 1st-order Markov process (see [2] for details). We call such a derived Markov chain a *Pattern Markov Chain* (PMC).

Once we have obtained the PMC corresponding to an initial pattern, we can compute certain distributions that are useful for forecasting. At each time point the DFA and the PMC will be in a certain state and the question we need to answer is the following: how probable is it that the DFA will reach its final state (and therefore a complex event will be detected) in k time points from now? The answer to this question depends on the state of the PMC. Hence, for each such state we need to calculate a separate distribution. These distributions are called waiting-time distributions. As an example, Figure 7 shows a DFA and the *waiting-time distributions* for its states.

In order to estimate the final forecasts, another last step is required. Forecasts are provided in the form of time intervals, like $I = (start, end)$. When such a forecast is produced, its meaning is that the DFA is expected to reach a final state sometime in the future between start and end with probability at least some constant threshold θ (provided by the user). These intervals are produced by a single-pass algorithm that scans a waiting-time distribution and finds the smallest (in terms of length) interval that exceeds this threshold. As an example, Figure 7 shows a DFA being in state 2, the waiting-time distribution for this state is shown in blue color, together with the forecast interval extracted ($I = (2, 4)$).

Figure 8: Precision achieved for events' forecasting using different Markov process' orders.

The above described method has been implemented in a system called Wayeb, tested with real-world maritime annotated and enriched trajectories. We show results from one pattern applied to a single vessel. The pattern is as follows:

```
R=ChangeInHeadingNorth
(ChangeInHeadingNorth+ChangeInHeading East)*
ChangeInHeadingSouth
```

where $+$ stands for disjunction and $*$ for iteration and each *turn* event has additionally been annotated with the vessel's heading. This pattern attempts to detect a NorthToSouthReversal event where a vessel executes a series of turns, initially heading towards the northern direction and eventually ends heading towards the southern direction. Figure 8 shows the precision of the proposed forecasting method for this pattern using different prediction thresholds. The precision is defined as the percentage of forecasts which were accurate (i.e. the event was indeed detected within the forecast interval). It shows results both for the assumption of a 1st-order and for a 2nd-order Markov process. We can see how increasing the assumed order does indeed positively affect precision.

Promising such results as they may be, there still remain significant challenges ahead. The most fundamental concerns *reliability*, i.e., the ability to naturally (without a pre-processing step) handle events with attributes and relations between the attributes of different events in a pattern. For example, in the NorthToSouthReversal pattern, the information about the vessel's heading would simply be an attribute which could be checked with predicates like $IsHeading(North)$. Moreover, the method that we have proposed assumes *stationarity* which implies that the transition matrix of the PMC does not change. However, the statistical properties of a stream may indeed change over time in which case we would need an efficient method for updating online the probabilistic model.

7 VISUAL ANALYTICS

The purpose of the Visual Analysis approach is to combine algorithmic analysis with the human analyst's insight and tacit knowledge in the face of incomplete or informal problem specifications and noisy, incomplete, or conflicting data [33]. Visual Analysis therefore is an iterative process where intermediate results are visually evaluated to ascertain and inform subsequent analysis steps based on prior knowledge and gathered insights. From the perspective of Visual Analytics, analysis methods fall into two categories within the overall architecture (Figure 1).

On the batch layer, Visual Analytics (VA) augments a wide range of tasks from initial data exploration and curation, complex analysis workflows, to refining and evaluating the different

models. Synoptic analysis tasks that are the subject of such exploratory visual analyses presume availability of global measures like spatial extents, value ranges, (as yet undiscovered) patterns defined over large time spans/time cycles, and thus must be supported over sufficiently large data sets. Specifically, it is worth noting that due to the exploratory focus, VA does not prescribe a rigid pipeline of algorithmic processing steps, nor does it prescribe a fixed composition of specific visualizations, as opposed to typical dashboards [3].

To cope with these requirements in an efficient and scalable way, the VA component within the integrated architecture is itself of a modular, extensible design, as shown in Figure 9. It comprises four principal component groups – data storage, analysis methods, data filtering and selection tools, and of course, visualization techniques. Different components are typically composed in an ad-hoc fashion, through visual-interactive controls, to facilitate the workflow required by the human analyst’s task at hand.

The following paragraphs review several novel workflow compositions addressing different analytical challenges in both the ATM and maritime domains.

The ability to understand data properties and to assess their quality is a crucial first step in any data analysis setting. Dealing with massive movement data analysed in context (e.g., as weather data) amplifies both the importance of that first step as well as the technical challenge involved in dealing with such large data.

Investigation of quality of movement data, due to their spatio-temporal nature, requires consideration from multiple perspectives at different scales. In paper [4], we review the key properties of movement data and, on their basis, create a typology of possible data quality problems and suggest approaches to identifying these types of problems. In particular, we systematically consider different approaches to position recording and related properties of movement data, taking into account properties of the mover set, spatial properties, temporal properties and data collection properties.

However, while [4] lays the foundation for a structured approach to detect and rectify data quality issues, cleaning and repairing data for curation purposes are still largely manual tasks that rely on a combination of tools and technologies such as database SQL, scripts, and functionality available in the VA toolkit. Especially when handling large data sets (many moving entities, long time periods) these tasks can become tedious and time-consuming. Therefore, as one facet of datAcron objective is to create advanced and scalable spatio-temporal data integration and management solutions, a modular framework is being developed that combines Big Data processing technologies with interactive visual reporting to automatically evaluate the quality of large movement data sets.

To support preparatory data analysis for building appropriate detection and prediction models, specifically patterns targeting at trajectories, events, spatial time series and spatial situations, novel methods are required that combine interactive visualizations with appropriate computational methods such as clustering, event detection, summarization and abstraction, as well as providing possibilities for manipulating parameters of computational methods and evaluating sensitivity to parameters.

In [6] we introduced the concept of time mask, which is a type of temporal filter suitable for selection of multiple disjoint time intervals in which some query conditions on arbitrary attributes hold. Such a filter can be applied to time-referenced objects, such as events and trajectories, for selecting those objects or segments

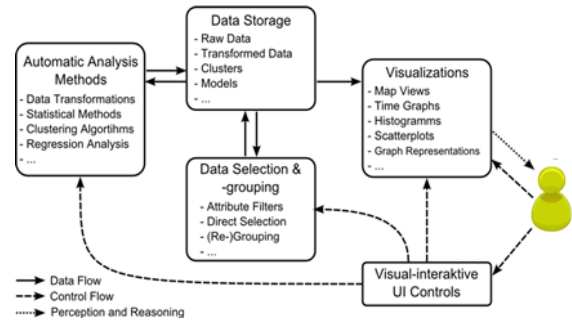

Figure 9: Principal components of the VA toolset.

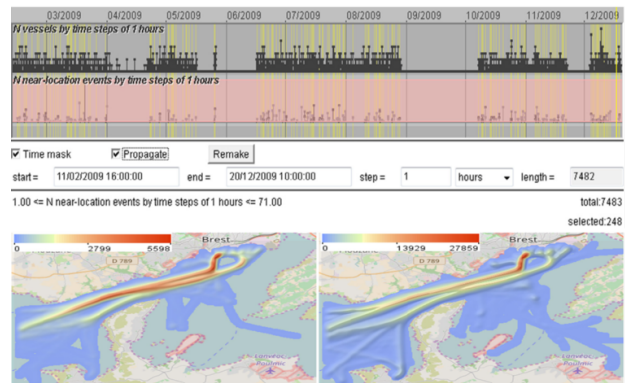

Figure 10: (Top) A time series display shows the counts of the vessels (upper row) and the near-location events (lower row) by 1-hour time steps. A query selects the intervals containing at least one event (yellow markers). (Bottom) The density of the trajectories in the times of occurrence of near-location events (left) and in the remaining times (right) [6].

of trajectories that fit in one of the selected time intervals. The selected subsets of objects or segments are dynamically summarized in various ways, and the summaries are represented visually on maps and/or other displays to enable exploration. The time mask filtering can be especially helpful in analysis of disparate data (e.g., event records, positions of moving entities, and time series of measurements), which in the considered scenarios even come from different sources.

To detect relationships between such data, the analyst may set query conditions based on one data set and investigate the subsets of objects and values in the other data sets that co-occurred in time with these conditions (e.g., see Figure 10).

Clustering of trajectories of moving entities by similarity is an important technique in movement analysis. Existing distance functions assess the similarity between trajectories based on properties of the trajectory points or segments [3]. The properties may include the spatial positions, times, and thematic attributes. There may be a need to focus the analysis on certain parts of trajectories, i.e., points and segments that have particular properties. According to the analysis focus, the analyst may need to cluster trajectories by similarity of their relevant parts only. For example, when analysing routing decisions taken by airlines in the ATM context, only the cruise phase of a flight is relevant for comparison, but not holding patterns nor takeoff and landing runway directions [5]. Throughout the analysis process, the focus

Figure 11: (Top) Bars in a time histogram show the counts of the flight arrivals in hourly intervals. Bar segments are painted in the colors of the clusters the flights belong to. (Bottom) The final parts of the flight trajectories in days 1 and 3 are colored according to the cluster membership [5].

may change, and different parts of trajectories may become relevant, e.g., due to weather conditions. In paper [5], we propose an analytical workflow that uses interactive filtering tools to attach relevance flags to elements of trajectories; subsequent clustering uses a distance function that ignores irrelevant elements. The resulting clusters are summarized for further analysis. The paper demonstrates how this workflow can be useful for different analysis tasks in three case studies related to ATM flow management (Figure 11). The paper [5] further proposes a suite of generic techniques and visualization guidelines to support movement data analysis by means of relevance-aware trajectory clustering.

For developing and evaluating trajectory prediction algorithms it is important to have the possibility of detailed comparison of predicted trajectories to actual ones, to see how accurate the prediction is. It is also necessary to compare predictions obtained with different parameter settings, to understand the impact of the parameters and to choose the most suitable settings.

On the real-time layer, in-stream processing algorithms operate directly on data streams under predefined parameter settings for monitoring purposes, i.e., trajectory & location prediction (Section 5) as well as event forecasting (Section 6). The main goal here is to provide a visual interface to the detection and prediction model output, presented in the context of real-time spatio-temporal data comprising the current situational picture (vessel trajectories, specific areas, weather information etc.). These visualizations provide a limited set of interaction for confirmatory analysis of detected outliers and patterns, as well as in-context validation of model predictions, and typically are offered as dashboard components.

A novel technique is the point matching method that is supplemented by interactive visual interfaces enabling the analyst to view and explore the results of point matching (Figure 12).

For the purposes of situation monitoring, a real-time visualization approach has been developed as an endpoint in the

Figure 12: Detail view of a significantly mismatched pair of actual (blue) vs. predicted (red) trajectories. The histogram shows the statistical distribution of the proportions of the matched points; the map shows the spatial footprints of both trajectories.

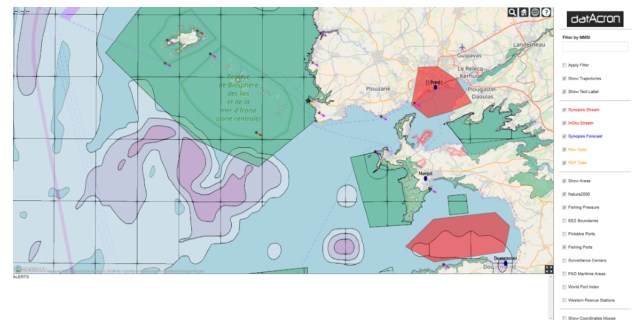

Figure 13: Real-time visualization dashboard for maritime situation monitoring.

Kafka-based communication infrastructure (Figure 13). The visualization visually encodes a selectable subset of information layers from the enriched stream provided by the data manager. This stream, as described in previous sections, includes pre-processed position data (i.e., trajectory synopses), dynamic and static context information (e.g., weather conditions, maritime areas), trajectory and location predictions, as well as detected and forecasted events (e.g., initiation of a turn manoeuvre, danger of collision).

Further work will evaluate which visual encodings and interaction capabilities (e.g., to interactively adjust event detection parameters) best match different use case requirements in both domain.

8 CONCLUSIONS

Given the user-defined challenges and the fact that more and more data of different nature and purposes is generated in the air traffic management and the maritime domains, this article reports on significant progress achieved in datAcron towards the real-time processing and analysis of big data for improving the predictability of trajectories and events regarding moving entities in those domains.

Albeit the progress, there are also significant challenges ahead in both domains: Discovery of spatio-temporal relations among entities in a timely manner, efficient query answering of very large knowledge graphs for online and offline analytics tasks,

cross-streaming synopses generation, long-term online full trajectory predictions and improvements in forecasting complex events together with learning/refining their patterns by exploiting examples; as well as, the provision of online visual analytics workflows.

ABSTRACT

Anomaly detection is a key feature of applications processing singularities using IoT sensor measures. In a recent project, we highlighted that to guarantee high quality detections, metadata providing spatio-temporal contexts on sensor measures are needed. These metadata hence become an integral component of the anomaly detection computation and need to be processed using a streaming approach. In this paper, we introduce Scouter, a generic tool that helps in capturing, analyzing, scoring and storing the contextual information of a given application domain. The processing depends on a semantic-based approach that exploits ontologies to score the relevancy of contextual information. The paper provides details on the system's architecture, describes lessons learned and introduces practical aspects.

1 INTRODUCTION

Large amounts of data generated by IoT streaming devices are continuously accumulated and processed in Big Data platforms. The analysis of these data supports intelligent software functionalities usually based on machine learning or semantic approaches. Among these features, singularities leading to anomaly detection is predominant and is tackling domains as diverse as medicine (e.g., to identify malignant tumors in MRI images), finance (e.g., to discover cases of credit card transaction frauds), information technology (e.g., to detect hacking situations in computer networks). In the WAVES project¹, we are interested in detecting anomalies in large potable water networks managed by an international company, i.e., Suez company, referred to as the domain field expert in the paper. The automatic detection of such anomalies is an important issue at both the environmental and economic levels: the volume of lost water in the world has reached more than 32 billions m³/year (corresponding to a loss of US\$ 14 billion/year) with 90% of them being invisible due to the underground nature of the network. As a matter of fact, water leaks can be detected based on pressure and flow measures retrieved from sensors installed on strategic spots within such a network. During several experiments, conducted on the French network, consisting of 100.000 km of pipelines equipped with over 3.000 sensors distributing drinkable water to more than 12 million clients, field

experts found out that to guarantee high accuracy in anomaly detection, a contextualization of the measures is needed especially when a singularity appears. For instance, abnormal high pressure or peculiar flow signatures could potentially indicate a water leak. However, in many cases of popular sport or cultural events, these singularities could easily be explained because of some arrangements made by the city hall to provide water fountains. The same singularities can also account for hot weather conditions implying garden watering in a suburb area or a wildfire forcing firemen to use important amounts of water. Hence, an efficient approach for singularity contextualization has to integrate a spatio-temporal dimension on the analyzed measures.

The tasks related to the capturing, analyzing, scoring and storing of contextual metadata are demanding since they require interactions between software components that may be hard to set up, especially in a distributed environment. These components generally handle stream, natural language and ontology processing as well as the storing of complex data structures. Designed as a generic system, Scouter² aims at simplifying these tasks by proposing implementations of the main functionalities and by taking care of installation and configuration aspects.

2 CONTRIBUTIONS

In this paper, we present Scouter, a novel singularity contextualization system built on top of Apache Kafka that automatically proposes relevant explanations to detected anomalies using a continuous filtering approach.

Scouter proposes a powerful web analysis tool leveraging on ontology building and semantic web technologies to automatically retrieve, score and rank relevant events extracted from the web. Scouter also exposes a powerful set of natural language processing functions such as topic extraction, topic relevancy, topic matching and sentiment analysis as well as an original method for geo-profiling to classify areas. Finally, Scouter reduces the time complexity of heavy web scrapping using big data frameworks and eliminates the dataset size limitation by implementing a continuous filtering method. In summary, the main contributions of Scouter are:

- An efficient method to fetch both streaming and static data from various sources on the web based on a hierarchy graph of concept labels, henceforth denoted an ontology.
- An original geo-profiling method that gives a detailed portrayal of the areas where the events occur.

Figure 1: Scouter Architecture

- A novel approach to select relevant non duplicate events using powerful Natural Language Processing (NLP) functions in a three dimensional pipeline: topic extraction, topic relevancy and sentiment analysis.
- A continuous dynamic data filtering technique based on a combination of media analytics scoring and geo-profiling annotations.

3 ARCHITECTURE

As a component of the WAVES platform [1], Scouter was developed to be a generic system that can handle both streaming and static events and analyze them using a powerful set of NLP functions and semantic methods. Fully configurable, the primary goal of Scouter is to fetch data efficiently from different web sources, process them in a short amount of time in order to score every event regarding its capability to explain anomalies detected by the platform. As detailed by Figure 1, the main components of our system are: a set of Web data connectors, a media analytics unit, a geo-profiling unit, a storage mainframe, a messaging broker and a web service provider.

The web connectors consume data from different data sources at a certain frequency based on predefined configurations which can be specified using a web interface. These sources include social networks namely Twitter and Facebook (*e.g.*, citizens commenting on water leaks nearby) but also media sources such as RSS feeds from various newspapers listed in Table 1 (*e.g.*, an article from the French newspaper Le Monde mentioning a fire), weather information from Open Weather Map (*e.g.*, climate conditions during a specific event), organized events from Open Agenda (*e.g.*, concerts, exhibitions or sporting events) and also specific information retrieved from DBpedia (*e.g.*, number of inhabitants or type of neighborhoods). All of these data sources are consumed in a powerful multi-threading mechanism using rest APIs. The concepts, subconcepts and properties used to fetch data are represented in an ontology that formalizes the different relationships in a sound manner. More details about the ontology are provided in the section 4.1.

The media analytics unit digests fetched feeds from Kafka and leverages on the Apache Spark distributed framework to analyze feeds in real-time. Feeds are recorded as events annotated with

location, start/end dates and description. In order to filter the most relevant events without any duplicates in the database, a topic extraction approach and a sentiment analysis are combined to match topics. The topic extraction parses the text of feeds to discover term occurrences. Then, the scoring module takes advantage of user defined weights, *i.e.*, a real value in the $[0, 1]$ range, associated to ontology concepts to provide an overall scoring for each text. The sentiment analysis classifies the feeds into positive or negative categories using the maximum entropy algorithm [2]. It builds a model using multinomial logistic regression to determine the right category for a given text. Simultaneously, the geo-profiling unit provides geographical characteristics for the analyzed area. It determines the type of terrain surrounding the anomaly location. Based on points of interest and terrains for a given zone, a profile is generated that describes the category of the targeted region using a configurable classification.

After the scoring step, events are recorded into a scalable and distributed document database (namely MongoDB). As a result, we obtain in real-time spatio-temporal and scored contexts that can assist the operator to explain an anomaly detected in the underground water pipeline network. Scouter also provides a metrics monitoring tool to track the performance of the system including query times, event processing times, events count and topic extraction training times. These metrics are stored in a time series database with very high read/write access (namely InfluxDB). Finally, the Web services component is used for configuring the system. It provides Rest-based interface that can be integrated with a graphical user interface to deliver configuration parameters in an user-friendly and readable way.

4 MEDIA ANALYTICS & NLP

In this section, we detail the methodology of collecting data from the various types of sources available on the web. This process is built on four major components that work together in order to:

- Extract the most relevant events based on a complex graph of concepts and properties.
- Identify the appropriate summaries from each event with the maximum expressiveness.

- Avoid duplicate events stored in the database by comparing summaries and assessing the similarity between them using sentiment analysis.

4.1 Ontology

Every scrapping tool relies on a configuration file that lists the properties of words, concepts or events that it tries to fetch [3]. In Scouter’s case, the fetching capabilities rely heavily on a pre-built ontology that lists the main concepts the user is looking for but also organizes the relations in two dimensions:

Vertical Hierarchy: A given concept (e.g., Fire) can have multiple sub-concepts (e.g., Blaze, Wildfire) or aliases and misspellings (e.g., fir, wild-fire, blayz).

Horizontal Dependency: A concept can have multiple properties that describe a specific state in a certain time period. For example, water can be potable, but can also leak or have a specific color.

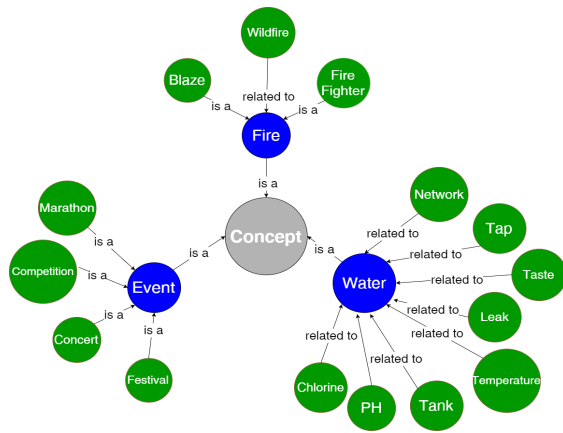

Figure 2: Ontology Overview

By combining the concepts and the properties through predicates, we can build a complex graph such as the one in Figure 2 used for the water leak use case. We can easily argue that this type of structure holds more expressiveness than a classic list of keywords exposed in a configuration file.

4.2 Topic Extraction

After fetching the proper events from the various sources based on the ontology of concepts and subconcepts, the next step is to extract meaningful topics from the events following the pipeline in in Figure 3.

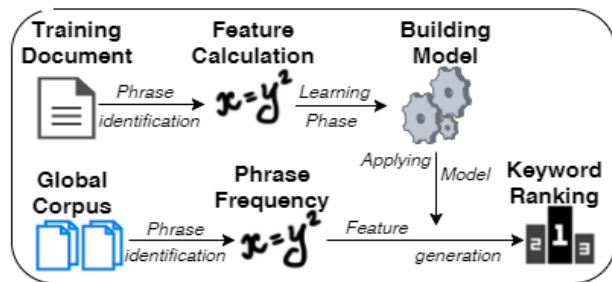

Figure 3: Topic Extraction Pipeline

The main preprocessing here concerns the cleaning of the input text, the identification of potential candidates, and finally the

stemming and case-folding of the phrases. Input files are filtered to regularize the text and determine initial phrase boundaries, then the splitting into tokens alongside several modifications are made (apostrophes are removed, hyphenated words are split in two, etc). Next, we consider all the subsequences in order to determine the ones that are suitable candidate phrases. To increase the accuracy, we use a list of french stop-word list containing more than 500 words in different syntactic classes (conjunctions, articles, particles, etc). Then we case-fold all words and stem them using the iterated Lovins method [4] to discard any suffix, and repeating the process until there is no further change. Stemming and case-folding allow us to treat different variations on a phrase as the same thing.

The main processing involves two calculated features for each candidate phrase : the phrase frequency in the input text compared to its rarity in general use and the first occurrence, which is the distance into the input text of the phrase first appearance. These two features are converted to nominal data for the machine-learning process and a discretization table for each feature is derived from the training data. Finally, we generate a model that gives the scores for every candidates and ranks them using Naive Bayes techniques [5].

4.3 Topic Relevancy

Several research works tackle the issue of automatic summarization [6]. The tools proposed generally mix several classes of features such as summary likelihood, use of topic signatures or syntactic analysis [7]. In our case, we chose a direct approach based on distributional similarity that compares input and summary content. In fact, we consider that a good summary should be characterized by low divergence between probability distributions of words in the input and summary, and by high similarity with the input. For this purpose, we used two common measures: the Kullback Leibler divergence and the Jensen Shannon divergence.

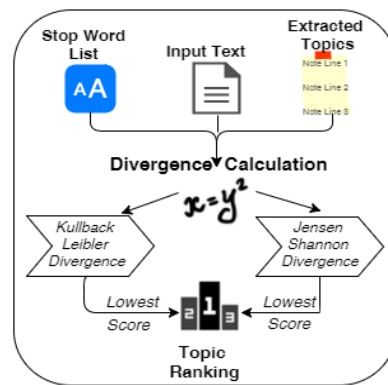

Figure 4: Topic Relevancy Pipeline

First, words in both input and summary are stemmed and separated before any computation. Then we compute the two measures:

Kullback Leibler (KL) divergence: It corresponds to the average number of bits wasted by coding samples belonging to P using another distribution Q, an approximate of P. It is given by:

$$D_{KL}(P||Q) = \sum_i P(i) \log \frac{P(i)}{Q(i)}.$$

In our case, the two distributions of word probabilities are estimated from the input and summary, respectively. Because KL divergence is not symmetric, both input summary and summary input divergences are introduced as metrics. In addition, we perform a simple smoothing using an approximating function that captures important patterns while leaving out noise and other fine-scale structures.

Jensen Shannon (JS) divergence: This one leverages on the fact that the distance between two distributions cannot be very different from the average of distances of their mean distribution. It is given by the following formula:

$$JSD(P \parallel Q) = \frac{1}{2}D(P \parallel M) + \frac{1}{2}D(Q \parallel M) \quad (1)$$

$$\text{where } M = \frac{1}{2}(P + Q) \quad (2)$$

In contrast to KL divergence, the JS distance is symmetric and always defined. We compute both smoothed and unsmoothed versions of the divergence as summary scores. The final step is to use the output of these two functions to rank the extracted topics and keep only the ones with the best summarization score (*i.e.*, lowest divergences).

4.4 Sentiment Analysis

During the last decade, sentiment analysis has known an exponential development due to the growing usage of social networks and the popularity of websites where people can state their opinion on different products and rate them. Many solutions have been proposed and packaged in several technologies [8], we propose in this section a simple approach based on some tools provided by the Stanford CoreNLP toolkit [9].

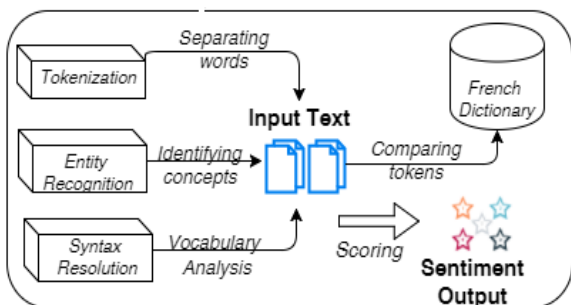

Figure 5: Sentiment Analysis Pipeline

Before applying the model, we need to launch several preprocessing steps that will improve the accuracy of the output score. Here, three steps are involved:

Tokenization: It separates the text into a sequence of tokens and saves the character offsets of each token in the input text. Then we split a sequence of tokens into meaningful sentences.

Entity Recognition: It checks if the tokens are consistent and conform to a predefined standard before trying to determine the likely gender information to names based on a dictionary. Then, the recognition algorithm annotates recognized tokens as persons, locations, organizations, numbers, dates, times or durations.

Syntactic Resolution: The system used a full syntactic analysis, including both constituent and dependency representation, based on a probabilistic parser.

Since our use case is to analyze media and social networks within the French territory, we used a French dictionary embedded in a wrapper to analyze the words.

After the preprocessing phase, we enter the main computation step where we apply the model. Among several models, we chose the compositional one over trees using deep learning. It relies on nodes of a binarized tree of each sentence, including, in particular, the root node of each sentence, that are given a sentiment score. In order to capture the sentiment of an input text, a Recursive Neural Tensor Network model (RNTN) is built based on the characteristics of the input phrases. These phrases are represented using word vectors and a parse tree, then we compute vectors for higher nodes in the tree using the same tensor-based composition function. This approach is inspired from the recursive deep models for semantic compositionality developed by Stanford[10].

4.5 Topic Matching

As stated at the beginning of this section, the goal of the different steps in the media analytics part is to extract the most relevant unique events by annotating them with a meaningful summary. Hence, we try to avoid duplicate events that refer to the same happening or occurrence. In order to complete this task with high accuracy, we are mixing several approaches relying on NLP processing from ontology building to sentiment analysis. The process follows the following steps: For each event fetched from the different sources, the topic extraction phase will propose a list of potential summaries based on a Bayesian approach. Then these summaries will be ranked using the lowest divergences (*i.e.*, KL divergence and JS divergence) in order to assess their accuracy. Among the highest ranked ones, we will check if they have the same sentiment (*i.e.*, positive, neutral or negative). If one of the selected topics during this process have the same sentiment, we assume then that they are referring to the same event in the same way. Therefore, we conclude that these events are duplicates and we only keep the content of one event. Also, we annotate the event with a reference from the other deleted event to show to the final user that this specific event is present in different sources. The overall pipeline of our media analytics module is detailed in figure 6.

Figure 6: Topic Matching Pipeline

Even though this module provides powerful functions to filter relevant unique even, a spacial dimension is required to fully contextualize the detected anomaly. This part will be explained in the following section.

5 GEO-PROFILING

5.1 Methodology

The goal of Scouter is to provide relevant information to contextualize and potentially explain detected anomalies. The media analytics module helped in filtering the relevant events and removing duplicates, however geographical information about the area where the anomaly is spotted could further fine-tune and improve the accuracy of the context. This task is handled by two complementary modules: Geo-profiling module and reasoning module. It can be performed before the reasoning, to orientate the research of events, or after, to change the ranking of the potential sources. It is composed of two methods, that are combined and enriched with a third consumption-based method for better results.

Method 1: It extracts points of interest (POI) present in a given sector, from online geographic data sources, to determine the proportion of different types of surfaces composing it. The domain field expert selected the types of surfaces relevant to our use cases, giving us five profiling parameters: residential, natural, agricultural, industrial and touristic. Then, we created a rating file, assigning notes to each POI, in order to compute a score for each type of surface, and calculate its proportion (*i.e.*, a real value in the $[0,1]$ range).

Method 2: It is also based on geographic data, but uses features modeled as polygons instead of POI. The inclusion tests are more complete, since some polygons may be included completely or partially inside the consumption sector. Also, the computation is not performed using the rating system, but the areas of the polygons, which are less arbitrary. Otherwise, both methods produce the same result: proportions (also as real value in the $[0,1]$ range) for each type of surface.

Method 3: For certain types of consumption sectors, our two methods can slightly differ. To decide which method should be used in each case, we added a third method that computes what we denote as the consumption ratio. For each sector, we compute the daily flow, and make an average over a long period of time to avoid anomalies; then we divide this flow by the pipeline length on the sector to obtain the ratio. A low ratio corresponds to a sector with few consumers, such as countryside zones, a high ratio is the opposite. The program selects the best profiling using those criterion.

In case of a mixed result, we compute the average of the methods, to reflect the fact that there may be both open zones and populated locations. In Figure 7, we sum up our profiling strategies by highlighting their collaborations and the input data for each method.

Figure 7: Profiling Overview

5.2 Tools & Resources

The geo-profiling module relies essentially on open data: the identification of the anomalies sources can only be performed with external sources, and so is their probabilistic classification.

The origins of the problems detected are generally external events that affect the quality parameters on the network. Several types of events can be responsible such as natural disasters, sport events or cultural exhibition. Some are not predictable and will be noticed by mining the proper sources, but others can be detected easily: sport events are announced a few weeks in advance, a cultural festival may be scheduled several months before. Some events can also be taken in account, even though they are not directly causing anomalies: meteorological data will help in deciding the relevancy of other events (*i.e.*, an open air festival will be more relevant as a cause of anomaly in the case of a warm weather). Static data may also provide accurate information such as Open Street Map. It has been selected because of its relative completeness compared to other online data like GeoNames. In addition to those geographic information, the Linked Open Data also provides a great amount of details on locations surrounding our water network. Some are useful to enhance the profiling or the classification of sources (*e.g.*, population density, touristic attractions or GDP), others are potential original events (*e.g.*, religious celebrations or regular typical events).

6 EVALUATION

In this section, we discuss the performance metrics used in our system, we evaluate the media analytics part on several dimensions such as the quality of events collected, then we focus on the geo-profiling module.

6.1 Media Analytics

In this section, we refer to an experimentation collecting for 9 hours events (feeds) from all the mentioned sources namely social networks (Facebook and Twitter), newspapers (RSS feeds), Open Agenda and DBpedia for organized events, Open Weather Map for climate conditions. The target geographical area of interest is a group of cities in the suburb of Paris, France, denoted as Versailles and having a coordinates bounding box. The parameters used for each of the data sources are explained in Table 1.

Source	Fetch Frequency	Pages of Interest	Concepts Scores
Facebook	12 hours	Mon Versailles Versailles Officiel Public Events	meter:1 damage:10
Twitter	Streaming	@Versailles @monversailles @prefet78 #sdis78	concert:10 spray:1 fire:10 water:10 blaze:1 wildfire:10
Open Agenda	24 hours		flow:5 tank:1 chlore:5
Open Weather Map	4 hours		
DBpedia	24 hours		
RSS News Papers	12 hours	Le Parisien 78 Actu versailles.fr Sdis78 yvelines.gouv.fr	pressure:5

Table 1: Data Sources and Concepts Scores

For instance, Twitter was run using a streaming API over all the tweets located in the bounding box, a special attention was given to extracted events from some feeds (e.g., @Versailles or @monversailles) since they are official accounts of the city. The keywords used to query these tweets are a set of 12 concepts (each one having sub-concepts in the ontology) with an affected weight that scores the relevancy of the keyword.

For this evaluation, the system is evaluated in terms of the following measures:

Number of collected and stored events: It represents the number of received feeds from all the data sources during the run time. Figure 8 shows the number of events collected during the run and the number of events stored in the database that have a score higher than 0. We can clearly see that many of the collected events (around 28% for this experiment) are not relevant, therefore they will be useless for the operator as a potential explanation for the anomalies.

Figure 8: Collected & Stored Events for 9 Hours

Kafka Queue Messages Per Second: It represents the number of messages (events) written to Kafka broker, it can indicate the load on the messaging queue. When Scouter is running, all processors start ingesting data, then each of them will sleep until the next round after certain frequency. This explains the peak at the starting time of the figure 9, while after that, only Twitter stream feeds are being written to Kafka queue.

Figure 9: Kafka Throughput

Topic extraction training and Average Processing time: They represent the time spent on building the training model for detecting topics and processing the incoming events.

Table 2 shows the average time needed to score all collected events, it is calculated by dividing the sum of scoring time for each of the events by the collected events count. It also shows the training time for topic extraction algorithm to build the model that is used to detect topics. We can see that Scouter performs very well with relatively large number of events coming to the system without any failure or delay.

Measure	Time in Millisecond
Average Processing Time	7.43
Topic Extraction Training Time	474

Table 2: Scouter Processing Time

6.2 Quality of Events Collected

To evaluate the quality of the events collected, we considered the water leaks use case, where the events were fetched from the mentioned data sources over 9 hours, using the ontology in Figure 2 and the assigned score listed in Table 1. The domain expert provided the time stamp and location of all the anomalies reported on 2016 which came to 15 in total. From the database, we fetched all stored events close to the time stamp and location of each anomaly and presented them to five domain experts. For each event, they were asked if they believe that this event can give a proper and relevant explanation for the anomaly reported. A constraint was imposed, the answer had to be binary, i.e., Yes or No, in order to simplify the interpretation of the results.

Table 3: Domain Experts Evaluation

Eval- uator	Events														
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
1	×	✓	×	✓	✓	✓	×	✓	×	×	✓	×	×	×	×
2	×	✓	×	✓	✓	×	×	✓	×	✓	✓	×	×	×	×
3	×	✓	×	✓	✓	×	✓	×	×	✓	×	✓	✓	×	×
4	×	✓	×	✓	✓	×	×	✓	×	✓	×	×	✓	×	×
5	×	×	×	✓	×	×	×	✓	×	×	✓	×	×	×	×

To evaluate the reliability of the annotation, we used Fleiss kappa measure [11]. It is a statistical measure that aims to assess the reliability of agreement between a certain number of annotators when assigning labels to categorical subjects. It can be interpreted as expressing the extent to which the observed amount of agreement among raters exceeds what would be expected if all raters made their ratings completely randomly. It follows the equation below with the calculated results for our 5 evaluators scenario:

$$kappa = \frac{\bar{P} - \bar{P}_e}{1 - \bar{P}_e} = \frac{0.84 - 0.5256888889}{1 - 0.5256888889} = 0.6626686657$$

$$where \bar{P}_e = \sum_{j=1}^k P_j^2 = \sum_{j=1}^k \left(\frac{1}{N} \sum_{i=1}^N n_{ij} \right)^2$$

$$And P_i = \frac{1}{n(n-1)} \sum_{j=1}^k n_{ij}(n_{ij} - 1)$$

P is the mean of P_i , the extent to which annotators agree for the event. P_e is the summation of squared P_j , where P_j is the proportion of all assignments which were to the j -th category. In these equations, N is the number of Events, n is the number of annotators and k is the number of categories we have (Yes and No in our use case).

Based on the table for interpreting kappa values[12], we can say that the annotators have substantial agreement on the events annotated as being a relevant explanation for a water leak anomaly. Therefore, we can say that Scouter system was effective in selecting the most relevant events and provided a substantial help to contextualize anomalies related to water leaks.

However, we are still aiming at improving the evaluation of stored events based on the following 2 key points :

- Only 5 experts participated in this evaluation which is not sufficient regarding the scale of the use case. Therefore, we are preparing a new evaluation with dozens of field experts from various companies to assess more accurately Scouter.
- Data are collected over a short period related to 2017. We would like to extend the evaluation to the anomalies reported in 2015 and 2017 in order to test the full capabilities of Scouter.

6.3 Geo-profiling

The profiling module can be executed "offline" in our system. This means that it does not need to be integrated within the stream processing. In fact, the data required as input are mostly static: geographic data are rarely updated, and the network configuration does not change much over time. We performed a series of tests on several data sets given by the domain expert on both national and international levels.

Area	# Sensors	Available OSM data (Mo)	Profiling		
			Consumption ratio (ms)	POI (ms)	Region (ms)
P. Laval	2	5.4	270	25	605
V. Nouvelle	16	53.8	620	282	630
Hubies D.	1	5.8	190	13	30
Brezin	1	3.1	150	8	72
Guyancourt	2	4.2	161	13	50
Louveciennes	19	123.2	850	1118	1290
Hubies H.	13	37.15	740	163	180
Haut-Clagny	4	8.6	260	21	32
Garches	3	7.0	220	205	46
Gobert	3	15.4	201	36	105
Satory	5	32.5	292	103	215

Table 4: Performance table of the different methods of the algorithm

The performances of the reasoning module mainly depend on the size of the data extracted from Open Street Map: larger consumption sectors will have more data taking more time in the end. The profiling with polygons is the longest since it needs the extraction of both POI and polygons to be processed. On average, the computation of the consumption ratio is the fastest, since it doesn't need any extraction from Open Street Map.

Table 4 details the performance of our different methods for the use case of the region of Versailles (an area of 350.000 inhabitants in the suburb of Paris), which is composed of 11 consumption sectors. For each of these sectors, we indicate the number of flow sensors present on each sector, and the size of the data to extract from Open Street Map (both POI and polygons), then we indicate the computing time for each method. As we can see, the regions with the more data and the more sensors have the longest processing time: it corresponds to the biggest zones.

7 CONCLUSION

In this paper, we presented Scouter, a system that demonstrated its usefulness in the WAVES project for improving the contextualization of identified anomalies. The primary goal was to offer a generic system that can adapt to any Big Data platform whatever

the engine used and without losing the capability to process various types of data sources. To achieve such target, we chose an approach based on data connectors relying heavily on messaging queue system and we offer multiple NLP functionalities such as topic extraction and sentiment analysis.

Because of its easy-to-use Docker package, Scouter is already used in other prototypes at Atos and we are aiming to extend it with novel features such as ontology enrichment based on a dictionary of concepts and the identification of duplicate events coming from different data sources. Finally, we plan to improve the implementation by supporting various ontology formats (e.g. ttl, N3, RDF/XML, etc.) and adding new data sources to fit most use cases (e.g. traffic information, etc.).

Lessons Learned: During this work, the research team learned several lessons along multiple distinct dimensions. Instead of trying to adapt our implementation to heterogeneous technologies in the Big Data world, the best approach was to create a simple but powerful bridge that would make the integration seamless. The right choice was to go with a messaging queue system such as Apache Kafka that is widely used and known for its robustness. Moreover, we found out that few data sources with high quality content outperformed multiple data sources with medium to low quality content. Therefore, we decided to keep only 4 different categories and for each one, we selected the most suited source.

Since we are aiming at designing a tool adjustable to multiple use cases, going for an ontology-based approach seemed to be a win solution. Hence, we could give the possibility to every domain expert to use his own ontology with the specific concepts, properties and keywords that suit her needs. However, the key component for a successful implementation is to find the right models and the proper scores. Even though a lot of libraries were available for NLP functions, many of them lacked robustness and flexibility. Instead of investing much time on finding the fittest technologies, we are quite positive that we can highly improve the results by investing more time on ontology modeling and scoring.

Finally, we found out that the best way to remove complexity was to package the code into a user friendly web application. Therefore, instead of asking users to plug Scouter to their framework, they would just have to enter the location of the analysis, the specific data sources alongside with the proper domain ontology. As for the deployment part, using containerization technologies such as Docker tend to remove the burden of deployment and can be launched within a minute.

8 ACKNOWLEDGMENTS

This work has been supported by the WAVES project which is partially supported by the French FUI (Fonds Unique Interministériel) call #17. The WAVES consortium is composed of industrial partners Atos, Suez and Data publica, and academic partners ISEP and UPEM.

ABSTRACT

Contrast set mining identifies patterns in the data that can best distinguish between groups. Most of the existing work focuses on categorical and batch data, and they do not scale well for large datasets. In this work, we focus on finding contrast patterns for *mixed* (quantitative and categorical) and *streaming* data. We adapt a discretization methodology, Supervised Dynamic and Adaptive Discretization, to identify meaningful bin boundaries. We then use the discretization result to find contrast patterns on streaming data. In order to achieve this, we identify frequent items and then contrast them to a group of interest. To handle potential concept drift, we propose an update strategy to keep the frequent items relevant. In addition, our algorithm samples feature combinations based on their "sampling" score and user feedback to reduce the search space as well as retrieving more interesting patterns.

1 INTRODUCTION

As the amount of data being collected during the semiconductors manufacturing process of increases, the time required to analyze the data and provide relevant feedback also increases. There is a growing need to develop machine learning algorithms to deliver fast feedback to the engineers so that adjustments in the manufacturing line can be made in a timely manner. While the behavior of manufacturing data is often predictable, at times there exist anomalies such as a low yield for certain batch of products. To find the possible cause(s) of this low yield, one approach is to create a model and compare this batch to a normal batch. To achieve this, an engineer needs to know what to look for (the number of features and instances are large), and even after that he/she needs considerable amount of time for analysis. Our intent is to quickly and automatically learn complex patterns in the "population" data (known normal data) and then use these learned patterns to detect differences in the groups. We note here that our goal is data understanding rather than prediction. In prediction such as classification, the goal is to predict an outcome early on in the manufacturing process to reduce costs such as testing. The algorithm typically works like a black box where the user may not understand why the algorithm predicted an outcome. However, in this paper we design a feedback system in which the goal is to identify interpretable patterns that might provide the users helpful insights on potential causes of the differences. Another key difference is that for a prediction algorithms, the "classes" such as "good chips" and "bad chips" need to be known or available in advance in order to build a model. In our proposed work, we seek to detect patterns from a single group of data (the "population"), which will then be compared with incoming data to detect potential differences.

There are several issues that need to be addressed. First, the data may contain both categorical and continuous features, and the features may have high order of interaction between them. Multiple features could contribute to a contrast simultaneously. In this work, we leverage our recently proposed binning strategy, Supervised Dynamic and Adaptive Discretization (SDAD) [8, 9], to address the challenge of dataset containing continuous features. The discretization technique automatically determines the size and number of bins needed in order to find meaningful contrast patterns.

The second challenge we face is the massive data size. A large amount of data is generated daily. To obtain an understanding of the "normal" behavior of the data, we create a frequent itemset database using historical manufacturing data that are known to be normal. However, this data can change as recipes for different chips change. The frequent itemset database must adaptively learn new patterns, update existing ones and discard outdated ones. This is necessary because the representation of the "population" (historical) data needs to stay relevant to the current state of the database. With the updated representation of the population, we can quickly identify potential contrasts between that and a group of interest. If we try to build a database with only a small sample of the population data (e.g. data collected from one day), the data may be biased to the specific machine settings and may not be representative of the population. If the data is too large, e.g. a month worth of data, the data may contain outdated information that bias the results. Building an incremental database of the population itemsets over time can be more efficient and can potentially identify more meaningful patterns. Our algorithm is also easily parallelizable. While this is out of scope for this work, we refer interested readers to [8, 10] for various ways of achieving parallelization to find frequent itemsets.

Moreover, as data streams are monitored, the groups to be compared are not known in advance. Traditional contrast set mining algorithms require the contrasting groups to be known, and then find itemsets which differ significantly across groups. Consider two cases. First, suppose a tester detects a large number of faulty chips on a particular day, and we want to know if there is a difference between chips arriving at this tester and the others. One approach, taken by traditional algorithms, would be to make all the tester IDs as the 'group' label and then find patterns that strongly separate the tester of interest from the rest. As the second scenario, if an oven gives particularly high yield, we would like to know if we can improve the yield of the other ovens. Keeping the oven ID as the 'group' feature, the contrast set algorithm finds itemsets that are different between this oven and the rest. Since the "groups" are not known in advance, our proposed method identifies all frequent itemsets in the population. Once the "sample" of interest (e.g. the oven resulting in high yield) is found, the difference in supports between the population and sample is calculated. This led us to develop an algorithm which identifies frequent patterns[8]. Using frequent itemsets we can identify contrast sets between a sample (data of interest to an engineer) and the population.

The main contributions of the proposed work are as follows:

- (1) Given historic data (the “population”) and a current data sample, we propose an algorithm that can find contrast sets between any subset of the streaming data and the population quickly. Based on frequent itemsets mining, our approach avoids a lot of re-computation when new groups are identified and new contrasts are needed.
- (2) The proposed algorithm leverages user feedback to calculate a sampling score, which improves the patterns returned and reduces computation costs.
- (3) We propose an updating strategy that keeps discovered patterns current, discards outdated ones and adds emerging new patterns.

The following section discusses related work. Section 3 discusses the background on contrast sets and the search strategy adapted in this paper. In section 4, we describe an adaptive and dynamic discretization algorithm for quantitative data that improves upon existing discretization algorithms. We propose an updating strategy for finding contrasts on streaming data, as well as a strategy to use user feedback to compute the sampling probability. In Section 5, preliminary experimental results show that using our approach, we are able to discover the same contrasts that existing algorithms discover, but much more efficiently. Section 6 concludes the paper.

2 RELATED WORK

We discuss related work in frequent set mining and contrast set mining. However, due to the maturity of these areas, the discussion is far from being comprehensive. To the best of our knowledge, there is no other algorithm that has the exact same end goal as ours.

Contrast-set mining has been formally defined as “conjunctions of features and values that differ meaningfully in their distribution across groups” [1]. It can be viewed as a variant of association rule mining. While association rule mining discovers rules or patterns that describe or explain the current situation, contrast-set mining finds patterns that differentiate groups of data by identifying features and values (or conjunctions thereof) that differ meaningfully across them [1]. Knowing the features that characterize the discrepancies across various groups can help users understand the fundamental differences among them, and make independent decisions on those groups accordingly. Therefore, contrast-sets are often presented as sets of rules. The authors in [1] provide the following classic example: on comparing different education groups by asking “What are the differences between people with PhD and Bachelor degrees?” we might find that $P(\text{occupation} = \text{sales} \mid \text{PhD}) = 2.7$ while $P(\text{occupation} = \text{sales} \mid \text{Bachelor}) = 15.8$. For manufacturing fault analysis, we might have a query such as “Given two sets of operation sequences: G (“good batch”) and B (“bad batch”), what are the differences between them?” The authors in [1] proposed an algorithm, STUCCO (Searching and Testing for Understandable Consistent COntrasts), to find such contrast sets. STUCCO employs efficient search through the space of contrast sets based on another rule mining algorithm, Max-Miner [2]. To assess the meaningfulness of the difference in support values across groups, they use chi-square test on the null hypothesis that the support value is independent of group membership.

Another approach, proposed by [17], discovers that existing commercial rule-finding system, Magnum Opus [18], can successfully perform the contrast-set mining task. The authors conclude

that contrast-set mining is a special case of the more general rule-discovery task. A good survey on contrast sets, emerging patterns and subgroup discovery algorithms is provided in [13]. CIGAR [7], apart from using the pruning criterion from STUCCO, adds support, correlation and difference in correlation between the parent and child contrasts. The authors claim that itemsets with a support less than the minimum support may be uninteresting to the analysts. We adapt this assumption for the streaming part of our algorithm. The authors also claim that if the itemset have low correlation, we may find spurious contrasts due to outliers. The authors in [4] use user feedback to sample the patterns and improve the patterns displayed to the user; however, they do not explicitly handle continuous and streaming data.

In [13] we see that Contrast Set Mining, Emerging Pattern Mining and Subgroup Discovery are compatible and hence techniques developed in one domain can potentially be used in another. There is considerably more work done for finding subgroups in numerical domains. The algorithms presented in [11, 15] finds bins for subgroups for mixed data and is implemented in an open source tool Cortana. These techniques usually use an initial discretization method and then merge spaces based on an interest measure. An interesting algorithm described in [6], finds bins for continuous attributes for the problem of subgroup discovery. The algorithm uses optimistic estimates and horizontal pruning to prune the search space. This heavily relies on pruning based on finding the top-k subgroups. Finding all initial split points (exhaustive search in [6]) is expensive but if the initial partitions are not exhaustive but rather frequency or entropy based, the algorithm may miss interesting patterns that occur lower down the tree due to multivariate interactions. The techniques mentioned above are developed for static databases, however the pruning techniques described may be helpful if the groups are known in advance (which does not apply for our application). The current trend of recent algorithms tend to use sampling to improve efficiency and quality of patterns [3–5]. We use some of the sampling techniques explained in these papers and incorporate user feedback to enhance it. This helps improve efficiency and potentially display more meaningful results to the user.

Although our main goal is contrast set mining, we tackle the streaming part of our work using frequent itemsets mining. Frequent itemset mining is typically the first step of association rule mining. This is also where the main computational complexity issues occur. Most existing work in frequent set mining focuses on batch processing and improving the efficiency of the algorithm. However, in many real world applications, new data is continuously generated, e.g. manufacturing processes, sensors etc. General frequent itemset mining algorithms require multiple passes over the database. However, this is not possible in a streaming scenario since data come in high volumes. If we miss a pattern, it may not be possible to go back and check the past data. Since speed is an important issue, some trade-offs in accuracy may be needed. In addition, the space required to store information for future runs and current knowledge may be large.

In general, many streaming algorithms adapt the window model [14]. In landmark window, the goal is to find itemsets between a fixed start point s and current time t . The other option is a sliding window where we are only interested in itemsets found in a time frame. For example, if the window width is w , the goal is to find itemsets in the time $[t - w + 1, t]$. In many cases newer data are more important than older data, in which case a damped window model assigns higher weights to more recent data by defining a decay rate. Time Tilted windows are

used to find frequent itemsets over a set of windows. Importance is given to newer data and hence granularity is adjusted as data arrive. Since our goal is to find the general behavior of the data, we use a sliding window strategy, assigning equal weights to all the data.

There are two types of streaming algorithms to find streaming frequent itemsets, true positive algorithms and true negative algorithms. A true positive algorithm does not allow any frequent itemset to be missed. The seminal work by Manku and Motwani [12], called *lossy counting*, uses a user-defined parameter ϵ , and the result contains no itemsets with a support lower than $\delta - \epsilon$. The main disadvantage of this approach is that the number of itemsets increases exponentially to guarantee the lower bound. On the other hand, true negative algorithms [19] do not find false positives, but have a higher probability of finding true frequent itemsets. The main limitations of these algorithms are that it is difficult to implement them in parallel; they cannot handle continuous features; and the space requirement may be too high if the data are very large. In this work we use a true negative algorithm; however, as will be discussed later, we can estimate the support of itemsets are missed in the stream of data.

3 BACKGROUND

3.1 Contrast Sets

Bay [1] formally defines contrast set mining as follows. Let $A = \{a_1, a_2, \dots, a_j\}$ be a set of all attribute values for the entire dataset. Let C be a set of all combinations of A . An *itemset* c is a subset of C . Let $G = \{g_1, g_2, \dots, g_m\}$ be a set of groups. Each instance belongs to only one group. If $|g_i|$ is the number of instances in group i and c_i is the itemset of interest in group i , then **support** s_{ic} of an itemset c in group i is the number of instances in g_i that contain c :

$$s_{ic} = \frac{\text{count}(c_i)}{|g_i|} \quad (1)$$

An itemset c is **large** between two groups i and j if

$$\text{abs}(s_{ic} - s_{jc}) > \delta \quad (2)$$

and **significant** if

$$\chi_{ij}^2(c) < \alpha \quad (3)$$

where α and δ are user-defined parameters.

An itemset is considered a contrast if it is large and significant.

Three pruning strategies are used to reduce the search space. (1) An itemset is pruned if it does not have a support over δ in any group (*minimum deviation size* pruning). (2) If its expected occurrence is less than 5 since statistical tests are not significant at that level. (3) By calculating the upper bound value of χ for the itemset's children. To reduce the number of false positives, the value of α is adjusted according to Bonferroni's adjustment explained in [1]. We note here that the pruning strategies used by STUCCO cannot be used in our application since we do not know the groups in advance. However, as will be seen later, we only find itemsets with support greater than δ for the streaming data, and if the group of interest has a support greater than δ , we estimate its support from the population sample.

3.2 Search Strategy

To find combinations of attributes, we need a search strategy. To this end, we adapt the OPUS [16] search tree for our algorithm. However, some modifications are needed since the original tree is designed for categorical attributes. Figure 1 shows the modified

Figure 1: OPUS Search Tree for Mixed Data

OPUS tree so that it is compatible with continuous attributes and attribute-value pairs instead of directly handling itemsets. Consider an example with one categorical attribute *Attr1* having possible values a and b , and two continuous attributes *Attr2* and *Attr3* having values $u_1, u_2 \dots u_n$ and $v_1, v_2 \dots v_n$ respectively where n is the number of instances. The order in which the nodes are traversed is indicated by the number in each node. In this example, node 2 with itemset $\{a\}$ is first explored. If it can be asserted that node 2 can be pruned, then we do not need to explore nodes 5, 8 and 11. It should be noted that the traversal order is the reverse of depth-first search. The reason that we use this approach instead of a depth-first approach is to maximize pruning. Although breadth-first search can also be used, we opt for OPUS since the storage overhead is less at each level.

3.3 Streaming Frequent Itemsets / Patterns

Frequent Itemsets (FI's) are itemsets which are present in the dataset with a frequency greater than a user-defined threshold. The formal definition follows closely to that of contrast sets but notice the subtle differences. Using the definition of c from the earlier paragraph, let T be a dataset of transactions. If $|T|$ is the number of rows in the dataset then **support** s of an itemset c is the number of times c occurs in T :

$$s_c = \frac{\text{count}(c)}{|T|} \quad (4)$$

A streaming dataset τ is a sequence of indefinite number of datasets of transactions $\{T_1, T_2, T_3, \dots\}$. Let $T_{k,l} = \{T_k, T_{k+1}, \dots, T_l\}$ where $k < l$. The support s of an itemset c in a time window $[k, l]$ is:

$$s_{c[k,l]} = \frac{\text{count}(c_{[k,l]})}{|T_{k,l}|} \quad (5)$$

4 STREAMING CONTRAST SETS

Figure 2: Sliding window for Data Streams

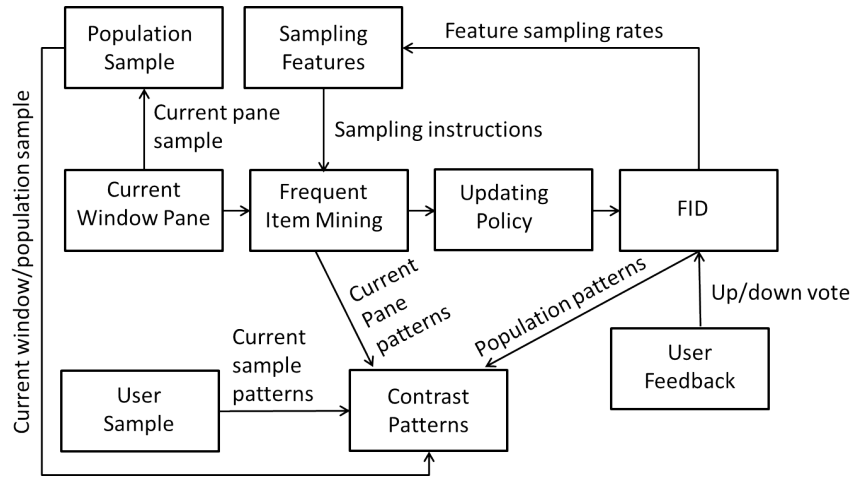

Figure 3: Data flow

We start our discussion by explaining some of the basic terminology used in this section. As shown in Figure 2, data continuously arrive in a data stream. Each block of data is called a **pane**, and a group of panes that are relevant is called a **window**. In Figure 2, suppose a pane represents a day’s worth of data, then the window size, $\lambda=3$, represents 3 days. Itemsets that are no longer frequent in this window can be discarded.

Figure 3 provides a high-level view of our proposed algorithm. In the next few subsections we discuss what is computed in each block and what information is communicated by each arrow. Simply stated, we pre-compute the frequent itemsets for the current window pane from the population data. This is a time-consuming task, given the massive size of the database. The frequent itemsets discovered from the population data will be saved in a **Frequent Itemset Database** (FID from here on). We note here that this database is not static; it is updated with the arrival of new data as shown in the figure. A data structure such as a prefix tree (like Figure 1) can store this information. When a new **window pane** arrives, frequent itemsets from the current pane will be computed, using techniques explained in a later section. These frequent itemsets are then compared with the population frequent itemsets computed previously to obtain potential **Contrast Patterns**. If the new pane does not conform to the patterns found in the previous panes, the engineers can be notified in a timely manner.

The user can also provide a sample dataset that he or she wishes to compare against the population data, or generate the sample from the archived data on the fly as seen in the **User Sample** block in Figure 3. The frequent itemsets from the sample data are extracted and they will be compared against the itemsets retrieved from the FID for the population data to find **Contrast Patterns**.

Sometimes a pattern that is found in the Current Window Pane or the User Sample may not be in the FID since its support in the population may be below the threshold. To overcome this, we keep a **Population Sample** if the algorithm encounters such a situation. The supports of the population are then estimated from this sample.

The intuition behind our algorithm is that the patterns for the population data represent the “normal” behavior of the population, and comparing the set of patterns from sample data against this “normal prototype” would reveal any differences between the

two datasets. Such discovery could potentially identify anomalies in the current or sample data, and shed some light on the causes of the anomalies (by examining the rule differences).

After finding the frequent itemsets for the current pane, the algorithm updates the FID with the new frequent itemsets found using our **Updating Policy**. As new data come in, the distribution and relationships may change among the features. To keep the FID relevant, we need to remove patterns that are no longer relevant and add emerging patterns. If the algorithm finds a new pattern, we delay adding it to the database until we keep finding the same pattern in multiple iterations and if an existing pattern is no longer significant, it is phased out. The user can keep track of these changes in a timely manner.

The **User Feedback** block lets the user decide if a pattern is subjectively interesting. This in turn is fed to the **Sampling Features** block which improves the efficiency and displays more interesting patterns.

In addition to offering the ability to compute the contrast-set in real-time given the sample data, another advantage that our approach offers is that the contrasting patterns are not restricted to having only the values of a feature representing group membership. We will provide more detail on the algorithm in the next section.

4.1 Finding Frequent Itemsets for Current Window Pane

While traversing the OPUS search tree explained in the previous section, if we reach a node with only categorical features, finding frequent itemsets for the current window pane for categorical variables is straightforward, i.e., we just need the support count of the itemsets in the current pane. Therefore, we will concentrate on itemsets that contain continuous features. To this end, we use Supervised Dynamic and Adaptive Discretization for frequent itemsets (SDAD-FI) [8]. We note that any frequent itemset mining algorithm that can handle mixed attributes can be applied here; however, we opt for SDAD-FI since it can handle datasets with mixed attributes and is parallelizable. We also show in [8, 9] that SDAD is able to find better quality bins for frequent itemset mining and association rule mining in a reasonable amount of time compared to other state of the art binning and rule mining algorithms. As opposed to standard discretization techniques such as equi-width or equi-frequency, SDAD-FI does not need to

Figure 4: (a) Simulated dataset with 3 features (b) After first partition between feature 1, 2 and 3 (c) After second partition between feature 1, 2 and 3 (d) After merging

know the number of bins to partition in advance, nor the sizes of the bins. It tries to find the "best" bins with respect to the distribution and relationships between features.

The main idea of SDAD-FI is to first employ a top-down approach where the algorithm iteratively partitions the space between features and calculates an interest measure with the goal to obtain regions that satisfy a user-defined homogeneous threshold. We use the interest measure *purity* as defined in [8]. The intuition behind purity is to find the most homogeneous space of the current set of features. We will describe the algorithm with an example. Consider Figure 4a. This dataset contains three features: Attributes 1, 2 and 3. Attributes 1 and 2 are continuous and Attribute 3 is categorical with 2 values indicated by the color and shape of the markers in the scatter plot. In Figure 4b, SDAD-FI divides the continuous features into 4 spaces. Space 1 and 4 (numbers shown in figure) are homogeneous, i.e. it contains only one categorical feature value. However, space 2 and 3 are not. SDAD-FI again divides those spaces as shown in Figure 4c and now finds pure spaces. Since dividing pure spaces do not find "better" bins, the algorithm stops, and this concludes the top-down process.

The next step is to merge contiguous and similar spaces in a bottom-up fashion. Similar spaces are those that are not significantly different according to the χ -squared test. SDAD-FI starts with the smallest contiguous spaces in terms of *n-volume* (area in this case). It first merges space 21 and 23, then 31 and 33, and then 32 and 34. It further merges the combined space of 21 and 23 into space 1, and 32 and 34 into space 4. The final bins are shown in Figure 4d.

Obviously, the example shown is an ideal case. In real world datasets, we usually do not find such clear cut boundaries. However, this example illustrates the flow of the algorithm. In general, SDAD-FI is a greedy algorithm and continuous features are split until splitting does not result in statistically significant differences between the spaces (instead of looking for pure bins). The

example discusses a case in which categorical and continuous features co-exist in the itemset. However, SDAD-FI also works when there are only continuous features in the itemset. In this case, the splitting and merging operations are as explained above, with the modification that the interest measure is now the correlation between the continuous features. See [8] for more details.

4.2 Updating Policy and FID

If an itemset contains only categorical values, the Frequent Itemset Database (FID) is updated if a difference in the supports of a Frequent Itemset (FI) is detected between the current pane and the FID using the following update policy. Consider the example in Figure 2. Let the minimum support be δ . If the size of the window is λ , then in Figure 2 we have used $\lambda=3$. Now suppose there is an FI in the FID with support s_{FID} , and the same FI is found in the current pane with support $s_{current}$, we calculate the approximate support of the itemset $s_{expired}$ in the expired pane from the population sample (explained later). The support of the FI in the FID can then be updated using a simple weighted average technique.

$$s_{new} = s_{FID} + \frac{s_{current}}{\lambda} - \frac{s_{expired}}{\lambda} \quad (6)$$

If a new FI is found in the current pane with a support greater than δ , but it is not in the FID, then applying the updating strategy explained above would not work since $(\lambda-1)*s_{FID}/\lambda$ would be zero and $s_{current}/\lambda$ may not be big enough to be greater than δ to be added to the FID. For example, suppose $\delta = 0.1$. If in the current pane we find an itemset with support of 0.9, and if $\lambda = 10$, then s_{new} would be 0.09. As a result, the FI would not be able to enter the FID even if it is found consistently after a certain point. To overcome this, we approximate the support (s_{FID} in the above formula) from the **population sample** and keep a temporary database of new FI's.

The itemset is stored in a temporary database until the itemset attains a support greater than the minimum support. After this

point, we say the itemset is indeed frequent and add it to the FID, as well as deleting it from the temporary database. There is a possibility that the current itemset is an anomaly and is not truly frequent. In this case, the itemset needs to be purged from the temporary database. Let the number of panes, starting from the first pane the itemset was found to be frequent, be n . The algorithm keeps track of the actual support (s_{act_supp}) as soon as the itemset was discovered as frequent, and it is calculated by

$$s_{act_supp} = \frac{(n-1) * s_{act_supp} + s_{current}}{n} \quad (7)$$

As long as s_{act_supp} is above the minimum support threshold, the algorithm keeps the itemset in the temporary database.

We use this approach to add or purge itemsets because our goal is to maintain a consistent FID which is representative of the population. For example, if an FI is in only one pane, it may be an outlier and not representative of the population. However, if an itemset appears regularly in multiple panes, but is absent for some reason for a short period of time, the algorithm should not purge it out. We note here that keeping the population sample to estimate the support of unknown itemsets reduces the number of frequent patterns needed to be stored like in [11, 19], resulting in less computation. Although the storage overhead is higher to keep the population sample, it serves another purpose. It also helps when the user wants to find contrast patterns on the fly, and the itemset is not present in the FID.

Figure 5: Bin movement

The method explained can be used for frequent itemsets containing only categorical features. Updating FI's with continuous features needs a different approach. Binning is an expensive operation and, for each pane, it is unlikely to have exactly the same bin boundaries even if the distributions are statistically the same because of noise in the data. Instead of calling SDAD-FI at every pane, first, the continuous variables of the current pane are binned by re-using the bin boundaries of the current FID. If the supports between the FID and current pane are not significantly different using the χ -squared test, the bins in the FID are kept unchanged. However, if that is not the case, we discretize the itemset in the current pane by running SDAD-FI. At this stage, we check if there is a slight concept drift or if a completely new relationship is learned between the features. The algorithm conducts a test to check if the new bin boundaries overlap with the current boundaries, and if so, by how much. To do this, there has to be an overlap in every axis. For example, suppose the current itemset has 2 continuous features (the bin boundaries in this case form rectangles, see Figure 5), x_1 and x_2 are the vectors of the x coordinates, and y_1 and y_2 vectors of the y coordinates of the 2 rectangles, then there is an overlap between the rectangles

if $((\min_{x_1} \leq \min_{x_2} \ \&\& \ \min_{x_2} \leq \max_{x_1}) \ || \ (\min_{x_2} \leq \min_{x_1} \ \&\& \ \min_{x_1} \leq \max_{x_2})) \ \&\&$

$((\min_{y_1} \leq \min_{y_2} \ \&\& \ \min_{y_2} \leq \max_{y_1}) \ || \ (\min_{y_2} \leq \min_{y_1} \ \&\& \ \min_{y_1} \leq \max_{y_2}))$

In general, to decide if there is significant overlap, the ratio of the n-volume of the overlapping space to the minimum n-volume of the original space and the new space is calculated. This is a user-defined value (we use 0.8 in our experiments). If there is significant overlap, the algorithm moves the current boundaries towards the new boundaries as shown in Figure 5. The figure shows the distribution of the data points in the FID and the current pane represented by the blue and red points respectively. The bold rectangles represent the bin boundaries of the FID, and the dotted lines are the new bins boundaries found. The arrows indicate the directions of movement of the boundaries of the new bins. The movement is again calculated by using a weighted average method, with the weight determined by the number of days the original pattern was in the FID. For example, if the number of days the pattern was in the database is n and the perpendicular distance to the new hyperplane is x , then the actual distance the current hyperplane moves is x/n . We note here that each plane (in this case line segment) moves independently of each other. The number of days in the FID is then incremented by 1, and the support is approximated using Equation 6 by calculating the supports of the new bins. More specifically, we add the support of the current pane and subtract the support of the expired pane calculated from the population sample.

If the new boundaries of the current pane are significantly different from the original boundaries, the new itemsets with the new bins are stored in the temporary database. In the next panes, the algorithm checks if the data conforms to these new bins or if this behavior was just an anomaly. This procedure is similar for itemsets containing just categorical features.

4.3 Sampling Patterns and User Feedback

During the manufacturing process, the interaction between features are not expected to change drastically. We can exploit this predictability by using a sampling method to decide which itemset should be checked in each pane. Sampling helps reduce the search space for each run (and potentially display more interesting contrasts to the user). This is achieved by calculating a "sampling" score for each itemset in the database. We identified three factors that should contribute to this score.

- (1) Number of days in database
- (2) Change in support
- (3) User feedback

4.3.1 *Number of days in database.* In the manufacture of semi-conductors, we do not expect the interaction between the features to change drastically on a daily basis once the recipe for a chip is fixed. However, concept drift is possible due to aging of machines or inherent properties of the process. This is potentially interesting for our algorithm. Patterns that have been found consistently tend to be stable and show very little variability on the daily basis and hence it is less useful to calculate its interest measure in every pane. Patterns that are newly discovered (i.e. the patterns in the temporary database) tend to have more variability and need to be sampled at a higher rate. If n is the number of days since a pattern is found, and λ is the window size, the $score_{nd}$ is calculated by

$$score_{nd} = 1 - \frac{n}{\lambda} \quad (8)$$

This linear equation produces results ranging from 0 to 1. The score is inversely proportional to the number of days the pattern is present in the database.

4.3.2 Change in support. If a pattern is newly discovered, not found any more or has a high difference in support from what was found previously, the algorithm should sample this pattern at a higher rate. We calculate the score_s as

$$score_s = \frac{abs(s_{FID} - s_{current})}{max(s_{FID}, s_{current})} \quad (9)$$

This score also ranges from 0 to 1, with 1 meaning that the pattern is new or is not found in the current window. It is also proportional to the change in support.

4.3.3 User feedback. Pattern mining algorithms tend to find spurious patterns due to the bias of the interest measures or due to the domain knowledge of the user (some patterns may be obvious or inherently not interesting). To overcome this bias, the proposed algorithm lets the user up vote or down vote a pattern displayed. Doing so allows the algorithm to learn more important combinations of features over time. With the user voting information, the algorithm will sample these interesting combinations at a higher rate so as to be less likely to miss changes of these features. Let v_{max} be the maximum number of up votes a pattern can receive, v_{min} be the maximum number of down votes a pattern can receive, and v_{up} and v_{down} be the numbers of up and down votes a pattern actually receives from the users, respectively, then

$$score_u = \frac{v_{min} + (v_{up} - v_{down})}{v_{max} + v_{min}} \quad (10)$$

Different users may have different preferences on the types of patterns that are interesting. Hence, we cannot remove the pattern from the FID when a user down votes a pattern. Rather, the algorithm needs to keep track of the votes and not display such pattern again to the same user.

If \mathbf{w} and \mathbf{score} are the vectors representing the weight for each score and score calculated, then

$$score_{total} = \mathbf{w} \cdot \mathbf{score} \quad (11)$$

Once the score is calculated, we use a logistic function to calculate the probability ϕ of sampling the itemset

$$\phi = A + \frac{K - A}{1 + e^{score_{total} - mean(score)}} \quad (12)$$

where A and K are the lower and upper bound of the probability of sampling. The expected number of panes after which a pattern's interest measures are calculated is $1/\phi$

4.4 Finding Contrast Patterns and Population Sample

Given a sample, we wish to compare against the population. To this end, we explore the search space of the sample using OPUS search. At each node, the algorithm checks the FID to see if it is an itemset that has been previously found. If it is, and the itemset has only categorical values, then comparing them is straightforward. Let λ be the window size and σ be the average number of tuples present in each pane, then the total number of itemsets (needed for χ -squared calculation) is given by:

$$N = \lambda * \sigma \quad (13)$$

Furthermore, let s_c be the support of itemset c in the database, the number of times c is present in the database is:

$$N_c = s_c * N \quad (14)$$

After finding the counts of an itemset, the algorithm can proceed to check whether the itemset is large and significant as explained earlier in the background section. Notice here that we are only interested in itemsets that are more frequent in the sample than the population.

If the itemset is present in FID and contains at least one continuous feature, the algorithm discretizes the continuous features using the bin boundaries previously found and recorded in the FID for these same features. Once discretized, the algorithm can treat the features as categorical features, and can continue as explained above. If the itemset is not large and significant, this suggests that the distribution and relationship between features is not different in the sample.

A problem arises if the distribution or relationship between features change, or if the itemset is not frequent in the population but found in the sample (since that information is potentially lost). To overcome this, we keep a population sample \mathbf{d} that fits in memory. At each window pane, the algorithm randomly samples k instances of the current transactions. If the algorithm has not finished running for at least (λ) panes, k instances are added to the end of \mathbf{d} . Otherwise, when a new window pane arrives, the algorithm removes the first k instances and adds the current sample to the end. Therefore, the maximum number of tuples in \mathbf{d} is $k * \lambda$. Now, if an itemset which is frequent in the current window pane is not found in the FID, the algorithm can go to \mathbf{d} and calculate the approximate support. Again, if the itemset contains only categorical features, this is straightforward. If the itemset contains continuous features, the algorithm discretizes the samples itemset using SDAD-FI, and uses the bin boundaries to calculate the support of those bins from \mathbf{d} .

5 EXPERIMENTAL EVALUATION

Experimental Setup: For all the experiments, we keep *min pr* difference 0.1 (for merge step in SDAD-FI), $\lambda = 5$, $\alpha = 0.05$ and $\delta = 0.1$ (same as [1]). The datasets used to quantitatively compare the performance of the algorithms are shown in Table 1. Each dataset is divided into 5 random partitions. The parameters A and K are set to 0.2 and 0.8 respectively, which means that each itemset has a minimum of 0.2 and maximum of 0.8 probability to be tested in each pane. For user feedback, we randomly up vote or down vote an itemset with probability 0.1. The population sample is capped at 10% of each partition. A minimum support of 0.05 is used for experiments in Table 3.

5.1 Public Datasets

These are static datasets. By creating random partitions, we should find similar distributions of the features in each partition. We are not aware of any algorithm that works similarly to ours, or finds contrast patterns for mixed and streaming data. Hence, the goal of these experiments is to verify that the proposed approach is able to find contrast patterns comparable to the actual contrasts found if the entire static dataset were used. We compare our algorithm with STUCCO on the entire dataset (since it is a batch algorithm), by binning the continuous attributes using the bins found by SDAD-FI, and then running STUCCO on the discretized data.

Table 1: Public Datasets

Dataset	Sample	No. of instance Dataset/ Sample	No. of Features/ Contin- uous Features
Adult	Doctorate	48842/594	13/5
Spambase	Spam	4601/1813	57/57
Shuttle	High	54489/8903	9/9
Credit Card	Yes	29998/6635	24/23
Census Income	Above 50K	199523/12382	39/11

Table 2: Average Time in seconds to find Frequent Patterns in each Pane for Public Datasets

Dataset	Support=0.05	Support=0.1	Support =0.2	Support=0.3
Adult	17.36	16.49	10.37	10.69
Spambase	27.18	23.88	24.11	26.09
Shuttle	9.13	11.02	7.68	11.03
Credit Card	29.41	28.08	23.7	32.56
Census Income	232.25	189.77	154.98	157.08

Table 3: Quantitative Analysis of Contrast Sets for Public Datasets

Dataset	Time to find Contrast us- ing SDAD FI (seconds)	Time to find Contrast on entire dataset (seconds)	True Positive	False Positive	False Negat- ive
Adult	3.09	65.02	40	14	26
Spambase	121.59	952.87	27	2	2
Shuttle	4.25	62.33	9	0	0
Credit Card	45.25	482.74	8	0	0
Census Income	148.72	1654.85	228	0	24

The 5 partitions are fed into the algorithm sequentially and the FID is updated. Finally, the "User Sample" (shown in the table as sample of interest) is compared to the FID.

In Table 2, we report the average time it takes to find frequent patterns for each pane for different minimum supports. The results indicate that not only the minimum support affects the running time, but the number of items needed to be updated in the FID also matters. We notice that for some datasets, even increasing the minimum support increases the running time, which is counter intuitive. We can compare the first column (Support = 0.05) of this table with running SDAD-FI on the entire dataset in Table 3. The total running time is actually greater (average time multiplied by 5) because of the time require for updating and computation, however, we see that once the algorithm pre-computes the frequent itemsets, it can find contrast patterns quickly (see first 2 columns of Table 3). We also compare the difference between the contrasts found using the windowing procedure and the actual difference in support by showing the true positives, false positives and false negatives.

The results show that our approach finds contrasts comparable to contrasts found when using the entire dataset. It also shows that the time it takes to find the contrasts is much faster at run time than using the entire dataset.

5.2 Simulated Dataset

We simulated a dataset which is a simple but typical scenario in our application, semiconductor manufacturing. This dataset gives an overall idea of what we are trying to achieve. The dataset contains 4 features: the date, the oven id, temperature and a

**Figure 6: Simulated dataset temperature data distribution****Table 4: Frequent-1 Items found in Population by SDAD-FI for Simulated Streaming Datasets**

Frequent Item	Support
Response0	0.93
Response1	0.07
Temperature <= 150.08	0.5
Temperature > 150.08	0.5
Oven2	0.33
Oven1	0.33
Oven3	0.33

Response which indicates a pass or fail for a particular test. Each instance represents a chip and has a unique id. In the simulated data, we have 3 oven ids, and for each oven the temperature is controlled individually and follows a normal distribution. We simulate this for 10 batches, each having 600 instances, 200 for each oven. The probability distribution of the data is shown in

Table 5: Contrast Sets for Simulated Streaming Dataset

Serial Number	Contrast Set	Support for Population	Support for Sample
1	<i>Temperature</i> <= 150.08	0.5	0.31
2	<i>Temperature</i> > 150.08	0.5	0.69
3	<i>Temperature</i> <= 150.08	0.5	0
4	<i>Temperature</i> > 150.08	0.5	1
5	Oven3	0.33	0.58
6	Oven1	0.33	0.11
7	<i>Temperature</i> <= 150.08	0.5	0.45
8	<i>Temperature</i> > 150.08	0.5	0.55
9	Response 1	0.07	0.11
10	Response 0	0.93	0.89

Table 6: Contrast Sets for Semiconductor Manufacturing Streaming Dataset

Serial Number	Contrast Set	Support for Sample	Support for Population
1	<i>Tester</i> – KAWM	0.51	0.27
2	<i>Tester</i> – KAWM and Burn in Flag – 80	0.51	0.25
3	<i>Unit Location at CAM</i> – JVFT and <i>Entity at Deflux</i> – VAKM	0.55	0.33
4	<i>CAM Location</i> – 70	0.50	0.33
5	10.6435 <= CAM PEAK TEMP STD <= Inf	0.55	0.42
6	91.5456 <= CAM DIE TIME ABOVE AVG <= Inf and <i>PRODUCT</i> – YBDF	0.47	0.33

Figure 6. Ovens with IDs 1, 2 and 3 have mean temperatures 145, 150 and 155 respectively, and each has a standard deviation of 10. Instances that failed the test have Response = 1, while those that passed have Response = 0. The probability of failure follows a sigmoid distribution where the mean of the sigmoid is 165, as shown in Figure 6. The minimum probability of failure is 0.05, and maximum is 0.9. Hence the probability of failure for an instance is given by

$$\phi = 0.05 + \frac{0.9 - 0.05}{1 + e^{temperature-165}} \quad (15)$$

Using this scenario, we try to answer 3 questions: (1) We notice that the oven with *OvenID* = 1 yields a high number of chips that passed the test. What is the difference between the daily runs of *OvenID* = 1 and the population? (2) On similar grounds as (1) but globally, given a sample of chips that have failed the test, can we find meaningful differences? (3) If, on a particular day, we change the temperature, can we provide a timely feedback on how it is affecting the Response? We note here that to answer the questions above, a traditional contrast set algorithm needs to be run thrice on the entire data, which is time consuming since the data is large in a real world scenario. Table 4 shows the Frequent 1-Items found.

For the first scenario, we took a sample that contains only *OvenID* = 1. In Table 5, the first 2 contrasts are the ones that are significant at *level* = 1. As the contrasts show, *OvenID*=1 is operating at a lower temperature.

In the second scenario, looking at contrasts 3 to 6 we notice that the bad samples are baking at a higher temperature, and *Oven3* is failing much more than average. Looking at the contrasts, the analyst can recommend operating the oven at a lower temperature.

In the third scenario, we increased the mean of each oven by 2, keeping the standard deviation at 10 for a particular batch. When the algorithm runs daily, it finds that this batch has a higher

rate of failure than usual and can notify the analyst as soon as something goes wrong. From the contrast, we see again that the increase in temperature might be the cause of the high rate of failure.

All the contrasts shown find very simple contrasts but provide useful feedback to the analyst. Some of the frequent 2-itemsets found are *Temperature* <= 165.02 and *Response* = 1, *Temperature* > 165.02 and *Response* = 0. In a real life scenario, contrasts can be more complex, and bin boundaries can be fuzzy. The frequent itemset mining algorithm is capable of finding these rules [8]. In initial runs, the date feature was listed as strong contrasts. This was down voted by the user and soon the algorithm learned it was not an important feature, hence reducing its sample rate to the minimum.

5.3 Semiconductor Manufacturing Dataset

We conducted experiments on real production data of a certain product group. Note that the data was cleaned and modified to remove any proprietary information, although relationships between attributes remain unchanged. The goal of this experiment is to see whether one can quickly identify the root cause of why parts are failing a specific test. The dataset consists of 15 days worth of data. Each day consists of 3,000 to 20,000 instances of individual units, and each instance has 174 features. We built an FID, and we then contrasted the failing units to this database. The contrasts found are shown in Table 6.

The contrasts found shed some light on the potential causes of the problems. In Table 6 contrasts 1 and 2 show that most of the failed parts are routed through the same tester and had been flagged for burn in. Contrasts 3 and 4 show there was a higher likelihood a particular chip attach tool was used (*CAM Location*) and location of the unit in the tray (towards the back of the oven) was used. This may explain contrasts 4 and 5 which state that the chip attach reflow temperatures were on the higher end of the

spectrum. So in summary, this situation exhibits a marginality between the chip attach process, the presence of burn-in and potential marginality at that specific test equipment. With this information, engineers can make changes at these particular stages of the manufacturing line, which may in turn improve the process yield.

As mentioned earlier, we do not expect the distribution and relationships between the features to change a lot on daily basis, and hence the sampling procedure will help improve the running time. The first pane of the algorithm is run without any sampling. Since the FID is empty, all bin boundaries have to be calculated. The average time for the first run is 2456 seconds. After the first pane, the average time for a pane to update the FID with the sampling procedure explained earlier is 182 seconds, and without sampling it is 515 seconds. This improvement in the running time is significant, but the contrasts found do not differ significantly. We calculated the difference in supports between the population and sample for the top 25 contrasts in the experiment without sampling. The corresponding contrasts from the experiment with sampling were extracted. As expected, the continuous attribute bins were slightly shifted when compared between the 2 experiments. The absolute average difference of differences of supports for population and sample between the 2 experiments is 0.017 with a standard deviation of 0.041. Their distributions are not significantly different at $\alpha = 0.05$ according to the Wilcoxon signed rank test.

6 CONCLUSION

In this paper, we propose a method to find Contrast sets in mixed and streaming data by extending a well-studied approach. Using a binning strategy that automatically finds the size and number of bins for the continuous features, we are able to find meaningful contrasts even when higher order interactions occur. An updating strategy was discussed to keep patterns relevant. To find contrast patterns, we first find the frequent patterns for the population, which is then contrasted to the sample of interest. This algorithm does not need the group information in advance. The main motivation to find these types of contrast patterns in streaming data is to provide timely feedback to analyst during the semiconductor manufacturing process. The next step for our work is to improve the parallelization capacity for our algorithm to run on even larger datasets. To achieve this, we plan to distribute the work evenly among the cluster, based on the estimates we calculate from previous iterations.

ABSTRACT

As business decisions and strategies become more and more automated, real-time, and data-driven, enterprises need to create, manage and execute end-to-end analytics workflows that process increasing data volumes, from new heterogeneous data sources, on specialized processing engines. Workflows become more complex and time-consuming to design and execute, since they span a variety of systems and the amount of data being processed grows. Therefore, it becomes increasingly difficult to debug workflows in order to handle errors, as well as adjust the workflow design and calibrate task parameters for applications that perform exploratory data analysis. Towards this end, the workflow management system should provide *recalibration* methods i.e. methods to monitor and to influence workflow processing at runtime. We demonstrate novel manual and automatic recalibration techniques for analytics workflows, on real use cases and data from the telecommunication domain and web analytics, but also on synthetic use cases and data.

1 INTRODUCTION

The analysis of Big Data is a core and critical task in multifarious domains of science and industry. Such analysis needs to be performed on a range of data stores, both traditional and modern, on data sources that are heterogeneous in their schemas and formats, and on a diversity of query engines. Workflow execution can be extremely resource- and time-consuming. Thus, a system that enables such long-term analytics processes on Big Data needs to be able to show the progress of the execution and the intermediate results. This means that the user should be able to monitor which workflow tasks have been executed, their produced results, which tasks are currently executing, as well as data accessing and resource utilization based on input from the runtime machines or the visualization tool. Further, the system should allow the user to influence workflow processing. This means that the system should provide methods that enable the analytics expert to change a workflow by altering task parameters or infusing new tasks manually at runtime, or even to predefine automatic changes while she creates the workflow by providing alternative workflow branches. Such *recalibration* methods constitute a powerful functionality of a workflow management system, since they enable the gradual design of exploratory analytics workflows based on feedback from intermediate results, as well as efficient error handling of complex and long-running workflows.

In this demonstration we focus on the novel functionality of PAW¹ (Platform for Analytics Workflows) for workflow recalibration. PAW is a platform for the design, management, analysis,

optimization and execution of analytics workflows. The first version of PAW is presented in [1, 2] and includes the functionalities of workflow design and analysis in order to clarify execution semantics, single workflow optimization and multi-workflow optimization. In this demonstration we present for the first time the new functionality of PAW on workflow recalibration. It includes novel techniques for (a) manually changing a workflow at runtime and re-executing it avoiding repeated computations, called *recovery and monitoring points* technique (3.1); (b) automatically changing a workflow at runtime based on conditional structures *if-then-else* (3.2) and *goto* statements (3.3).

Several existing workflow management systems support conditional structures to some extent. Each of these systems implements these structures in different ways and with some limitations: Kepler [7] allows the design of scientific workflows and executes them efficiently using emerging Grid-based approaches to distributed computation. It offers a structure called *Comparator*, which takes two inputs and performs a numerical comparison. Taverna [8] is a well-known workflow management system that does not include conditional structures in the workflow model, but tries to achieve the *if* and *switch* functionality at a higher layer of workflow management. In Taverna such conditional behavior is implemented using processors *fail_if_false* and *fail_if_true* placed as first vertices of parallel branches. Depending of their input one of those processors fails, another satisfies and only satisfied branch continue execution. UNICORE is a grid middleware, aims to provide seamless, secure and intuitive access to distributed resources [9]. UNICORE has a programming environment to design and execute workflows. It supports three specific types of *if-then-else* conditions, *ReturnCode*, *FileTest* and *TimeTest*. The first performs a numerical comparison, the second checks if a file exists or is executable and the third checks the current time. Recalibration in PAW offers an abstract *if-then-else* task that can be customized for a variety of input data and complex conditions that involve the execution of fully-fledged procedures. Only Taverna offers the same level of flexibility in the design of conditions as PAW does. The rest of the considered systems are very limited in possibilities to construct a condition. Also, they don't provide *goto* statements.

A new system that offers interactive debugging framework for big data processing is BigDebug [10], which provides a set of debugging primitives: (a) simulated breakpoints and on-demand watchpoints that allow users to selectively examine intermediate data of computation; (b) data provenance capability, crash culprit determination, tracing and (c) capability to fix code at runtime by the user, avoiding a program re-run from scratch. Unlike PAW, BigDebug is a single-engine system and works only on top of Apache Spark. Moreover, debugging is only one of the several uses of the manual recalibration of PAW.

Overview of PAW. PAW implements a novel workflow model [4, 5]. A workflow W is a directed, acyclic graph (DAG) $G = (V, E)$. The vertices V represent data processing tasks T and the edges E represent the flow of data. Each task is a set of *inputs*, *outputs* and an *operator*. Data and operators need to be accompanied by a set

¹Source code and live demo can be found on
<https://github.com/project-asap/workflow>

Figure 1: ‘Peak Detection’ of mobile calls workflow

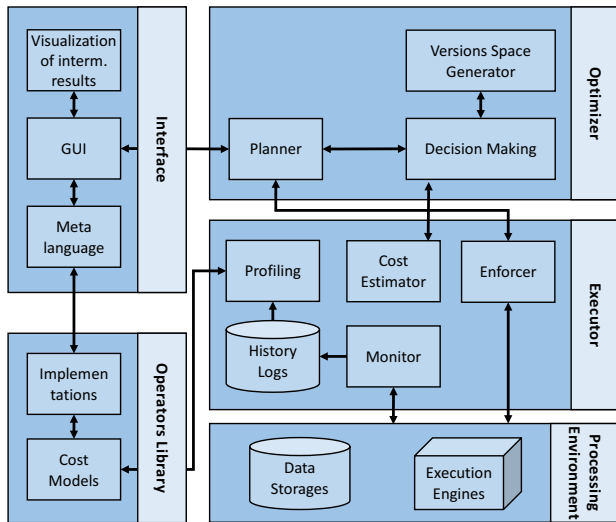

Figure 2: The architecture of PAW

of metadata, i.e., properties that describe them. Such properties include input data types and parameters of operators, the location of data objects or operator invocation scripts, data schemas, implementation details, engines etc. PAW is a part of the system ‘Adaptable Scalable Analytics Platform’ (ASAP) [3], but it can also stand as an independent tool for workflow management and optimization. Figure 2 depicts the architecture of PAW, as well as its interaction with the rest of ASAP. ASAP components include execution, visualization of results, online adaptation etc. PAW enables workflow design by users with various expertise, the automation of workflow analysis in order to clarify and specify execution semantics, single and multiple workflow optimization with respect to time efficiency, over a diverse collection of data stores and processing engines, monitoring of workflow execution and manual and automatic workflow recalibration.

2 MOTIVATING EXAMPLE

Figure 1 shows a real-world analytics workflow from a telecommunication company, which involves processing of the anonymised Call Data Records (CDR), collected in Rome for 2015 year and stored in HDFS, to populate a report on a dashboard. The report lists peaks in calls and their ratios to an averaged number of calls over a training period (one month). Peaks are defined by “differences from typical”. The workflow extracts the day of the week and the hour of the day from the timestamp of each call record (*extract_ts*). The task *calc_num* counts the number of calls at one-hour intervals. Then, two filters split the data to training

and test datasets. Further, the analysis is limited to specific geographical regions and, then, the number of calls in the training period is averaged over each mobile tower region, day in a week and hour in a day (*week_aggr*); this is the typical distribution of calls. Next, *calc_test_sum* and *calc_train_sum* produce the sum of calls in each day of the test and training datasets. Then, the test and training data are joined and the ratio of calls to the average number is produced. The *filter_peaks* finds ratios that are over a specific limit. These peaks is the sought information.

Initially, this workflow comprised three complex UDFs, (*DataFilter*, *DistrComp* and *PeakDet*), implemented in PySpark. Later on, for optimization needs [6], they were decomposed to smaller basic tasks, the operators of which have implementations in Spark and PostgreSQL. It is quite common that industrial workflows, like this one, are versioned and updated with time, resulting in a design that may not be optimal for the exploration procedure that the analytics expert needs to follow. In this example, the expert needs to explore the peaks one by one. This requires a complete restart of the workflow changing each time the search regions, a parameter of the *filter_region* tasks. This problem can be solved with recalibration methods that allow for the re-usage of the intermediate results produced by the tasks leading to the *filter_region* tasks, without re-executing the first. Also, recalibration methods would enable the expert to monitor the result of *filter_region*, visualized on a geographical map, so that she can observe faster call congestions and decide to change the search region. Furthermore, methods for automatic recalibration enable the expert to predefine conditions on intermediate results and, moreover, predefine decisions to be taken according to the outcome of condition evaluation.

3 WORKFLOW RECALIBRATION

We propose three techniques that perform recalibration in an online manner, i.e. during workflow processing.

Recovery and monitoring points. This technique offers to the user manual recalibration. It enables the user to monitor intermediate results, make workflow changes and if the changes are in the already executed workflow part, then re-execute only the changed part, avoiding to repeat computations; if changes affect only the non-executed part then workflow changes are applied and execution continues.

Conditional points. This automatic technique allows the execution of alternative predefined workflow branches.

Goto points. This automatic technique conditionally changes an executed workflow part to a predefined alternative and re-executes it.

Figure 3: ‘Peak Detection’ workflow augmented with recovery and monitoring points

Figure 4: Monitoring intermediate results of ‘Peak Detection’ in PAW

3.1 Recovery and monitoring points

This recalibration technique allows the user to change a workflow during its execution and avoids to unnecessarily repeat computations in the already executed workflow part. It involves the employment of two novel types of tasks: recovery and monitoring points. A *recovery point* rp_T is a task that stores the result of task T . A *monitoring point* mp_T is a task that invokes the visualization of the result of task T or part of it. We use the phrase *intermediate result* to refer to the result of a task T that has been executed, while the whole workflow execution is not yet finished. The visualization of intermediate results assists the user in making a recalibration decision.

Recalibration using this technique is performed in four steps: (1) the user augments a workflow with recovery and monitoring points and starts the workflow execution; (2) when the execution reaches a recovery point the system stores the intermediate results of the preceding task, required for a possible re-execution of the workflow part following this recovery point; (3) when the execution reaches a monitoring point the user observes intermediate results of the preceding task; the workflow keeps executing after the monitoring point, while the user observes the intermediate results; (4) the user changes the workflow part following a recovery point and performs a re-execution of the workflow from this recovery point and on.

When the user changes the workflow and re-executes it, PAW determines which intermediate results are required to re-execute the changed workflow part that follows a specific recovery point (or points). It prepares this workflow part as a new materialized workflow with these intermediate results as input datasets and runs it. The execution of the previous (original) workflow is aborted.

Figure 3 displays the workflow from the motivating example augmented with recovery and monitoring points. The user observes the result of *filter_regions* at *monitoring points*, decides

to change the parameters of *filter_regions* and re-executes the workflow from the *recovery points*. So the most time-consuming part of *DataFilter* is not re-executed.

Figure 4 displays a ‘Peak Detection’ workflow in the interface of PAW. Green and yellow tasks are executed and currently executing, respectively. Using the geographical map on the bottom the user monitors intermediate results at the monitoring point marked with a blue stroke.

3.1.1 Implementations of points. Monitoring points invoke the visualization of the result of the preceding task. PAW includes monitoring points for specific operators, such as implementations of *k-means*, for which the result is visualized as a map of centroids or the histogram of cluster sizes. It also provides three basic monitoring operators, for the visualization of: geographical, numerical and categorical data. PAW includes recovery points for HDFS, Elasticsearch and PostgreSQL and operator-specific monitoring points for *k-means* and *tf-idf*.

3.1.2 Partial execution. We propose two improvements of the *recovery and monitoring points* technique:

Execution of a task until a deadline or a milestone is reached. The preceding task of a monitoring point is executed for a predefined time (deadline) or until it has processed a predefined amount of the input data (milestone). The partial intermediate result of the task is received by the following monitoring point, which invokes its visualization. This partial intermediate result is observed by the user, who decides on recalibration faster.

Execution on a part of a dataset. Data processing between recovery and monitoring points is made on a part of the input dataset. This enables the user to observe intermediate results on a part of the input data, and take the recalibration decision faster.

There is no general method for preparing operators so that they produce partial intermediate results. However, in some cases we can have a general methodology. For example, we can break up a query into multiple queries by dividing the input data in chunks, and then combine the results after the execution of all statements. PAW has several SQL query operators, which can be split up in this way.

```
SELECT * FROM db
WHERE field BETWEEN 1 AND 10000;
SELECT * FROM db
WHERE field BETWEEN 10000 AND 20000;
...
```

3.2 Conditional points

PAW includes a new type of task that realizes the conditional structure of the form *if-then-else*. The latter allows the design of a workflow with several alternative workflow parts. Depending on the intermediate results of the task preceding the *if-then-else* task,

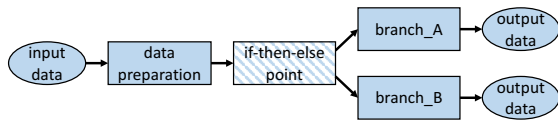

Figure 5: A workflow with an *if-then-else* point

Figure 6: A workflow recalibrated with a *goto* point

a workflow branch is chosen for execution, over another one. These workflow branches are not yet executed. Figure 5 displays a workflow that has been augmented with one *if-then-else* point and two following workflow branches. The *if-then-else* task has two outputs; the boolean condition evaluates to true or false, depending on which PAW executes one of two branches.

The operator of the *if-then-else* point is implemented for any particular data. For example, for *tf-idf* PAW has an *if-then-else* task that evaluates if the weight of some word is above a certain value. Additional conditional points can be added through the interface of PAW.

3.3 Goto points

The workflow is augmented with two tasks: *goto label* and *goto condition* points, and an alternative workflow part related to the *goto label* point (Fig. 6). When the workflow execution reaches the *goto condition* point and if this task triggers ‘goto’ to *goto label*, then it re-executes the workflow from that point choosing for execution the alternative workflow part. Therefore, this technique is a combination of the *recovery and monitoring points* and *conditional* techniques.

The *goto condition* task has two outputs and a boolean condition evaluating to true or false, depending on which PAW continues execution or jumps to the *goto label* alternative workflow branch. The implementation of *goto condition* is similar to the *if-then-else* point.

4 DEMONSTRATION

In the following, we describe the proposed demonstration.

System setup. PAW is demonstrated on a cluster, with the following configuration: The cluster consists of 4 server-grade physical nodes. Each one of those is equipped with a 3rd generation i5 CPU (@ 2.90 GHz) and 16GB of physical memory and an array of two HDDs on RAID-0. The operating system is Debian 6 (squeeze) Linux. For the time being, four software platforms are running: Hadoop (CDH 4.6.0), Spark (1.4.1), Elasticsearch (5.1) and Weka (3.6.13).

Workloads. The demonstration uses synthetic and real workflows on real data. The real workflows and data come from the two use cases of ASAP [3] and belong to the domains of telecommunications and web analytics. One of the telecommunication workflows is described as a motivating example (Section 2). The web analytics use case involves anonymization of web content (WARC files) stored in Elasticsearch. The workflows are implemented in Spark and run over varying data set sizes ranging from 1 million to 4 billion rows. There are two types of workflows: one models entity recognition/disambiguation and k-means, and

another models continuous processing of incoming data, e.g., subscription/notification at scale.

Demonstration scenarios. The demonstration focuses on the recalibration functionality of PAW. It includes four types of scenarios that aim to show each a distinct view of the recalibration benefits and create discussion on the potential of recalibration of analytics workflows. The demonstration is interactive with the audience. The participants are invited to experience all functionalities of PAW, create workflows from scratch or change existing ones, watch the processing of the workflow, as well as review the internals of the platform, e.g. internal workflow representation. Even more, the participants are guided to play with the recalibration of workflows, by adding recovery and monitoring points, *goto* and *if-then-else* points, and change the workflow while monitoring intermediate results in GUI of PAW.

Scenarios A. These demonstrate the recovery and monitoring points technique. Specifically, they show real necessities to change workflows during execution. We show real workflows which need infusion of new tasks or alteration of task parameters during the execution.

Scenarios B. These also demonstrate the recovery and monitoring points technique. Specifically, they show how the user can design a workflow in a gradual and modular manner, while he is testing and debugging already created parts by monitoring intermediate results. We show how this workflow design process benefits exploratory data analysis.

Scenarios C. These demonstrate the *conditional* technique for workflows with a natural conditional branching, for which data analysis based on some conditions follows different paths, and the selection between these alternative paths should be made at runtime.

Scenarios D. These demonstrate the *goto* technique using workflows that benefit from the *goto* point in order to find anomalies in data, narrow or refocus the search or analysis, as well as meet deadlines and milestones of analysis.

ABSTRACT

Researchers and scientists have been using crowdsourcing platforms to collect labeled training data in recent years. The process is cost-effective and scalable, but research has shown that the quality of truth inference is unstable due to worker bias, work variance, and task difficulty. In this demonstration, we present a hybrid system, named IDLE (Integrated Data Labeling Engine), that brings together a well-trained troop of domain experts and the multitudes of a crowdsourcing platform to collect high-quality training data for industry-level classification engines. We show how to acquire high quality labeled data through quality control strategies that dynamically and cost-effectively leverage the strengths of both domain experts and crowdsourcing.

1 INTRODUCTION

Hand-annotated training data, such as ImageNet ¹[2], have been the basis of many machine learning research. In recent years, crowdsourcing has become a common practice for generating training data [3], empowering researchers to outsource their tedious and labor-intensive labeling tasks to workers of crowdsourcing platforms. Crowdsourcing platforms provide large and inexpensive workforce for better cost control and scalability. However, the unstable quality of work produced by crowdsourcing platform workers is the main concern for crowdsourcing adopters.

Recent research by Zheng et al. [15] shows that the best truth inference algorithm is very domain-specific, and no single algorithm outperforms others in most scenarios. Sometimes an intuitive approach like an Expectation-Maximization algorithm could be a practical solution. In the literature, research advances focus on handling task difficulty [7, 13], worker bias [9], and worker variance [10, 12]. Specifically, *task difficulty* describes the degree of ambiguity of a question for which an annotated answer is sought; whereas *worker bias* and *variance* model the quality of

¹<http://www.image-net.org/>

workers – describing how likely a worker gives a wrong answer, assuming all tasks have equal difficulty.

The ability to collect high-quality and stable training data (i.e. the inferred truth) is essential for powering many supervised algorithms. These algorithms are often the foundation for modern business solutions, such as search engine rankings [6], image recognition [2, 11, 14], news categorization [8], and so on. Even though research [15] has unveiled the challenges of crowdsourcing labeling, it is undeniable that cost-effectiveness and scalability make crowdsourcing an attractive approach to generate training data.

In this study, we present a practical end-to-end multilevel solution based on a hybrid strategy. On the first level, we collect cost-effective truth inference from crowdsourcing workers whose answers have potentially high bias and variance.

On another level, we train a group of domain experts who are expected to perform labeling tasks with low worker bias and variance due to the training and financial incentives they receive. Our trained experts are intimately familiar with our product category taxonomy as well as the guidelines for assigning the most appropriate product category label to any given product item. They are instructed to mark high-difficulty tasks as “*unsolvable*” to circumvent ambiguous cases.

We propose IDLE as a system to facilitate the automated collaboration between our well-trained domain experts and the crowdsourcing workers to deliver high-quality hand-annotated training data. The IDLE framework streamlines the workflow for generating high quality training data by automating data filtration (by crowdsourcing) and data relabeling (by in house domain experts). It also provides an integrated environment for managing training data generation tasks as well as for assessing quality of classification results generated by our product classification engine as described in details in section 2.3.

2 SYSTEM FRAMEWORK

Figure 1 shows the architecture of our system. There are 4 key components in our framework: (1) **Multilevel Worker Platform**: a system that assigns tasks to domain experts and various crowdsourcing platforms through **Adapters**; it also performs **Worker Quality Assessment** and **Answer Aggregation**. (2) **Sampling Strategy**: with a unified user interface, job requester

Figure 1: IDLE system framework

can choose among various sampling strategies. (3) **Job Processing**: job requester can launch jobs of various types. (4) **Data Reporter**: a dashboard showing the aggregated results from crowdsourcing and the improvement of the machine learning model.

2.1 Multilevel Worker Platform

With a unified interface, the job requester can submit a job through **Adapters** to various crowdsourcing platforms, such as MTurk² and Crowdfower³. Furthermore, the job requester can assign difficult labeling jobs to domain experts who sign into their **IDLE** account to label data. We also design a uniform **Function** interface for common features, such as **Worker Exclusion** and **Answer Aggregation**, across various crowdsourcing platforms.

Adapter: Using MTurk API⁴ as a reference, we design the interface through which job requester can (1) launch a job, (2) stop a job, and (3) retrieve results. Adapters allow us to easily integrate with different crowdsourcing platforms without making significant changes to the user experience or the rest of the IDLE platform.

Answer Aggregation: Since answers returned by crowdsourcing workers are not always consistent and worker’s quality varies (for example, master vs. non-master workers in MTurk), we have the challenge of inferring ground truth from the returned answers. To tackle the answer aggregation challenge, we implement three algorithms : **Majority Voting**[1], **Weighted Majority Voting**[4], and **Bayesian Voting**[5]. Through the provided interface, developers of IDLE platform can easily implement customized answer aggregation algorithms. Moreover, job requester can specify rules in the form of [#answer, #yes] for determining the final answer. The rule template is interpreted as seeking #yes/#answer level of consensus in total #answer number of answers. More elaborate answer aggregation strategies may be expressed through a sequence of rules. For instance, rules [3, 3] followed by [4, 3] together instruct the system to first seek unanimous consensus among 3 answers ([3, 3]). For questions whose answers fail to meet the first rule, the system needs to try again by soliciting an additional answer (#answer= 3 + 1) hoping to reach the specified 3/4 consensus.

²<https://www.mturk.com/>

³<https://www.crowdfower.com>

⁴<https://aws.amazon.com/documentation/mturk/>

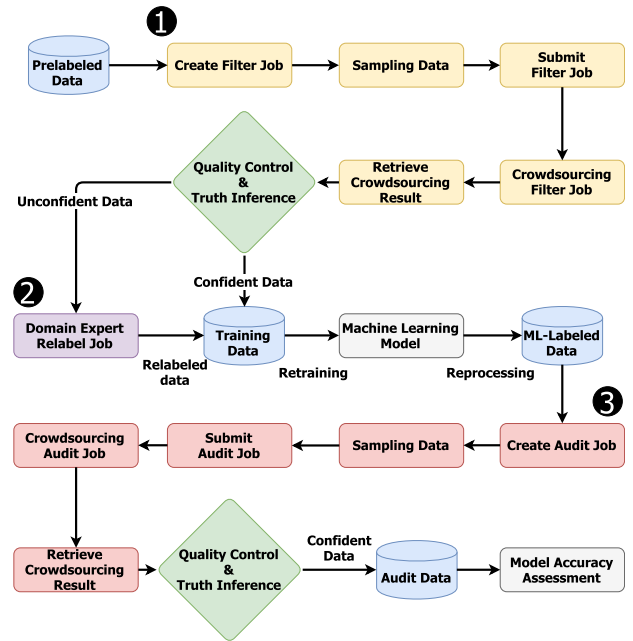

Figure 2: Control Flow

Worker Quality Assessment: Worker’s quality varies widely on crowdsourcing platforms. The fact that this quality is unknown to us in advance makes it even more important to assess worker’s quality. In IDLE, we randomly select questions from a curated pool of questions with ground truth answers (called *golden tasks*) to estimate worker’s quality. We apply two strategies: (1) **Qualification Test**: BEFORE performing the job, workers must first pass the *golden tasks*; (2) **Hidden Test**: mixing the *golden tasks* with the regular job questions, and we assess worker’s quality based on the *golden tasks* AFTER the job is completed. In our platform, job requester may use either one or both strategies to estimate worker’s quality.

2.2 Sampling Strategy Interface

There are many statistical sampling techniques. In IDLE, we design the general interface for developers to implement the required sampling strategies. The goal is for job requester to obtain sampling data from a diverse data set. We incorporate two hierarchical sampling strategies for IDLE in this version: (1) data clustering followed by stratified sampling; (2) topic modeling followed by stratified sampling.

2.3 Job Processing

As illustrated in Figure 2, there are three types of jobs in IDLE: Filter jobs, Relabel jobs, and Audit jobs.

Filter Job: A small set of data are sampled from pre-labeled data and sent to crowdsourcing platform for confirming their labels. Questions of a filter job are presented either as yes/no questions (e.g. Does the given label match this datum?) or multiple choice questions (e.g. Which of the following labels best matches this datum?). *Golden tasks* questions used for excluding poor-quality workers are also included in the filter job. After the workers submit their answers, the results are collected through the answer aggregation techniques described above in section 2.1. The results that are identified with high confidence level by our answer aggregation algorithm become new training data for the machine

learning model. The remaining (filtered-out) data are treated as mislabeled data and become input data for relabel jobs which are handled by domain experts as described in section 1. We expect data that are trivial for crowdsourcing workers can quickly pass through and data that are difficult to label are filtered out, hence, the name 'Filter' job. The cost of domain experts is much higher than that of crowdsourcing workers, which is why it is more cost-effective to have crowdsourcing workforce perform filter jobs on large number of trivial questions first and leave a small number of more challenging relabel jobs to domain experts.

Relabel Job: As mentioned above, mislabeled data are automatically collected and made available in IDLE framework to domain experts for relabeling. These domain experts are trained to assign correct labels to the provided data. Thus, data relabeled by domain experts do not require quality control or truth inference measures before they become training data for the machine learning model. With that said, there might be some data that even domain experts cannot label, thus are regarded as rejected data and recorded for further analysis.

Audit Job: After the filter job and the relabel job are done, all the sampled data are either identified as new training data for the machine learning model or as rejected data for analysis. After retraining the machine learning model in our product classification engine with the new training data, the model reprocesses data and updates the product category labels. Up to this point, all the efforts for enhancing the performance of the machine learning model are completed. We then assess the accuracy of this retrained model with an audit job. Similar to a filter job, a small set of data are sampled and sent to crowdsourcing platform for identifying correctly labeled data. We then apply our answer aggregation algorithm to identify data with high confidence level and calculate model accuracy while the mislabeled ones are simply discarded.

2.4 Data Reporter

To maximize the effectiveness of crowdsourcing and minimize the costs, there are certain questions that analysts would be curious about: for example, what is the ratio of filter job questions that need to be handled by a relabel job? The data reporter is a data visualization dashboard for administrators and analysts to evaluate the effectiveness of crowdsourcing and the performance of the machine learning algorithms. There are two parts of data reporter: (1) **Crowdsourcing Report** (2) **Machine Learning Model Report**.

Crowdsourcing Report: The purpose of crowdsourcing report is to evaluate the effectiveness and the efficiency of crowdsourcing. Therefore, it is designed to provide insights, such as the answer distribution and processing time. The crowdsourcing report includes the stats and results of crowdsourcing jobs. For filter jobs and audit jobs, the stats would include the ratio of YES vs. NO besides job completion time. For relabel jobs, the report would display the ratio of relabeled rate and job completion time. To estimate the overall performance of crowdsourcing for each job, the dashboard would also show the ratio of mislabeled data vs. data with high confidence level in addition to the total processing time.

Machine Learning report: The machine learning report is used to track the rate of improvement for the machine learning model. Thus, the report shows not only the history of accuracy for the model but also the ratio of data processed through crowdsourcing.

Algorithm 1 Adaptive Task Assignment

Require: Label confidence scores of prelabeled data $PC = (pc_1, pc_2, \dots, pc_n)$, task confidence threshold θ , worker set \mathcal{W} , budget B

Ensure: $(|W_1|, \dots, |W_n|)$

- 1: $(W_1, \dots, W_n) = (\emptyset, \emptyset, \dots, \emptyset)$
- 2: $PC_{order} = Order(PC)$ ▷ reverse sort PC
- 3: **for all** $pc_i \in PC_{order}$ **do**
- 4: $(W_i^*, C_i^*) = \underset{Conf(pc_i, W_i) \geq \theta, W_i \in \mathcal{W}}{\arg \min} Cost(W_i)$
- 5: $B = B - C_i^*$
- 6: **if** $B \leq 0$ **then**
- 7: **break;**
- 8: **return** $(|W_1|, \dots, |W_n|)$

3 ADAPTIVE TASK ASSIGNMENT (ATA) ALGORITHM

To best utilize available resources (such as a given budget), we further study the mechanism to adaptively assign the number of workers for each crowdsourcing task. In practice, the equal assignment of workers per task is not the most effective approach to achieve satisfactory quality when dispatching large-scale crowdsourcing tasks. Advances in machine learning research provide powerful labeling capabilities in predicting the label for each task along with a confidence score. Keeping the confidence granularity and the importance of a task in mind, we adjust the number of workers for each task in pursuit of overall optimization. Therefore, we propose **Adaptive Task Assignment Algorithm** to optimize the crowdsourcing resource utilization.

In Algorithm 1, we outline the steps to determine the number of workers for each task. Each crowdsourcing task consists of one single product item with category label predicted by our product classification engine. Initially, we are given prelabeled data and *label confidence score* pc_i of each task (provided by our supervised learning algorithms). *Label confidence score* ranges from 0 to 1. Next, we assign workers to crowdsourcing tasks that are reverse ordered by their label confidence scores. Here we introduce a threshold called θ , to ensure that the task confidence score of each task (calculated by the $Conf(pc, W)$ function described below) exceeds θ eventually. In addition, we use $Cost$ function to represent the cost for a worker set in search for the optimal worker set W_i^* , where the total cost C_i^* of the worker set is minimal for a task's confidence score to exceed θ . When the sum of cost C_i^* is equal to budget B , the algorithm terminates and returns the optimal number of workers $|W_i^*|$ to assign to each task.

The task confidence is calculated based on the given *label confidence* of prelabeled data and the quality of the assigned worker.

$$Conf(pc, W) = \max_{a \in \{Yes, No\}} Conf_a(pc, W)$$

We use label confidence score of prelabeled data pc_i and worker's quality q^w to calculate the Bayesian probability [5]. Worker's quality $q^w \in [0, 1]$ is the probability that the worker answers the correct label. As an example, assuming the supervised learning algorithm provides the prelabeled data with label confidence score of 0.45; the confidence threshold $\theta = 0.75$, and we have four workers with quality scores 0.5, 0.8, 0.6 and 0.4 respectively (assessed through golden tasks described above): Initially, we

pick the first two workers in the first iteration, and their answers are *No* (rejecting the label assigned by machine learning) and *Yes* (confirming the label assigned by machine learning). We can calculate the task confidence score as the following:

$$Conf_{Yes} \propto 0.45 \cdot (1 - 0.5) \cdot 0.8 = 0.18$$

$$Conf_{No} \propto (1 - 0.45) \cdot 0.5 \cdot (1 - 0.8) = 0.055,$$

which lead to

$$Conf_{Yes} = \frac{0.18}{0.18 + 0.055} = 0.76$$

$$Conf_{No} = \frac{0.055}{0.18 + 0.055} = 0.24$$

Since $Conf(pc_i, \{w_1, w_2\}) = 0.76$ exceeds $\theta = 0.75$, it is not necessary to assign additional workers to this task. In other words, the ATA algorithm can confidently confirm the machine-assigned label (*i.e.*, concluding the answer *Yes*) based on answers from merely two crowdsourcing workers.

4 DEMONSTRATION

Our system implementation of IDLE is based on Flask (a Python web framework) and ReactJS. We use distributed task queue Celery to handle asynchronous tasks, such as data sampling and crowdsourcing result retrieval. At the time of writing, IDLE is undergoing beta testing at Slice Technologies, and we are actively improving the system. The screenshots for the following demonstrations can be found in the GitHub repo⁵ of IDLE:

Data Ingestion: Job requester first selects pre-labeled data to ingest into IDLE by picking a category from a data set, uploading a file, or querying the database with SQL commands. Afterwards, job requester chooses a sampling strategy and sample count for filter job creation.

Crowdsourcing Job Configuration: After sampled pre-labeled data are ingested, job requester configures parameters of a crowdsourcing task, *e.g.* reward per assignment and number of assignments per HIT (Human Intelligence Task, a term to denote a single crowdsourcing task on Amazon Mechanical Turk platform). To estimate worker's quality, the system can also be configured to automatically include golden tasks (quality control questions) in the job.

Crowdsourcing Job Creation: Configurations of a crowdsourcing job are reviewed and confirmed prior to job creation. After publishing a job to crowdsourcing platform, IDLE automatically performs answer aggregation.

Stats Reporting: Job status and other job-related information are displayed on the main IDLE dashboard. History of the machine learning model's performance is also available for evaluation purposes.

5 CONCLUSIONS

In this study, we present IDLE, an integrated data labeling platform consisting of two main features: quality assessment and answer aggregation. The platform incorporates the adaptive task assignment algorithm, an algorithm that enables us to provide a cost-effective process for training data generation. This streamlined process alleviates the impact of highly difficult tasks as well as of crowdsourcing's worker bias and worker variance. As a result, IDLE system empowers researchers to effectively and efficiently collect high-quality training data through collaboration

between in-house domain experts and external crowdsourcing workers in an automated and integrated manner. IDLE provides us an integrated platform for generating large amount of training data with higher quality, faster speed, and optimal cost.

ABSTRACT

Every year, the number of scientific publications increases, adding complexity to the networks of collaborations, citations, and topics, in which papers are embedded. Analyzing these networks with efficient tools is important to help researchers identify relevant works and understand scientific impact. However, available tools face several limitations, indicating that there is still room for improvement. We present HERMES, a prototype for exploring large and heterogeneous scholarly networks. HERMES allows users to seamlessly navigate diverse types of networks within a single graph, spanning hundreds of millions of nodes and relationships. Our prototype achieves reasonable responsiveness on commodity hardware through: *a*) comprehensive indexing, *b*) a careful coupling of a graph database and a search engine, and *c*) incremental processing of temporal queries. In this demonstration, we explain the techniques we adopt and illustrate how to use HERMES for exploring the MICROSOFT ACADEMIC GRAPH.

1 INTRODUCTION

The number of scientific publications increases every week, creating a large set of data about authors, citations, and collaborations. As a result, it becomes more and more challenging to determine which publications are relevant for a specific research goal [16]. In fact, new terms and fields, such as *big scholarly data* [22] and *science of science* [24], are emerging to cover data management challenges and novel analysis questions, which arise from scholarly information growth.

Scholarly network analysis (SNA): The traditional metrics of science (e.g., the *H-index*), that rely on network-unaware statistics, have been questioned by scholars [23], making a case for improving the analysis of scholarly networks by complementing such metrics with content & network-based analysis.

Types of scholarly networks: At least 7 types of networks are usually considered for SNA [23]; coauthorship/collaboration, citations, co-citations, bibliographical coupling, topics, co-words, and heterogeneous networks.

SNA and heterogeneous networks: Restrictive choices of network type and aggregation entity can limit the generalizability of SNA. To avoid this, researchers recommend to employ heterogeneous networks, and methods capable of extracting value from

Figure 1: Indexing approaches in HERMES.

these networks [23]. One of such methods is FUTURERANK [15], an approach for relevance ranking based on combining HITS, over a collaboration graph, with PageRank, over a citation graph.

Data management for SNA: SNA involves studies at macro (global), meso (community), and micro (individual)-levels of a network. Considering the scale of networks, in addition to the need for managing heterogeneity of entities and analysis (e.g. content & statistical analysis), efficient tool support for SNA poses several data management challenges. Among them, the foremost could reasonably be resource management: to provision for ad-hoc SNA within reasonable response times, while enabling queries across different network scales and representations. Other challenges include data cleaning, provenance, management of analysis results, and integration with external sources.

Existing tools for large scale SNA: Several scientific digital libraries and search engines exist that index large amounts of publications [12], however their services often fall short in several aspects, including consistency, available metrics, and possibilities for ad-hoc SNA [11]. Regarding the latter, for example, ARNET-MINER¹ [20] internally utilizes several kinds of network analysis, however only local exploration of ego networks is currently offered to its Web users. Among tools supporting SNA, CITESPACE [4], PAJEK [2], GEPHI [1], IGRAPH, [6] and NETWORKX [10] are some of the most popular.

Graph databases and SNA: Although RDF technology has been widely researched for semantic publishing [3], to date there is little research in specialized graph database technologies for SNA. Within our work we consider this research gap.

In this demo paper we describe the first version of HERMES, our proposed tool for SNA based on graph technologies. The core technical insight behind our work at this stage is in exploring opportunities for close search engine/graph database coupling in SNA tasks.

Distribution of this paper is permitted under the terms of the Creative Commons license CC-by-nc-nd 4.0.

With our tool we seek to enable users to seamlessly interact with large scale heterogeneous networks, performing ad-hoc SNA at different granularities, either through our APIs, or through native graph/search-engine query languages.

Overall, we hope to encourage the audience to use our tool for multiple purposes. We aim to: 1) help the audience in identifying relevant publications and performing SNA tasks; 2) receive feedback to improve HERMES; 3) introduce to the audience the key indexing solutions that improve the performance of HERMES; and 4) employ HERMES for user studies to investigate what could constitute representative SNA workloads. Based on our work, we intend to publish corresponding anonymous datasets of usage patterns as open-source artifacts—thus providing data for workload characterization to the research community. Furthermore, our tool will be freely available.

2 HERMES

In this section we describe the current architecture of our tool, and we present two techniques we currently explore in HERMES for improving its data access.

2.1 Architecture

For indexing and primary storage, HERMES relies on a search engine, i.e., ELASTICSEARCH, and a database, i.e., CASSANDRA. These two components are integrated through a property graph database, JANUSGRAPH²—which can also be configured to other back-end indexes and storages. JANUSGRAPH uses the TINKERPOP³ framework, and the corresponding GREMLIN query language. Data access in HERMES is provided via a web-interface with data management supported by GREMLIN and ELASTICSEARCH servers.

JANUSGRAPH provides three predefined types of indexes:

- *Composites* are traditional indexes tuned for point-queries. They rely on the primary storage. They cover one or multiple keys of either vertexes or edges of the stored graph.
- *Mixed* indexes are based on the search engine. They enable inexact querying, and relevance boosting.
- *Vertex-centric* indexes are supported by the primary storage. They are included in the same storage space of a vertex. Instead of indexing all entries in the database (global)—as the former two indexes—they only index the set of edges attached to a vertex (local). This allows to traverse faster through edges while filtering on labels and properties.

Apart from these predefined indexes, users of property graph databases can also use the "graph itself as an index". This is a straight-forward approach, which we, for lack of a better term, call GRAIN (graph as an index) [8]. In GRAIN meta-vertexes are added to the modeled data, acting as roots and nodes of a search tree, such that they lead within limited hops to a set of expected entities. A practical enhancement is to denormalize properties of the target vertexes unto the linking edges, such that filtering can be applied on the edges without visiting any vertex. In our system, the GRAIN approach is additionally adopted by using a set of meta-vertexes with temporal expiration. They serve as a cache for previous query results.

Within HERMES, we adopt a comprehensive indexing strategy that exploits all these opportunities. In Figure 1, we show an overview. We remark that the numbering corresponds only to the order in which we introduced each index.

  has("createdAt", P.lte(year0)).count().next();

titanGraph.V().
  hasLabel("journal").
  has("createdAt", year0+1).count().next();
```

2.2 Incremental Processing for Temporal Queries

Analyzing the evolution of publication networks can yield interesting findings. For example, studies on the MICROSOFT ACADEMIC GRAPH [18] have found the number of publications per year to be following an exponential growth for the last century—doubling every 12 years, with the top 1% of publications continuously accounting for around a quarter of citations each year [7]. Similar analyses with more localized perspectives can have practical value for researchers. For instance, they could help to assess the impact of given conferences over time or to identify high impact research topics.

Several works consider the formalization and evaluation of temporal graph queries—both, in graph databases [17], and in processing engines [13, 14]. Building on studies in this area [9], we design our temporal queries in HERMES by creating a type of meta-vertex, which we call *logger vertexes*. The set of edges in such vertexes provide a relative time-line for when items appear in the world represented by a graph. Analyzing the sequence of edges in a logger vertex allows reconstructing a graph from a certain point in time to another. Through this, it is possible to implement incremental computation of temporal data over a graph model that accumulates several snapshots.

We achieve incremental computation in HERMES by hand-tuned query rewriting. In Listing 1, we provide an example of a GREMLIN query for identifying the number of journals on a year-by-year basis throughout a specified period. Instead of adding up the number of items for all years within the interval, we only compute the existing journals for the first year. Then, we keep a rolling total, based on the number of journals created or retired in each successive year.

Recently, authors have considered automated rewriting of multi-snapshot queries for co-scheduling tasks by their common steps—in a style similar to SIMD processing [21]. The authors call this approach *Single Algorithm Multiple Snapshots*. Unlike their work, we do not store separate snapshots, and we do not include automated rewrites in our tool.

In other study, groundwork for *incremental view maintenance* on property graph databases has been proposed, over a formalization of OpenCypher [19]. In contrast, the rewrites for incremental processing illustrated with our current prototype are hand-tuned, and require further standardization.

2.3 Query Rewrites Across Graph and Search Engine Representations

Similar to other graph databases, such as NEO4J⁴, JANUSGRAPH can integrate a search engine to support full-text queries. This provides a set of search engine functionalities, which are either

⁴<https://neo4j.com/developer/elastic-search/>

Listing 2: Rewrite of degree centrality (DC) calculation for ELASTICSEARCH.

```
TermsBuilder termsBuilder = AggregationBuilders.terms(aggregationName).
    field("idOfTargetVertex").size(numberOfVertices);

XContentBuilder contentBuilder;
contentBuilder = JsonXContent.contentBuilder().startObject();
termsBuilder.toXContent(contentBuilder, ToXContent.EMPTY_PARAMS);
contentBuilder.endObject();

SearchRequestBuilder searchRequest= esClient.prepareSearch("index").
    setTypes("edges").
    setQuery(QueryBuilders.termQuery("edgeLabel", "label")).
    setAggregations(contentBuilder);
response = searchRequest.execute().actionGet();
```

offered through the graph API (e.g., launching so-called *index-Queries*), or directly through the search engine APIs. After verifying the potential of *external* access in previous work [8], we seek to leverage this concept in HERMES to improve its functionality by rewriting queries for the search engine APIs.

To make the case for such rewriting, we consider an example degree centrality (DC) calculation in GREMLIN that has to be rewritten for the search engine. The DC of vertexes is a measure to understand the actors of a network. It can be defined as the number of edges (either incoming or outgoing) connected to vertexes. The in-DC of a given vertex indicates how *prominent* it is within the network, while the out-DC indicates how *influential* it is. The average vertex DC for a graph is the average of the DCs of its vertexes. In GREMLIN, we can express the in-DC computation as a traversal that starts from all vertexes with an incoming edge having a specific label—grouping them by the vertex ID, and the number of edges. Here is an implementation based on recommendations by the TINKERPOP community⁵:

```
g.V().in("label").inV().group().by(____.ID()).by(____.inE(label).count())
```

For the search engine, we can increase the utility of the indexed data by adding to each edge the JANUSGRAPH ID of the connected vertexes. This design decision amounts to a limited use of denormalization, with few chances for inconsistency as the IDs of connected vertexes do not change. Finally, we can construct the average DC calculation as a single ELASTICSEARCH term query that searches for a given value over all edge labels. This query aggregates the count of results based on the IDs of vertexes (either the source or the target vertex). The result is an ordered list of vertexes and number of edges to which they are either the source or the target. We show a prototypical implementation in Listing 2.

For an initial evaluation of this rewrite we use the Pokec dataset, an online social network, and a commodity machine⁶. In Figure 2, we show the results, which indicate a speedup of 150x over the original, by employing the second query approach.⁷

The fundamental reason for the differences in performance is that the queries in fact map to entirely different algorithms. A GREMLIN traversal begins by querying a given set of vertexes (either using a composite index or a full-table scan). For each match, GREMLIN counts the number of incoming edges with a specific label, groups the results by vertex IDs, and returns these

⁵<http://tinkerpop.apache.org/docs/3.2.1-SNAPSHOT/recipes/#degree-centrality>

⁶We used an Intel Core™ i7-2760QM CPU (2.40GHz) processor with 8 cores and 7.7 GiB of memory.

⁷We would like to add the disclaimer that the performance gains we report are specific to the queries and database we selected. Further comparisons are pertinent to assess the benefits of these rewrites for other queries and databases.

Figure 2: Response times for computing the average degree centrality (DC) on the Pokec dataset.

values. In contrast, the ELASTICSEARCH implementation relies on a simpler representation of the same data: A set of documents that stand for the edges, further indexed with LUCENE’s inverted indexes. These serve well term-based searches, such as our *entry query*. Another index, covering as terms, the ID of source vertexes, can be matched with the document numbers found by our *entry query*. At last, the resulting collection is aggregated by counting for each term the number of matching edge documents.

In spite of the benefits, there are limits that need to be considered in adopting a search engine for graph tasks in a multi-store context. Namely, the *impedance mismatch* between domains, *inadequate performance optimizations* in the search engine, and *overheads from application-level mapping* of items between the different storage engines.

3 DEMONSTRATION OVERVIEW

Data: Our preloaded dataset is the complete MICROSOFT ACADEMIC GRAPH [18] as of early 2017, which is a property graph of scholarly publications. It is compiled and made publicly available by *Microsoft*. The graph consists of six entities: Field of study, author, institution, paper, venue, and event. Furthermore, the graph includes six standard relationships: Citations among papers, paper authorship, the venue or journal a paper was published at (or a field of study if no venue is available), the institutional affiliations of authors, and the relationships of events to venues. Overall, the MICROSOFT ACADEMIC GRAPH comprises around 166 million papers, representing a heterogeneous and large dataset for our tool.

Considering that the audience of our demonstration will be conformed by the database community, we have tagged some subgraphs of interest within the dataset. This includes a graph of papers with transitive reference relationships to the foundational paper of Edgar Codd on relational databases [5]. We call this the *Codd’s world* graph, on which we aim to undertake studies in future work.

Demonstration: We will start introducing the audience to the core functionalities of HERMES by searching for authors or papers, as shown in Figure 3. Based on the results, we navigate through some different network representations of the data and explore dependencies between the results. This will enable the audience to use the tool by themselves.

In the next step, we explain some representative scenarios for scholarly network analysis: *Impact evaluation*, *academic recommendation*, or *expert identification*. This selection is based on a recent survey [22]. We then carry out a task from the outlined cases. For every alternative, we first accomplish the task and then walk the user through the series of queries that conform it.

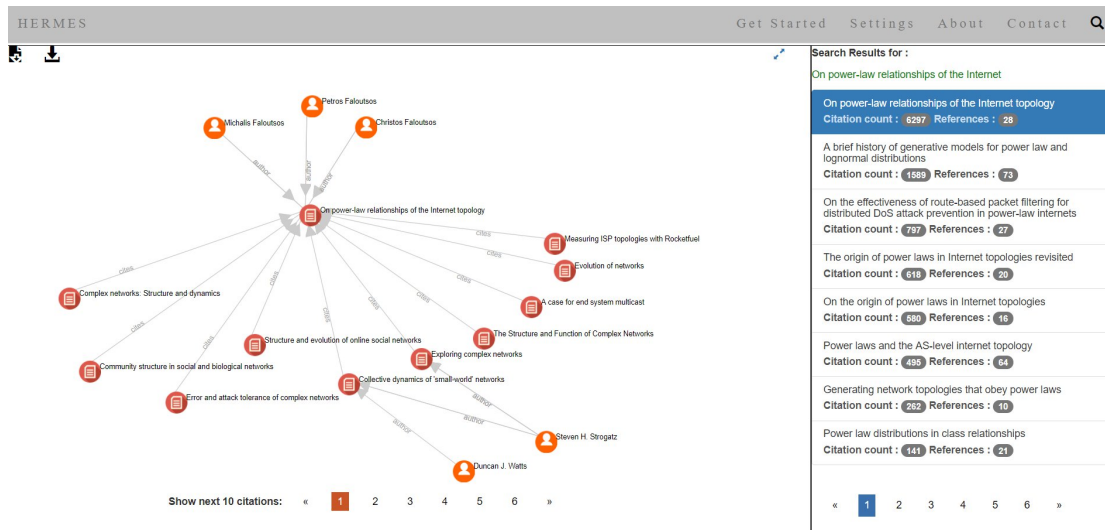

Figure 3: Exploring networks with HERMES.

Following this, we take the user to a JUPYTER notebook, where we submit alternative versions (with different optimizations) of a single query. For the queries we observe different execution times in spite of them achieving the same task. This provides insights into the practical, positive impact of the optimizations.

As a takeaway, we expect the user to understand the different indexing and incremental processing techniques, which can be used to build efficient prototypes based on mainstream graph databases. We hope to encourage them to use our tool when searching for literature, due to its supportive features.

4 CONCLUSION

In this paper we introduce HERMES, a tool for exploring and analyzing large scholarly datasets building upon on a graph database and an integrated search engine. While in an early phase, it already comprises a range of functionalities that motivate us to share our work with the community. We seek to encourage others to use our tool, helping us to improve it and, through user studies, contributing to the understanding and characterization of SNA workloads. For future work, we will enhance HERMES with additional analysis options and automated query rewrites. Other target features include support for cross-dataset exploration and for connecting to more data sources (e.g., ORCID). Potentially, we can also extend our tool to the purpose of supporting systematic literature reviews and research exploration, addressing the lack of suitable tools in these research areas [11, 16].

ACKNOWLEDGMENTS

We would like to thank the reviewers for their insightful feedback. We thank Jingy Ma for helping us to efficiently load large graph data. This work is supported by DFG grants SA 465/50-1 and LE 3382/2-1, and the DAAD STIBET Matching Funds grant.

ABSTRACT

We present a demonstration about optimizing two database storage engines by leveraging multi-streamed SSDs (MS-SSD in short). By storing data pages with similar lifetime together in the same physical flash blocks, MS-SSD can effectively reduce the overhead of garbage collection, improving the write performance and prolonging the lifespan. Thus, in order to benefit from MS-SSD, it is very crucial for database storage engines to precisely classify logical data pages according to their update intervals and to effectively map those logical data streams to physical streams in MS-SSD. Given that numerous new interfaces between host and flash memory SSD for better performance are emerging, this demonstration will provide a model case of physical database tuning on flash memory SSDs.

We have successfully multi-streamed two database engines, MySQL/InnoDB and ForestDB, by identifying several logical data streams with distinct update intervals in each engine and by taking the *stream-per-object* policy, instead of the naïve *stream-per-file* one. By running both vanilla and multi-streamed versions of two storage engines on real MS-SSD, we showcase that multi-streamed versions consistently outperform vanilla ones. In addition, we propose a set of guidelines on how to group logical streams with different update intervals into smaller number of physical streams with minimal performance degradation.

1 INTRODUCTION

During the last decade, we are witnessing that flash memory SSDs have relentlessly been replacing harddisks as the main storage because of several advantages such as high IOPS/\$ and low power consumption [9]. However, to prevent data loss due to electrical interference, flash memory chips do not allow overwrite. Hence, a costly erase operation against a block is necessary prior to overwriting the existing data pages in the block [5]. For this reason, most contemporary flash storage device takes the log-structured copy-on-write approach and, among many FTL schemes, the page-mapping FTL approach is most popular [10]. In FTLs, when no more clean block is available, a costly but inevitable garbage collection (GC) operation has to be triggered so as to secure new blocks to write new incoming page writes. During GC, valid pages from the victim block has to be copybacked to a clean block. It is well known that the excessive copybacks of valid pages during GC negatively affects the performance and lifetime of flash memory SSDs. Hence, one of the key challenges in modern flash memory SSDs is to reduce the GC overhead.

Meanwhile, every modern flash memory SSD has abundant computing resource which is affordable to support other new interfaces than the existing dummy read and write block interface. In fact, numerous new interfaces between host and flash

memory SSD have been actively proposed for various purposes including better performance. Among them, one notable interface is Multi-Streamed SSD (MS-SSD in short) [8]. The interface is recently standardized in the SCSI interface [11] and the commercial SSDs which support it exists. The goal of the MS-SSD is to minimize the GC overhead. That is, by storing data pages with different lifetimes in different physical flash memory blocks (i.e., different write streams), MS-SSD expects that it can reduce, compared to the existing non-multi-streamed SSD, the number of pages to be copybacked in victim blocks, and thus can improve both the write performance and the lifespan. In short, instead of writing all data pages in one stream regardless of lifetime, by explicitly allowing to cluster data pages with different lifetime into different write streams, the MS-SSD interface is intended to reduce write amplification due to GC.

However, the performance benefit of MS-SSD depends heavily on the accuracy of classifying logical data streams according to update interval [7]. Therefore, it is very crucial for storage engines to precisely classify logical data pages base on their update intervals and to effectively map those logical data streams to physical streams in MS-SSD. For this reason, the first step in making any database engine multi-streamed is to understand its write patterns and then to figure out all logical data streams distinguishable from each other in terms of update intervals.

In this demonstration, we will show how to make two database storage engines multi-streamed, MySQL/InnoDB and ForestDB, and present the benefit of each multi-streamed version over its vanilla engine in terms of transaction throughput and WAF. The contributions of this demonstration can be summarized as follows. First, we show that each database storage engine has several logical data streams with distinct update intervals. Second and more importantly, we show that, in database engines, the logical data streams with different update intervals can be found when the write patterns are analyzed *per-object*. Unlike the existing work on multi-streaming LSM-based NoSQL engines such as Cassandra and RocksDB using the *per-file* policy [6, 8], we found out that those two database engines used in this demonstration can not be effectively multi-streamed with the *per-file* policy. Given that numerous interfaces between host and flash memory SSDs for better performance are emerging, this demonstration will provide a model case of physical database tuning on flash memory SSDs. Our demonstration will proceed following the steps below:

- Using the logical data streams identified according to the *per-object* approach in each storage engine, we explain how to classify each of streams into *Hot*, *Cold* and *Warm* and the rationale behind it. (Section 2)
- Based on the classification obtained from the above step, we will show that there are numerous other combinations in mapping logical streams into physical streams than the naïve one-to-one mapping, run representative benchmark in each storage engine by changing the combinations, explain the results, and discuss its implications. (Section 4.2)

- While running benchmarks on both multi-streamed and vanilla version of each storage engine, we will show, using a GUI program, how the key metrics including CPU utilization, IOPS, TPS (transaction per second) and WAF dynamically change over time. (Section 4)
- Based on the performance results from several combinations in mapping logical streams to physical streams, we suggest a set of practical guidelines for making storage engines multi-streamed effectively. (Section 4.2)

2 BACKGROUND

2.1 MultiStream SSD

The goal of MS-SSD is to reduce the GC overhead by separating logical data pages with different lifetimes into different physical *streams* of flash blocks inside SSD [8]. Multiple *physical streams* will divide physical space in flash SSDs into several smaller spaces. Applications in the host are responsible for distinguishing data pages by explicitly attaching *stream-id* when making a write request to MS-SSD. Upon receiving write request for data page(s) with *stream-id*, SSD places the page(s) in the flash block belonging to the corresponding physical stream id. All the blocks belonging to each physical stream will be managed by the flash translation layer (FTL) separately from other blocks of other physical streams. Consequently, compared to the non-multi-streamed SSDs, MS-SSD expects that most pages in victim blocks upon GCs is invalidated for GC, thus minimizing the number of pages to be copybacked for GCs.

Although MS-SSD looks promising, there are at least two practical issues to be addressed when making any database engine multi-streamed. As noted above, the *stream-id* of data pages is not determined automatically by MS-SSD itself, but instead should be explicitly hinted by applications. Thus, the performance benefit of any multi-streamed database engine will be highly dependent on the accuracy of logical data stream classification. Next, because the number of physical streams available in an MS-SSD is limited in practice (e.g., 16 in the case of PM953), applications should be able to get best performance with the limited number of physical streams. For this, when the number of logical data streams from the applications is larger than that of physical streams supported by MS-SSD, a set of guidelines on how to group multiple logical streams into smaller number of physical streams with minimal performance degradation.

2.2 Logical Streams in Database Engines

As discussed above, the crux in leveraging the opportunities from MS-SSD is to accurately separate logical stream with different lifetime. In this section, we illustrate how logical streams from each of two real database engines, MySQL/InnoDB and ForestDB, are derived. From a set of separate experiments, where two storage engines were, likewise as in existing work [8] multi-streamed according to the *per-file* approach, any meaningful performance improvement was not observed. In some cases, the performance of multi-streamed versions was even worse than that of non-streamed vanilla ones. This is because the write patterns from those database engines do not reveal any distinguishable lifetime among different database files.

MySQL/InnoDB is a popular open source relational database engine, which takes the traditional in-place update policy. On the other hand, ForestDB, a storage engine for Couchbase NoSQL database [3, 4], is taking the out-of-place update

approach, likewise other popular NoSQL engines such as Cassandra and RocksDB. But unlike these LSM-based NoSQL engines used in the previous work on MS-SSD [8], ForestDB is a B-tree-based storage engine, which appends new key-value versions at the end of files (that is, copy-on-write). It periodically reuses the space occupied by the invalidated old versions of key-value documents and, when the size of a database file becomes larger, the compaction operation has to be carried out. In this section, although these two database engines of MySQL/InnoDB and ForestDB take different approaches in updating data, they are common in that each engine has several object types and in turn each object type exhibits distinct update intervals. This observation clearly confirms that there exist opportunities for improving database performance by making those engines multi-streamed using the *stream-per-object* approach.

Table 1: Characteristics of MySQL TPC-C’s Data Type

	avg update interval	total write (MB)	write ratio(%)
DWB (H1)	2	1330556	50
new_orders(H2)	226410	88349	3.32
order_line(C1)	26425310	202777	7.62
customer(C2)	7741410	157006	5.54
orders (W)	2861170	108706	4.085
stock (W)	2873060	771190	28.98

2.2.1 Mysql. In order to derive logical data streams, which are suitable to the purpose of MS-SSD, from MySQL/InnoDB engine we collected the write trace while running TPC-C benchmark [1]) with 200GB database size for one day. Using the trace, we calculated the average update interval, total write amount, and the relative write ratio for major object types in the database. Between the time point when data is written and updated in each LBA, write commands are issued to another LBAs. Average update interval represents the average of the numbers of intervening writes issued for all LBAs belonging to each object type. Therefore, the larger average update interval is, the less frequently the pages in the object type is updated. The results for major object types (with write ratio greater than 1%) are summarized in Table 1.

The most outstanding object from the table is *double-write buffer* (DWB), to which every dirty page evicted from the buffer cache has to be redundantly journaled to guarantee the page write atomicity. It shows very low value of average update interval and also occupies half of total writes in MySQL/InnoDB. For this reason, DWB is definitely a *hot* data object with very short lifetime and is thus denoted as H1 in Table 1. In addition, we see from the table that the *new_orders* table has relatively low average update interval and thus it is also regarded as *hot object*. Similarly, two tables, *order_line* and *customers* are treated as *cold objects* and all other object are as *warm objects*.

2.2.2 ForestDB. A ForestDB database consists of multiple files and each database file is comprised of four data types: database header, super block, index node, and document. As mentioned above, there was no performance gain when multi-streamed using the *stream-per-file* approach. Therefore, as in the case of MySQL/InnoDB, in order to verify that those four object

Table 2: Characteristics of ForestDB’s Data Type

	avg update interval	total write (MB)	write ratio(%)
DB Header (W1)	764571	6069	10.4
Index Node (W2)	848531	1048	1.8
Data Page (C)	1457589	44858	77.1
Super Block (H)	752	6222	10.7

types are suitable as logical data streams for MS-SSD, we collected the write trace while running ForestDB-Benchmark workload [2] with 7.5GB database for four hours. Using the trace, we calculated the average update interval, total write amount, and the relative write ratio for those four object types. The results are given in Table 2. From Table 2, it is obvious that Super Block is hot (denoted as H), DB Header and Index Node warm (denoted as W1 and W2, respectively), and Data Page cold (denoted as C. In addition, we verified that all data pages of each object type tend to have uniform update intensity.

3 SYSTEM OVERVIEW

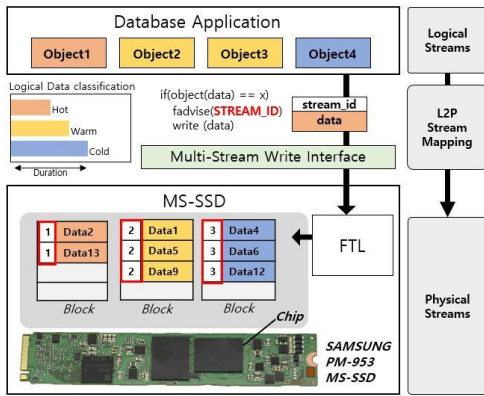

Figure 1: Multi-Streamed Database Engine: Architecture

Figure 1 shows the architectural overview of how a multi-streamed database engine interacts with MS-SSD. First, as shown in the bottom of Figure 1, a commercial MS-SSD from Samsung with NVMe interface (PM953 model) is used. The MS-SSD currently provides 16 *physical streams*. Next, as shown at the top of Figure 1, a multi-streamed database engine will, for each data page to be written, identify the *logical data stream* where the page belongs according to the *stream-per-object* policy explained in Section 2. Finally, as illustrated in the middle of Figure 1, the database engine is responsible for mapping its each logical stream to a specific physical stream in MS-SSD using the `posix_fadvise` system call. For example, the database engine can assign different physical stream to its each logical stream (that is, one-to-one mapping between logical and physical stream). As another example, as exemplified in Figure 1, four logical data streams in database engine can be combined to map to three different physical streams in MS-SSD (that is, many-to-one mapping between logical and physical stream).

The database engine will, before writing a data page, first check its logical stream, then assign the appropriate `stream_id` to the page according to the mapping between logical and physical streams, and finally call

the multi-streamed write interface using the `ioctl` command of `posix_fadvise(fd, stream_id, 0, POSIX_FADV_STREAMID)`. Upon receiving the command, FTL will place the data page in the physical stream corresponding to the given `stream_id`.

4 DEMONSTRATION DETAIL

4.1 Demonstration Scenario

The main goals of this demonstration are two-folds. First, we will show that real database engine can significantly benefit by accurately classifying its logical streams according to the *stream-per-object* policy and then by calling the multi-stream interface. Second, given the limited number of physical streams available in real MS-SSDs, we will show that it is possible to achieve nearly optimal performance by effectively using physical streams less than logical streams.

Table 3: Stream Combinations (MySQL/InnoDB)

5 streams	2 streams	
(H1, H2, C1, C2, W)	(H1, else)	(C1, else)
	(H1+H2, else)	(H1+C1, else)

Table 4: Stream Combinations (ForestDB)

4 streams	3 streams	2 streams	
H, C, W1, W2	W1+W2, H, C	(H, else)	(C, else)
	H+C, W1, W2	(W1, else)	(W2, else)

For this, by running TPC-C an ForestDB-Benchmark on MySQL/InnoDB and ForestDB, respectively, this demonstration will present the performances of vanilla version of each storage engine. In addition, we will present, as the baseline performance, the performance of its multi-streamed version when run by assigning one physical stream to each logical stream. As shown in the first column of Table 3 and Table 4, respectively, a dedicated physical stream is assigned to each logical stream in Table 1 and in Table 2, respectively. Then, for each database engine, we will present the performance of multi-streamed version when run by grouping logical data streams into smaller number of physical streams in several meaningful combinations. In the case of MySQL/InnoDB, we tested all four combinations shown in the second column of Table 3. For example, the combination (H1+H2, else) in the table represents that two hot logical streams of H1 and H2 share one physical stream while all other three logical streams do other physical stream. Similarly, in the case of ForestDB, we tested all the six combinations shown in the second and third columns of Table 4.

In order to show the effect of multi-streamed database visually, we made a GUI system to monitor status of computer resources utilization, which is illustrated in Figure 3. Using the GUI we will compare the effect of multistream SSD.

4.2 Preliminary Performance Evaluation

For each of MySQL/InnoDB and ForestDB engines, we have evaluated the performance of its multi-streamed version as well as its vanilla version. In the case of MySQL/InnoDB, we measured the write amplification factors over time while running

(a) TPC-C on MySQL/InnoDB

(b) ForestDB-Benchmark on ForestDB

Figure 2: Preliminary Experimental Results: Original vs. Multi-Streamed Database Engine

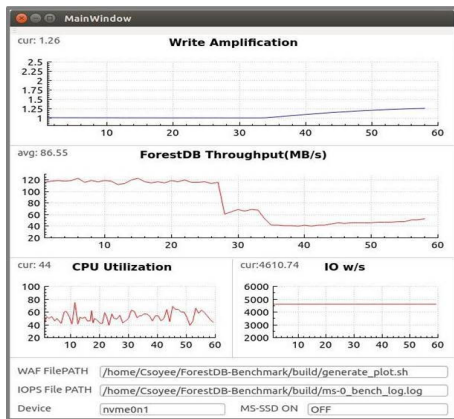

Figure 3: GUI used in Demonstration

TPC-C benchmark for twelve hours on its multi-streamed version for every five combinations in Table 1 as well as on its non-multi-streamed version. The results are presented in Figure 2(a). Similarly, in the case of ForestDB, we measured the write amplification factors over time while running ForestDB-Benchmark for six hours on its multi-streamed version for every seven combinations in Table 2 as well as the original ForestDB version. The results are presented in Figure 2(b).

From Figure 2(a) and Figure 2(b), we can make several common observations on the performance implications of combining logical streams into physical streams. First, since every multi-streamed versions always outperforms the vanilla version for both database engines, it is, obviously, always beneficial to separate at least one logical stream. Second, the best performance is achievable by one-to-one mapping between logical and physical streams. Third, it is better to combine data objects having similar lifetime rather than different lifetime. For example, when comparing the (H1+H2, else) case with the (H1+C1, else) one in the case of MySQL/InnoDB, the former case shows lower WAF value. Also, the (W1+W2, else) combination in ForestDB outperforms all other combinations except for one-to-one mapping logical and physical mapping case, in terms of WAF value. Fourth, it is always desirable to separate logical streams with extremely low update interval, such as DWB (H1) in MySQL/InnoDB and SuperBlock(H) in ForestDB. Lastly, though obvious, it is less effective to separate any logical stream with very low write ratio than to separate one with high write ratio, as exemplified by two streams of W1 and W2 in ForestDB.

5 CONCLUSION AND FUTURE WORK

In this demonstration, we have shown that database engines can significantly benefit from MS-SSD by appropriately identifying logical streams according to the *stream-per-object* policy. In addition, given that the number of physical streams available in real MS-SSDs is limited, we have derived a set of guidelines on effectively grouping logical streams into the fewest physical streams with minimal performance degradation.

One promising future research direction is to automatically identify logical streams out of any write-intensive application, which are suitable to MS-SSD, considering that we found out a set of logical streams from each of two database engines manually. Another challenging future work is to automatically group logical streams into minimum number of physical streams.

ELINDA: Explorer for Linked Data

Tal Yahav Oren Kalinsky Oren Mishali Benny Kimelfeld

Technion – Israel Institute of Technology
Haifa 32000, Israel

ABSTRACT

To realize the premise of the Semantic Web towards knowledgeable machines, one might often integrate an application with emerging RDF graphs. Nevertheless, capturing the content of a rich and open RDF graph by existing tools requires both time and expertise. We demonstrate ELINDA—an explorer for Linked Data. The challenge addressed by ELINDA is that of understanding the rich content of a given RDF graph. The core functionality is an exploration path, where each step produces a bar chart (histogram) that visualizes the distribution of classes in a set of nodes (URIs). In turn, each bar represents a set of nodes that can be further expanded through the bar chart in the path. We allow three types of explorations: subclass distribution, property distribution, and object distribution for a property of choice. To efficiently compute the exploration queries, we offer a query engine powered by a worst-case-optimal join algorithm.

1 INTRODUCTION

The potential of enhancing Artificial Intelligence with rich human knowledge intensifies with the growth of Linked Data resources with high quality, volume, and wealth of domains. To realize this potential, developers continuously explore emerging datasets and investigate their relevance to the application at hand. We present ELINDA—an exploration tool for RDF that implements a novel visual query language for exploratory search, designed especially to facilitate comprehension of unfamiliar datasets. To that end, we exploit the ontology that is typically associated to an RDF graph, describing its semantics in terms of *classes*, *class hierarchies* and *properties*.

The formal model underlying our visual query language applies in an iterative manner the basic principle for effective data visualization by Shneiderman [6]: “Overview first, zoom and filter, then details-on-demand.” Specifically, our formal model is based on histograms over focus sets of nodes (URIs) that are constructed iteratively by the user. In this model a *bar chart* consists of a set of *bars*, each representing a portion of the focus set. The user selects a bar and applies an *expansion operation* that transforms a bar into a new bar chart that now focuses on the portion of the selected bar. In addition, a *filter* can be applied to restrict the bar chart according to a search condition. The user can then continue the exploration of the new bar chart, and hence, construct focus sets of arbitrary depths. (See Section 2 for the formal model.)

We illustrate the mission and functionality of ELINDA through a hypothetical exploration scenario over the DBpedia dataset [1]. Suppose that the user is interested in understanding what information DBpedia has on cities where scientists were born. The initial bar chart shows how *all* DBpedia nodes are distributed among the 49 top-level classes (see Figure 1). For example, the user can observe that the most popular classes are Agent and Work. The

user then selects Agent and applies a *subclass expansion* to get a histogram over agents. Two additional subclass expansions are then applied to focus on the Scientist nodes (through class Person). Next, a *property expansion* is applied to get the distribution of properties of scientists, and from that the user selects the birthPlace bar. An *object expansion* over this bar results in the histogram over the birth places of scientists, and from there the user selects the City bar.

The basic implementation of ELINDA translates each expansion into a SPARQL query that is sent to an endpoint. A major challenge is the *execution cost*, since the queries often involve large numbers of nodes to extract and apply aggregates to, and a naïve translation to a black-box SPARQL engine yields impractical responsiveness. For example, computing the distribution of properties over all DBpedia nodes takes around 10.5 minutes on a standard Virtuoso endpoint. Therefore, we have implemented a novel query engine that is specialized (and restricted) to support ELINDA’s exploration model. For that, we adopt and extend the *Cached Trie Join* (CTJ) of Kalinsky et al. [5], an algorithm from the breed of *worst-case-optimal joins*, to an evaluation algorithm that we refer to as CTJ*. Specifically, CTJ* supports reachability queries and grouped aggregations. Our engine often achieves 1.5-2 orders of magnitude speedups compared to Virtuoso.

In addition to CTJ*, ELINDA supports a *remote* execution mode that works on Virtuoso endpoints that are accessible only through a standard Web interface. In that case, ELINDA accelerates responsiveness by retrieving data *incrementally* and *caching* results. ELINDA has an accompanying demonstration video that is available at <https://tinyurl.com/y9hu2gxl>.

Related Work. ELINDA is inspired mostly by LD-VOWL [8] that extracts ontological information from the actual RDF graph by sending SPARQL queries to the RDF endpoint. The results are visualized in a graph-based fashion. The fundamental difference between LD-VOWL and ELINDA is the iterative exploration model of the latter—we use the visual tool for iteratively constructing focus sets of arbitrary description depth (as described earlier). Another important difference is our handling of efficiency that does not have any correspondence in LD-VOWL. Many of the existing ontology visualization tools, such as FlexViz [3] and GLOW [4] visualize an ontology, yet independently of the data. On the other extreme, a family of tools known as *linked-data browsers* [2] are able to provide informative insights into the details of a dataset by supporting the exploration of individual nodes via properties and relations with other nodes. Examples include *Marbles*¹ and *Sig.ma* [7]. In contrast to ELINDA, browsers are appropriate in cases where the task at hand is to look for specific information from a dataset that the user is familiar with.

2 FRAMEWORK

In this section, we give the formal definition of the data and interaction model underlying ELINDA.

Figure 1: Initial chart in the exploration pane over DBpedia.

RDF graphs. We adopt a standard model of RDF data. Specifically, we assume collections U of *Unique Resource Identifiers* (URIs) and L of *literals*. An *RDF triple*, is an element of $U \times U \times (U \cup L)$. An *RDF graph* is a finite collection G of RDF triples. In the remainder of this section, we assume a fixed RDF graph G . A URI u is said to be *of class* c if G contains the triple $(u, \text{rdf:type}, c)$.

Bar charts. eLINDA enables the visual exploration of the RDF graph by means of bar charts that are constructed interactively (see Figure 2). We have two kinds of bars: a *class bar* represents URIs of a common class, and a *property bar* represents URIs with a common property. For a bar B , we denote by $U(B)$ the set of URIs represented by B . The *category* of B is the corresponding class or property, depending on the kind of B . A *bar chart* (or just *chart* for short) is a mapping from categories to bars.

Bar expansion. A *bar expansion* is a function E that transforms a given bar B into a chart $E(B)$. eLINDA supports three specific bar expansions E that we define as follows.

Subclass expansion: This expansion is enabled for class bars B ; in this case, the category c of B is a class. The categories of the chart $E(B)$ are all the *subclasses* of c , that is, the URIs c' such that G contains the triple $(c', \text{rdfs:subClassOf}, c)$. The bar $B_{c'}$ that $E(B)$ maps to category c' is a class bar with the category c' , and $U(B_{c'})$ consists of all the URIs $u \in U(B)$ such that u is of type c' .

Property expansion: This expansion is again enabled for class bars B . The categories of the chart $E(B)$ are the properties of the URIs of B , that is, the URIs p such that G contains (s, p, o) for some $s \in U(B)$. The bar B_p that $E(B)$ maps to p is a property bar with the category p , and $U(B_p)$ consists of all URIs $s \in U(B)$ that have the property p , that is, $(s, p, o) \in G$ for some o .

Object expansion: This expansion is enabled for property bars B ; in this case the category of B is a property p . The categories of the chart $E(B)$ are the classes c of the objects that are connected to the URIs in $U(B)$ through the property p ; that is, the classes c such that for some triple $(s, p, o) \in G$ it is the case that $s \in U(B)$ and o is of class c . The bar B_c that $E(B)$ maps to category c is a class bar with the category c , and $U(B_c)$ consists of the p -targets

of type c , that is, all URIs o of class c such that $(s, p, o) \in G$ for some $s \in U(B)$.

The property and object expansions are defined above for *outgoing* properties, that is, the URIs of B play the roles of the *subjects*. We similarly define the *incoming* versions, where the URIs of B play the roles of the *objects*.

Exploration. Finally, eLINDA enables the exploration of G by enabling the user to construct a list of charts in sequence, each exploring a bar of the previous chart. The exploration begins with a predefined *initial chart* that we denote by B_0 . In our implementation this bar has the form $E(B)$ where E is the subclass expansion and B is a bar that consists of all URIs of a predefined class. A sensible choice of such class is a general type such as `owl:Thing`. By *exploration* we formally refer to a sequence of the form $(c_1, E_1) \mapsto B_1, (c_2, E_2) \mapsto B_2, \dots, (c_m, E_m) \mapsto B_m$ where each chart B_i is obtained by selecting the bar B of category c_i from the chart B_{i-1} and applying to B the expansion E_i . As a feature, eLINDA enables the user to generate SPARQL code to extract each of the bars along the exploration.

In addition to the expansion tasks, eLINDA allows, at any stage, to *filter* the current chart by a filtering condition (e.g., the name of the node contains a certain string). The semantics is straightforward—every bar is restricted to the nodes that satisfy the condition.

3 USER INTERFACE

eLINDA is implemented as a single-page Web application that points to an online SPARQL endpoint hosting the explored data. During an exploration, eLINDA fetches data from the endpoint by sending numerous SPARQL queries. The user experience is *visual*, and no SPARQL knowledge is needed. The user should have only a basic understanding of ontology classes and properties.

eLINDA's basic UI component is a *tabbed pane* as in Figure 1. Each tab in the pane presents a specific bar chart, which is the result of an expansion applied on a bar of a previous pane. The opened tab in Figure 1 shows the initial subclass expansion for DBpedia. The bar chart visualizes the distribution of all DBpedia

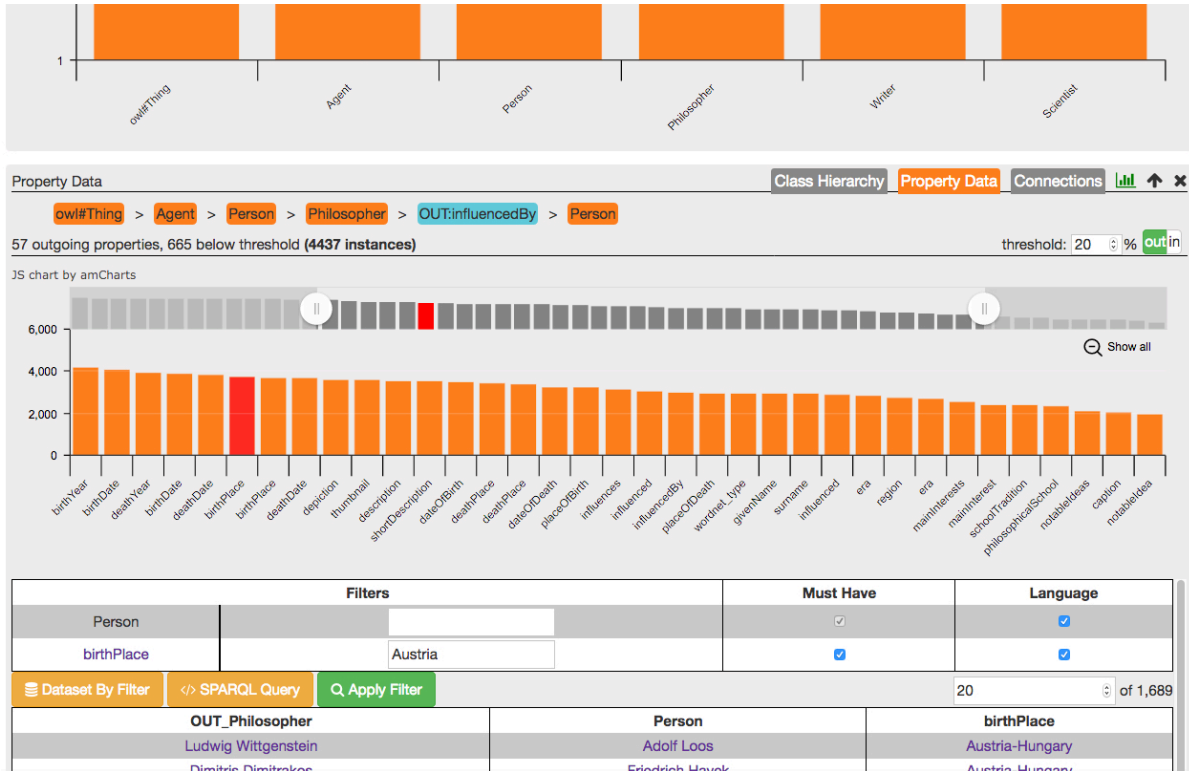

Figure 2: Screenshot of two exploration panes over DBpedia (upper is partially visible). Lower pane shows property data about persons who have influenced philosophers.

subjects (instances of class owl:Thing) into subclasses. Each bar matches a specific subclass, with a height proportional to its number of instances. The bars are sorted by decreasing height. Hovering over a bar opens a pop-up box with basic information, for instance, DBpedia’s Agent class has more than 2 million instances, 5 direct subclasses, and 275 subclasses in total.

To support visualization of large charts, a widget allows to control the visible part of the chart. Class navigation is done by clicking a bar, which opens a new pane under the current one. For example, navigation to type Philosopher involves opening three panes: Agent → Person → Philosopher. Alternatively, an autocomplete search box for class types may be used, in cases where top-down class navigation is less intuitive.

Property and object expansions. A pane has a second tab with a *property chart*—the result of a property expansion. Figure 2 shows a property chart for Person subjects who have influenced philosophers. Here, a bar represents instances that share a specific property. (Switching to an *incoming* chart shows incoming properties, as explained in Section 2.) Bars are sorted by *coverage*—the percentage of instances that feature the property. The number of possible properties may be very large, and thus, ELINDA filters out properties with a coverage lower than a threshold (defaults to 20% and adjustable by the user). In the figure, only 57 properties out of 722 possible properties are shown.

The property chart in the figure was derived *after* applying an object expansion to a previous pane of type Philosopher. In that previous pane (partially shown in Figure 2), an influencedBy property was selected in its property chart. Then, via a third *object chart*, ELINDA was asked to open a new pane (current pane) with instances of type Person connected to philosophers through

the influencedBy property. This allows the user to further explore *only* persons who have influenced philosophers.

A user interested in looking into the details of the dataset, may use the *data table* that appears below the chart. Upon selection of properties (bars) in the chart, columns are added to the table and filled-in with values fetched from the dataset. The SPARQL query used to generate the data table may be retrieved by the user for future consumption. *Data filters* attached to table columns may restrict the displayed data. In Figure 2, only persons born in *Austria* (and have influenced philosophers) are presented.

4 SYSTEM ARCHITECTURE

The architecture design of ELINDA is driven primarily by responsiveness, aiming for bar chart expansions to occur instantly. This is challenging, since some of the queries that are submitted to the endpoint require an execution time of up to several minutes on a Virtuoso endpoint. This is mostly because Virtuoso utilizes traditional join algorithms, which generate up to billions of intermediate results that are not part of the final result.

ELINDA expansion queries retrieve the subject distribution between subclasses or properties of a given class. Retrieving all subjects of a class incurs a reachability query that retrieves the subjects of all transitive subclasses. For example, when applied to class Thing, the query retrieves all of its subjects, including those of direct and indirect subclasses. The subjects are later grouped by each Thing subclass or property and counted distinctly.

To provide the required responsiveness, we built a novel exploration query engine called ELINDA-QE. Our query engine is based on *Cached Trie Join* (CTJ) [5], a worst case optimal join algorithm. CTJ generates only partial intermediate results that will accelerate the join query. CTJ shows orders of magnitude

Figure 3: Basic system architecture of eLINDA.

speedup over traditional approaches on graph workloads. Yet, CTJ supports only equi-join queries, and COUNT and SUM aggregations. To support eLINDA expansions, we extended CTJ and refer to the extended algorithm as CTJ*. First, our CTJ* can compute reachability queries. Second, CTJ aggregations were extended to support group aggregations. Queries containing outer joins, such as queries containing the OPTIONAL clause, are not supported by CTJ*. Such queries are offloaded to a Virtuoso endpoint. We plan to add outer join support to CTJ* in future work. Different orders of (s, p, o) indexes are maintained and used by CTJ*, similar to the indexes managed by Virtuoso.

Figure 4 shows the runtime of the slowest and most commonly used queries by eLINDA on an Ubuntu server with 16 cores and 128GB RAM. These queries construct the bar charts of the outgoing and incoming property expansions and the subclasses expansions in the first levels. The Virtuoso endpoint is configured to utilize all available memory if needed. For all the queries in Figure 4, the eLINDA-QE is 1–2 orders of magnitude faster than Virtuoso. For example, the runtime of class Thing property expansions on the Virtuoso SPARQL endpoint is 630 and 96 seconds for the incoming and outgoing bar charts, respectively. On the eLINDA engine, the runtime is 11 and 3 seconds, respectively. The speedups are consistent with other heavy queries we tested.

eLINDA remote mode can work with any Virtuoso SPARQL endpoint. Remote mode incorporates two methods to provide effective latency for a user interface. First, an incremental evaluation is being applied. eLINDA builds the chart of an expansion by computing it on the first N triples in the RDF graph. It then continues to compute the query on the next N triples and aggregates the results in the frontend. It continues for k steps, or until the full chart is computed. The parameters N and k are determined by an administrator configuration. Second, caching is used to reduce the latency. These methods allow eLINDA to quickly present information to the user that otherwise will take minutes or be rejected by the endpoint for running too long.

Figure 4: Running times of property and subclass expansions on different engines (log scale).

Figure 3 depicts the architecture of eLINDA. The frontend is implemented as a Web page that communicates with the server via AJAX. Expansion queries are sent to eLINDA engine (running CTJ*) while OPTIONAL queries are offloaded to a Virtuoso endpoint. The eLINDA engine is a Web server developed in C++17, incorporates a multithreaded Web API for query evaluation, and uses OpenMP for fine-grained parallelism in CTJ*. In remote mode, all queries are sent to the remote endpoint and are cached either in the reverse proxy or in the browser.

5 DEMONSTRATION SCENARIOS

During the demonstration, participants will explore several RDF datasets such as DBpedia and LinkedGeoData with eLINDA. Several kinds of explorations will be exercised.

The first kind will tackle the task of understanding a large and unfamiliar dataset. The participants will examine the bar chart showing the first-level classes of the dataset (subclass expansion). They will be presented with key statistics that may be inferred from the chart, such as the three largest classes, the number of instances these classes have, and the number of their direct and indirect subclasses.

In the second scenario, the participants will analyze the property chart of the largest class in the dataset (property expansion). They will examine the twenty most significant properties, then select a few of them and see their values appear in the data table. Selected properties will be added with filters, and the data presented in the table will be reduced. The participants will adjust the default coverage threshold to 50% and see the number of presented properties decreasing. Similarly, incoming properties will be explored. Additional scenarios will look into sophisticated exploration paths such as “the types of people that influenced philosophers,” “cities where scientists were born,” and “spouses of former US presidents.” These scenarios will involve opening several charts in sequence to achieve the desired goal.

Another scenario will demonstrate the performance issue elaborated in Section 4. The participants will be presented with several explorations that entail heavy queries with the discussed solutions turned on and off. This demonstration will include working with the described eLINDA engine, as well as working in remote mode where standard Virtuoso SPARQL endpoints are used “as is.” In the remote mode, incremental evaluation of queries and the use of caching will be illustrated.

The last scenario will demonstrate how eLINDA can be used to detect *erroneous* data such as “people who are indicated to be born in resources of type food.”

ABSTRACT

In this paper, we present *FAIMUSS* a tool for data transformation from a wide variety of heterogeneous streaming and archival sources to RDF. This is a typical situation in the analysis of mobility data, such as maritime and aviation, where streaming position data of moving objects need to be associated with static information (such as crossing sectors, protected geographical areas, weather, etc.) in order to provide semantically enriched trajectories. *FAIMUSS* is designed to perform “near-to-the-sources” integration, by interaction between a streaming source and an archival source, thus generating linked RDF graph fragments. Most of the existing approaches operate either on streaming or on static sources, thus fail to address our problem setting. In addition, *FAIMUSS* supports reusable user-defined functions that are applied to input data and achieve the desired data transformations and cleaning. We demonstrate our prototype by using data from the maritime and aviation domains.

1 INTRODUCTION

The Resource Description Framework (RDF) enables the description of physical entities as resources, in favor of data interoperability, integration and exchange. As a result, a wide range of solutions exists for converting a data source to RDF, based on a schema specified by RDFS or OWL profiles. For instance, R2RML [5] is a mapping language that translates SPARQL queries to SQL (and vice-versa). Ontology Based Data Access (OBDA) [2, 3] also focuses on relational data sources, but again requires advanced knowledge to define the (usually complicated) mappings between the data source and the ontology schema. SPARQL-Generate [10] provides an extension of SPARQL 1.1 that allows generation of RDF fragments from documents. Solutions tailored for specific RDF stores also exist, for example Virtuoso Cartridge¹, however they are tied to a particular product.

Moreover, the amount of streaming data sources has increased rapidly in recent years, and such sources pose new challenges for data integration [13]. Apart from the obvious performance challenge raised by high stream rate, streaming data are typically

semi-structured, and contain noisy data. As such, the problem of integrating streaming data sources is still open, and there is a lack of flexible tools that transform streaming data to RDF, integrate it with external sources, and are easily configurable to new sources.

Figure 1: *FAIMUSS* consumes streaming and archival sources and produces (linked) RDF data.

Our work is motivated by the need to produce enriched representations of moving object trajectories expressed in RDF, by ingesting streaming surveillance data in real-time and associating it with other sources, both streaming and archival. Figure 1 illustrates this process, focusing on mobility data in maritime [4] and aviation domains recording positions of moving objects, such as vessels and aircrafts. However, this is simply for demonstration reasons, as our work is readily applicable to any other category of streaming data, including social data consumed through an API (e.g., Twitter API).

In this paper, we present *FAIMUSS* (Flexible dAta TransformatIon to RDF from Multiple Streaming Sources), a flexible, user-friendly system for end-to-end data transformation of streaming data to RDF and integration with external sources. Given an ontology, *FAIMUSS* converts streaming data (but also other data sources) into RDF triples, which are also integrated with other archival data sources. We employ the datAcron ontology [12] for representing trajectories at multiple levels of analysis. However, the system imposes no constraints on the use of a specific ontology, while it supports a wide range of input source data formats. Salient features of *FAIMUSS* include its flexibility and user-friendliness: the process of triple generation is determined by a *Graph Template* that is easily edited by the user with the support of a rich editor. Furthermore, *FAIMUSS* supports “near-to-the-sources” integration, by generating *linked* RDF graph fragments during the process of data transformation. Finally, the implementation of *FAIMUSS* also addresses scalability issues and aims at high performance.

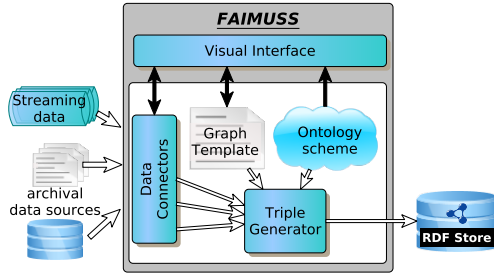

Figure 2: System architecture of FAIMUSS. White arrows indicate data flows and black arrows indicate user interactions.

2 SYSTEM ARCHITECTURE

In this section, we describe the system architecture that consumes data from a variety of data sources and outputs RDF graph fragments. This process is designed in a generic fashion, so as to accomplish multiple objectives, including flexibility, extensibility and scalability. FAIMUSS comprises the following main components, a) the *Data Connector*, b) the *Triple Generator*, and c) the *Visual Interface*. Figure 2 illustrates the overall system and the individual components and their interactions, which will be described in detail. The prototype system has been implemented in Oracle Java 8 (64-bit) and is platform-independent.

2.1 Data Connector

The *Data Connector* component implements the functions that accept data from an individual data source. Moreover, it performs data conversion on values of specific fields as provided by the source and basic data cleaning operations. As the data sources can vary significantly in terms of representation, size, rate of data access, and noise, FAIMUSS provides a Data Connector for each type of source. The implemented system currently supports data consumption from a wide range of sources/formats, such as: a) CSV format, b) direct access to databases, c) JSON messages, d) XML files, e) METAR/SPECI weather reports from offline/continuous feeds from online services, f) binary (GRIB2) files for weather reports, g) SPARQL endpoints to online open data, h) ESRI shape-files to convert information about spatial object to entities and relations of the ontology, and i) proprietary formats of streaming. The list of supported data formats can be easily extended, to support the inclusion of any other data format required in the future.

As an abstraction of the data source in hand, the Data Connector considers all data sources as streams, i.e. it consumes data record-by-record (or tuple-by-tuple), to be processed with minimal latency. This data access model makes no distinction on the nature of data (e.g. archival data or streaming data). In addition, it minimizes the memory footprint of Data Connectors, and enables scalability and parallelization as a multi-threaded process, both for a single source and across sources.

2.2 Triple Generator

The role of *Triple Generator* is to consume the data provided by the Data Connector and generate the corresponding set of triples. This procedure depends on configuration files providing a Graph Template G_T , and a vector of variable names V . The vector V contains the variables that appear in the Graph Template, and binds the values of the input record to the variables in G_T . The

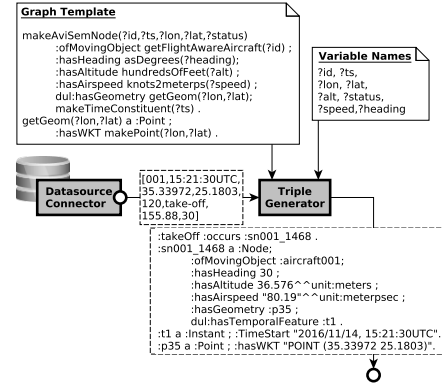

Figure 3: A Graph Template and Variable Vector example in Triple Generator.

Graph Template consists of a set of *triple patterns*, i.e. any of the three elements in the triple (subject, predicate, object) can be replaced by a variable. The Graph Template differs from the standard RDF Graph Pattern, in that variables can be used as arguments in functions, to compute dynamic values at runtime. Furthermore, the implementation of *Triple Generator* is parallelized in a multi-threaded process, due to the record-by-record conversion to triples.

Figure 3 illustrates the application of a Graph Template on a single record from a stream of aircraft surveillance data to generate the corresponding triples. Specifically, the Triple Generator consumes the data provided from the Data Connector and constructs a new resource (`:sn001_1468`) of type `:Node`, based on the Graph Template depicted at the top of the figure. This new resource is the spatio-temporal representation of the moving object (aircraft). The Triple Generator also relates the `:sn001_1468` to the resource representing an aircraft (using the property `:ofMovingObject`), as well as information regarding the status, the altitude and position of the moving object.

Figure 4 shows another example of data transformation where two data sources are processed and integrated, by having two instances of Triple Generator interact with each other. The positioning data connector provides surveillance data of vessels to a Triple Generator instance, similar to the previous example. The GRIB connector accesses binary files that contain weather forecasts and can extract the related weather attributes for a given spatio-temporal position. As soon as a new position is received, a request is made to the Triple Generator instance that retrieves the weather information and provides it in RDF representation based on the respective Graph Template. This allows data transformation of selected weather information, namely this corresponding to the area defined by the positioning information. More interestingly, the weather Triple Generator returns the URI of the weather condition to the positioning Triple Generator, which can then create the `:hasWeatherCondition` property and associate the position with the weather. This is an example of lightweight, “near-to-the-sources” integration.

2.3 Visual Interface

The *Visual Interface* enables the configuration of Data Connector and Triple Generator, the preview of input data, the visualization of output triples on a map, and output validation. Specifically, the user can select the ontology to be used, which will provide

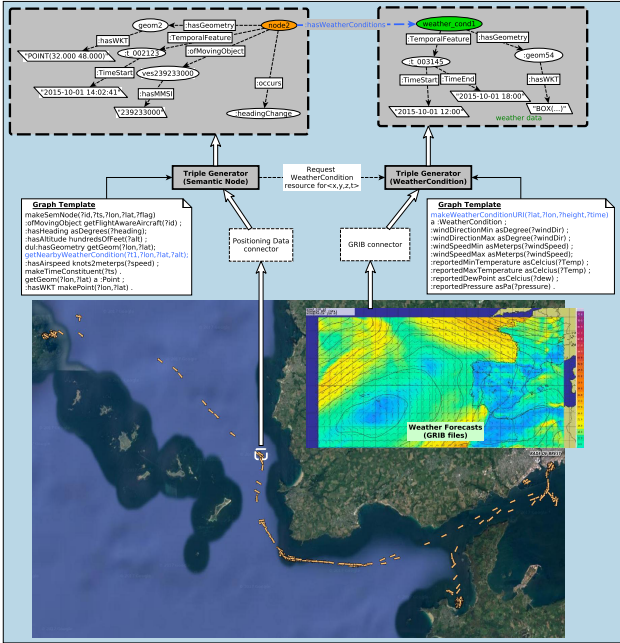

Figure 4: Example of data transformation and “near-to-the-sources” integration (maritime domain).

the vocabulary for the Triple Generator. Obviously, the ontology should be taken into consideration when editing a Graph Template, to guarantee consistency of the generated triples.

Figures 5 and 6 provide screenshots of the Visual Interface using data from the aviation domain. As illustrated in Figure 5(a), the user can select and configure the data source that will be processed (e.g., specify the IP and port of remote endpoints, or folder/file for local access), and the type of Data Connectors that should be used for consuming the data. A sample of the data available in the configured data source, for visual inspection. The user can also select the fields of the input data source that should be converted to triples, and specify the *Variables Vector* to be used in the Graph Template. Figure 5(b) shows the editor for composing the Graph Template. On the right side, the set of available functions is provided, from which the user can insert in the editor by a double click. Also, the Variables corresponding to the input source are also available. The editor uses different font color for functions and variables to improve readability. In addition, import (export) of Graph Templates from (to) disk is supported. It should also be mentioned that automatic validation of a sample (or the entire output) of triples generated w.r.t. the provided Graph Template is supported. Figure 6 depicts a map-based interface provided by FAIMUSS, which enables the illustration of spatial and spatio-temporal RDF data. In this example, it depicts trajectories of moving objects (aircrafts), which correspond to RDF data generated by our system.

3 DEMONSTRATION SCENARIOS

We have used FAIMUSS in two domains, maritime and aviation, thus showing the generic nature of our system and its applicability in different domains. The selection of these domains originates from our involvement in the H2020 research project

datAcron (<http://datacron-project.eu/>), where one of the objectives is to *integrate heterogeneous and voluminous archival data with streaming data sources*.

Scenario 1: Flexible Integration of New Sources. We intend to show in the demo that a new streaming data source can be added to FAIMUSS, after a small set of steps that can be performed by selections from the GUI. The aim is to demonstrate the ease of use of FAIMUSS in practice. In more detail, the streaming data source is going to be surveillance data from vessels travelling in the Mediterranean Sea. Each record in the stream contains the spatio-temporal position of a moving object, along with its unique identifier. From the GUI of FAIMUSS, we are going to input the necessary information for establishing a connection (IP address, port, and authentication details). Thereafter, a Graph Template is going to be specified from an editor of the GUI, which guides the Triple Generator and determines the transformation of stream records into RDF triples. As already mentioned, the editor facilitates the composition of Graph Templates even for moderately familiar users, not only by loading existing Graph Templates that can be modified, but also by providing access to lists of available functions and variables that generate Graph Template code in the editor.

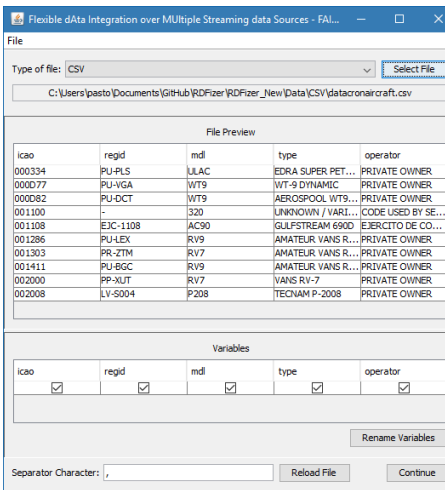

Scenario 2: Trajectory Enrichment. We will show in the demo how we can generate enriched trajectories from moving objects’ positions, where the positional information can be integrated with arbitrary data sources. Continuing scenario 1, the spatio-temporal position of each vessel is going to be integrated with weather conditions. Weather conditions are available as forecasts for a temporal period (e.g. three hours) in the form of large binary files (GRIB2 format), and mainly define 3-dimensional cells that contain multiple variables describing weather condition (e.g., temperature, humidity, pressure, etc.). In this scenario, upon receipt of a spatio-temporal position of a moving object, the Triple Generator instance responsible for surveillance data is going to produce RDF triples. By communication with a Triple Generator instance for weather data, which produces weather-related triples, the resulting positional RDF data is linked with weather information. In this way, we generate enriched trajectories of moving objects represented in RDF, which will be illustrated on a map for visual inspection, and provide additional (weather-related) information for each spatio-temporal position of a moving object.

4 RELATED WORK

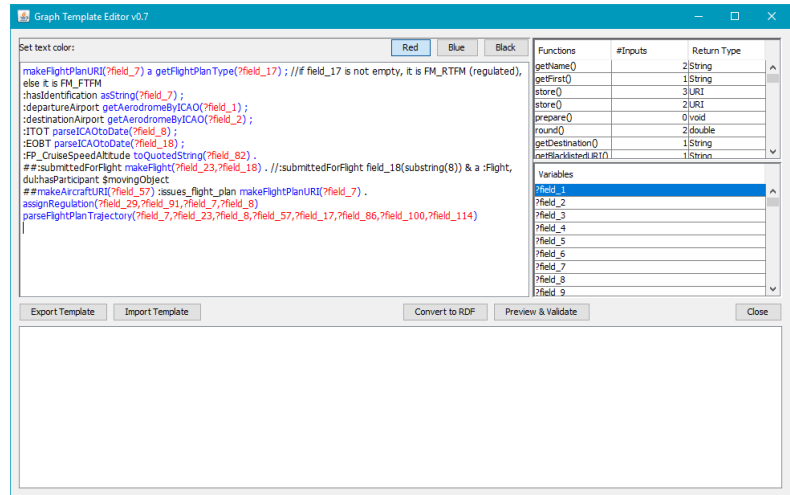

A wide list of data transformation and conversion tools exists, and such tools² have been evaluated during the design of our system, however these are mostly ad-hoc solutions tailored for converting archival data in specific file formats. For example, Omnidator [1] converts any CSV or HTML online file into RDF triples. GeoTriples [8] employs automatically generated R2RML mappings given a source and a configuration, but demands the use of a relational database, which is not applicable for streams. SPARQL-Generate [10] provides an extension of SPARQL 1.1 that allows generation of RDF fragments from documents.

Data integration over streaming data poses new challenges compared to traditional data integration [13]. The Graph of Things [9] targets an IoT setting where many sources provide data for integration and querying, and supports spatial and temporal data, but it is not optimized for mobility data. Also related to our work is StreamLoader [11] which provides a user-friendly,

(b) Editor for Graph Templates

Figure 5: Screenshots of the Visual Interface of FAIMUSS (aviation domain).

Figure 6: Map-based visualization.

web-based environment for ETL (Extract-Transform-Load) of streaming data from heterogeneous sensors. However, it deviates from our objective, namely to provide representations of streaming data in RDF, thus allowing linking with other external (web) sources. Moreover, it does not explicitly address the domain of moving objects and trajectories thereof, which is the motivation of our work. Only recently, Optique [6, 7] proposes an approach for integration of streaming with static relational data. Again, this problem is much narrower than the one addressed by our work, since we make no assumptions on the availability of a relational database nor do we impose such requirements. None of the existing approaches targets streaming mobility data of vessels or aircrafts explicitly. Moreover, our work goes one step further, by introducing a system for flexible data transformation to RDF, with a particular focus on mobility data, also supporting linking of generated RDF graph fragments.

5 CONCLUSIONS AND FUTURE WORK

In this paper, we present the FAIMUSS system for flexible data transformation of streaming and archival data sources to RDF. Despite the generic and extensible design of our system, the focus of our attention is on moving objects and integrating their spatio-temporal positions with a variety of heterogeneous data sources, including weather conditions, spatial areas of interest, as well as external databases. In our future work, we intend to

fully parallelize our system, thus providing a scalable solution to the problem of data integration from different data sources.

ABSTRACT

The volume of RDF data is now growing tremendously. It is thus considered prudent to store and process massive RDF data with distributed SPARQL engines instead of relying on a single-machine system. Many sophisticated index and partitioning schemes have also been proposed to support SPARQL query evaluations. However, existing SPARQL engines have mainly followed *one-at-a-time* scheme so that query evaluation is focused only on processing each query separately. We showcase *SAMUEL*, a distributed SPARQL engine that simultaneously evaluates many SPARQL queries for a massive RDF dataset with MapReduce. *SAMUEL* provides an efficient optimization algorithm to evaluate many SPARQL queries simultaneously in a shared and balanced way. Extensive experiments present that without any sophisticated partitioning or index mechanisms, our approach significantly outperforms other MapReduce-based SPARQL engines as well as an *ad-hoc* query engine equipped with various indexes and partitioning tools for evaluating multiple SPARQL queries.

1 INTRODUCTION

The Resource Description Framework (RDF) is a versatile graph data model that enables users to express facts and their relationships in the form of triples $\langle \textit{Subject}, \textit{Predicate}, \textit{Object} \rangle$ where a predicate (*P*) expresses a relationship between a subject (*S*) and an object (*O*) [2]. Many knowledge bases are now defined in the RDF format, e.g., DBpedia [16], Bio2RDF [6] and UniProt [7] and they shape a very large set of graphs having millions of triples interlinked each other and are queried by using SPARQL query language [1]. It has been a major challenge to find subgraph patterns described in given SPARQL queries from a massive set of RDF graphs with supporting both efficiency and scalability. To address the issue, numerous SPARQL query engines have been devised based on MapReduce [15] or their proprietary distributed architectures [3]. Meanwhile, multiple SPARQL queries often need to be evaluated together as the queries can be prepared before runtime in some scenarios [13, 20]. Motivated by these facts and our previous work on XML data [8], we devise a MapReduce-based SPARQL engine called *SAMUEL*, which simultaneously evaluates many SPARQL queries in a *shared* and *balanced* way. Major features of *SAMUEL* are as follows :

Support of parallel multi-SPARQL query processing

SAMUEL provides an efficient means to process a massive set of

RDF data in parallel. It does not require any sophisticated partitioning or index mechanisms for SPARQL query evaluation. Nonetheless, *SAMUEL* easily outperforms other MapReduce-based distributed SPARQL engines by simultaneously evaluating multiple SPARQL queries with a short series of MapReduce jobs.

Sharing input scans and intermediate results

SAMUEL enables computing nodes to share input scans and their intermediate results with each other. While joining RDF triples for evaluating queries, a group of join operations assigned to each reducer share their input and intermediate results associated with distinct subquery patterns that multiple queries commonly contain. Consequently, it saves many I/Os by removing many redundant subquery matchings while evaluating queries.

Runtime load balancing and multi-query optimization

In a distributed system, a straggling task delays overall job execution. This problem deteriorates with the use of MapReduce since MapReduce typically enforces barrier synchronization between Map and Reduce tasks. MapReduce's native runtime scheduling algorithm also proved to be inefficient especially in the reduce stage [12, 15]. To address the issue, *SAMUEL* rather exploits *dynamic shuffling* scheme that balances workloads across reducers at each MapReduce job in accordance with the cardinality of RDF triples that each reducer consumes for joining. It decomposes a given set of SPARQL queries into distinct triple patterns and then *gradually* builds a bushy query plan tree that covers all RDF join operations required to evaluate the given SPARQL queries. Since processing join operations at each level in the query plan tree requires a single M/R job, *SAMUEL* always tries to build a bushy plan tree with the lowest possible height. Then, it partitions the join operations at each level into n groups and then assigns them to n reducers. To balance workloads across reducers that actually perform join operations, *SAMUEL* computes the cost of each join operation at each level of the plan tree before actual joining. It then assigns join operations into reducers at each level such that every reducer has the same overall cost of join operations and the lowest communication cost by avoiding redundant RDF triples being transferred to multiple reducers so far as possible.

The rest of this paper is organized as follows. Section 2 introduces previous studies directly related to our work. Section 3 describes how we evaluate multiple SPARQL queries together at a time and our system architecture that provides workload balancing as well as multi-SPARQL query processing. Section 4 presents our demonstration scenario including the major results of performance evaluations.

2 RELATED WORK

Numerous distributed SPARQL engines have been devised to store RDF data and to evaluate SPARQL queries so far [3, 9, 11, 14, 19, 21, 22]. Readers are referred to a recent survey on distributed SPARQL query engines [3]. These systems fall into

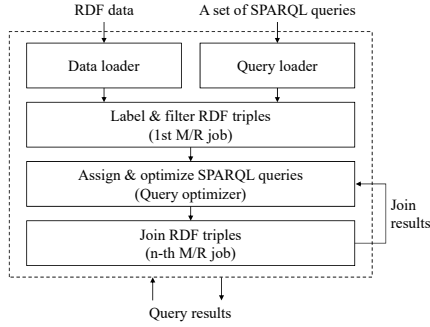

Figure 1: System architecture

two categories in the aspect which framework these systems rely on : (i) general-purpose framework such as MapReduce and (ii) specialized RDF systems. In this paper, we only deal with MapReduce-based RDF engines due to the limit of space.

MapReduce-based RDF engines

MapReduce is a popular parallel processing tool that provides high scalability as well as simple abstraction. Therefore, many studies have been done with MapReduce although it has some inherent limitations [15]. It is noteworthy that most M/R-based RDF engines do not well utilize index mechanisms since MapReduce is originally devised for *batch processing* rather than *ad hoc queries*. Indexes are considered inefficient for batch jobs due to their expensive building cost only for one-time use.

SHARD [21] is a distributed RDF engine built with MapReduce. All the RDF triples are stored in a single file in HDFS and RDF triples are hash-partitioned across nodes. SPARQL queries are evaluated as M/R job iterations. A subquery pattern is evaluated within a M/R job and its results are transferred to a subsequent M/R job. SHARD does not utilize any indexing scheme so that it needs to scan the entire dataset for query evaluation. HadoopRDF [11] is another RDF engine built with MapReduce. It partitions RDF triples into multiple files in the way that each file contains all the triples that have the same predicate. It also locates non-duplicate binary joins together into a M/R job to minimize MR job iterations. SHAPE [14] also uses MapReduce but it uses semantic hash partitioning scheme to group vertices on the basis of URI hierarchy for improving data locality. However, these systems suffer from workload imbalance if a few triple patterns dominates overall data distribution. H2RDF+ [19] is a distributed engine based on both MapReduce and HBase, the open sourced version of BigTable. It materializes combinations of RDF triples and store them into HBase tables in order to utilize some features of HBase, *e.g.*, sorted keys and range-partitioned tables based on the keys. However, H2RDF still join RDF triples with M/R job iterations thus a complex queries can expand the iterations. CliqueSquare [9] partitions RDF triple in three ways, by hashing them on the basis of subject, predicate and object for increasing data locality. It exploits the data replication feature of HDFS to locally process all first-level joins on each node. It also tries to minimize the number of M/R job iterations for RDF joins with a shallow query plan tree and multi-way join operations.

Multi-query optimizations

Multi-query optimization on MapReduce is regarded as an extended version of the classical *job-shop problem* [5] that has a long history. A few studies related to multi-query optimization on MapReduce have been reported in the literature [18, 23] in the context of relational processing. They provide generalized grouping techniques that merge multiple jobs into a single job

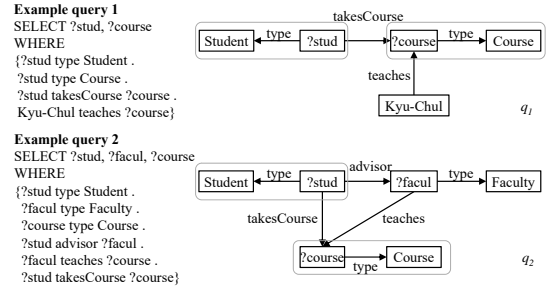

Figure 2: Example of common subquery patterns in two SPARQL queries

thereby enabling the merged jobs to share input scans and common mapped outputs. Some studies address the issue in the context of SPARQL queries [13, 20]. Multi-query optimization for SPARQL is also proven to be *NP-hard* so that they rather propose heuristic algorithms that partition a set of queries into groups such that queries in each group can be optimized together. However, their algorithms [13, 20] are focused only on working on a single-machine engine rather than a distributed environment such as MapReduce. Therefore, all the approaches are hard to be directly applied to distributed SPARQL engines. On the contrary, we focus on multi-query optimization on MapReduce-based distributed SPARQL engines. To the best of our knowledge, this is the first work that provides a solution for the multi-query optimization problem in MapReduce-based SPARQL engines.

3 MULTI SPARQL QUERY PROCESSING

SAMUEL performs its query evaluation in three phases: (i) preprocessing phase, (ii) labeling & filtering phase, and (iii) iterative joining phase (see Fig. 1). In the preprocessing phase, RDF data and a set of SPARQL queries are loaded on HDFS. In our system RDF triples are simply stored in a single file where each triple is recorded as a single line as it is, except that redundant URIs and labels are substituted by unique IDs for saving storage volume and I/Os. Note that we do not use any partitioning or index mechanisms for RDF data since we only show the effect of our approach, distinguished from the benefits that we can get with the mechanisms. Query loader decomposes SPARQL queries into a set of distinct triple patterns, and then associates each triple pattern with a set of queries that contains the triple pattern like Fig. 2. It also builds an in-memory radix tree where a tree node at each level represents a unique *S*, *P*, and *O* of triple patterns, respectively. With the radix tree, SAMUEL rapidly finds triple patterns matched to an input RDF triple while query evaluation.

The labeling & filtering phase is implemented with a single M/R job. In the phase, RDF triples are labeled with IDs for their corresponding triple patterns by traversing the radix tree and also are filtered out if they have no corresponding triple patterns. This work has an analogy to filtering stream data. Since reducers aggregate RDF triples that has the same pattern, it allows us to easily compute the cardinality of each triple pattern in the phase.

Based on the cardinality information, our query optimizer builds a global query plan tree that has the lowest possible height to minimize the number of M/R job iterations for joining RDF triples. Redundant join operations are removed as each join operation is shared by multiple queries. When assigning binary RDF join operations to reducers, we consider both join cost and transmission cost to minimize and balance workloads across reducers. It is achieved by summing the cost of every RDF join operation

Dataset	LUBM-100M	WatDiv-1M	WatDiv-10M	WatDiv-100M	WatDiv-1B
# of triples in total	138,280,374	1,098,468	10,989,614	109,795,305	1,098,717,244
# of distinct triples	133,573,856	1,085,817	10,906,204	109,051,965	1,091,667,092
# of distinct patterns matched to queries (1,000 queries for WatDiv and 14 queries for LUBM)	23	361	355	358	355
Data size(GB)	23.02	0.14	1.45	14.63	148.23

Table 1: Statistics of RDF Datasets

Figure 3: Data skewness in two datasets

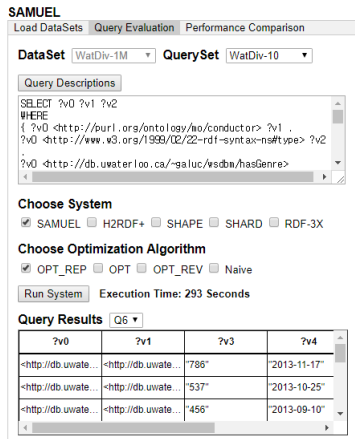

Figure 4: SAMUEL GUI

assigned to each reducer and the cost of each RDF join operation, implemented with binary hash join, is computed by summing the sizes of two input RDF triple pattern lists. Triples are grouped on the basis of distinct triple patterns and the groups are ordered in a descending order of cardinality. We devise a heuristic optimization algorithm based on *first-fit decreasing* scheme whose input is a set of ordered lists of the distinct triple pattern groups. Some triple patterns have very high cardinality as shown in Fig 3. We thus allow splitting a very large triple pattern list into multiple small lists for better workload balance. Note that our global query plan tree is gradually built. That is, the n -th level in the tree is computed right before running the n -th joining phase. In each joining phase, implemented by another M/R job, mappers read grouped RDF triples and tag reducer IDs to the triples according to the global plan tree. Since mapped outputs are shuffled by intermediate keys, triples tagged by the same reducer ID go to the same reducer together and are then joined. Again, each reducer computes the cardinality of its joined outputs and the cardinality information and joined results are stored in HDFS. Then, our optimizer repeats building the $n+1$ -th level of the plan tree with the cardinality of the results of the n -th joining phase.

4 DEMONSTRATION

During the demonstration, audience are invited to compare our system with other distributed SPARQL engines based on the MapReduce framework, interacting with the system to run queries and to check the influences of optimization techniques.

Hardware setup: We implemented our system with Hadoop version 1.2.1. SAMUEL as well as compared systems were installed and run on a cluster of 15 nodes, each of which was equipped with an Xeon E5-2620 2.1GHz CPU, 64GB memory and an 1TB 7200RPM HDD, running on Ubuntu 12.04. All the nodes were connected via Gigabit switching hub and a node is designated as a master node. We basically used the same settings for our cluster for fair comparison. However, the settings were sometimes tuned for showing the best performance of compared systems.

Dataset: We used two datasets, which had been widely used for measuring SPARQL engines in the literature [4, 10]. Table 1 and Figure 3 present the statistics for datasets used in our demonstration and their data distributions. Both datasets exhibited high skewness in their data distributions in that only a few of triple patterns dominated most of the data distributions (see Fig. 3).

Compared systems: In our demonstration, we compare our system with RDF-3X [17], a single-machine SPARQL engine that utilizes various indexes, and three other MapReduce-based systems, *i.e.*, SHARD [21], SHAPE [14], and H2RDF+ [19]. For evaluation, the performance of each system was averaged over five runs excluding the maximum and minimum values.

Demo scenarios and interaction

We provide a user interface shown in Fig. 4 to demonstrate the performance of SAMUEL using large-scale RDF datasets, *i.e.*, LUBM and WatDiv. In our demonstration, we however use only a few fractions of the two datasets due to the limited time and computing resources. However, we still present our evaluation results performed with all the datasets (see Fig 5). Currently, SAMUEL supports a subset of SPARQL language, *i.e.*, basic graph pattern matching. In our demonstration, users will be given a list of SPARQL queries generated from WatDiv for the datasets in Table 1. Users are also allowed to load their own queries and RDF data into the system and run the queries themselves. During the processing, users will be explained with Hadoop GUI and our own UI how our system processes multiple SPARQL queries simultaneously. Users will also check how features of SAMUEL affect the overall performance as they turn on and off the features, *i.e.*, sharing input scan and filtered solutions, optimization policies, and so on.

ABSTRACT

Existing trajectory patterns, such as flock, convoy, swarm, and gathering, are to detect moving clusters staying or travelling together for a certain time period. But these patterns model group movement behaviors after moving objects' gathering together. This may result in losing golden opportunities to detect emergency incidents earlier, such as traffic congestion and serious stampedes. In this work, we propose a novel group pattern, called converging, which can model converging behaviors of moving objects. As a proof-of-concept, we implemented a visual analytic system GEDetector based on trajectory streams to detect gathering events as early as possible. A user-friendly interface is designed to help users gain insights into gathering events from spatial and temporal aspects. Finally, we demonstrate the effectiveness and efficiency of our system by using a real world dataset.

1 INTRODUCTION

The existing group pattern mining methods, such as flock [1], convoy [2], swarm [3], travelling companion [4], and gathering [5], are to discover a group of objects that stay or travel together for a certain time period [6]. Analysis tasks based on group patterns can be used for enormous applications, including transportation optimization, public security, advertisement delivery, travel recommendation, and animal movement study and so on [7]. In this work, we develop a visual analytic system GEDetector to detect gathering events in trajectory streams.

Previous studies on group patterns are unsuitable for detecting gathering events despite of wide applications of group patterns. It is worth pointing out that, most of group patterns can capture group movement behaviors only after moving objects gather together. For example, convoys require that each group of objects travel together during the whole pattern lifetime. Gatherings also require that all participators stay together at the most timestamps in the pattern lifetime. However, in real life, people are more interesting in modelling and identifying group converging behaviors before the gathering events actually happen, since

this helps to proactively report and handle the coming public incidents, such as traffic congestion and serious stampedes.

However, the efficient discovery of convergings in trajectory streams is a challenging task due to two main reasons: (1) the existing group patterns cannot capture intuitively converging behaviors of gathering events; (2) the discovery of convergings may face huge search space and incur high cost. In this work, we propose a novel group pattern, called converging, which can model the converging behaviors of moving objects and detect gathering events in trajectory streams. Furthermore, we propose a converging pattern mining method based on cluster containment join (CCJ), which utilizes a signature quad-tree based index, called SQTI, to organize clusters hierarchically and spatially. The SQTI based mining algorithm enables us to rapidly reduce search space and efficiently identify interesting and useful converging patterns.

In this demo, we present a novel Gathering Event Detection system, named GEDetector, which is designed to achieve an early detection of gathering events through mining converging patterns in trajectory streams. The GEDetector has been deployed on a virtual machine of Alibaba Cloud, which can be accessed at <http://103.242.175.191:5456/gedetector>.

2 PROBLEM FORMULATION

The identifying characteristic of a gathering event is a *converging*, which is a group of moving objects gathering from different directions for at least k_t timestamps. It is easy to see that, converging patterns focus on the earlier stages of gathering events compared to other existing patterns. To accurately model converging behaviors, we introduce *participators*, which are used to indicate the objects appearing in at least k_p consecutive clusters of this converging, and require that a converging should contain at least k_m participators.

Now we use Fig. 1 as an example to illustrate the converging pattern, and let $k_t = 2$, $k_p = 2$, $k_m = 4$, in which there are six moving objects joining a gathering event from different directions and forming one cluster. Additionally, there are two clusters (i.e., c_1 & c_2) that are gathered at t_2 and later join the cluster c_3 at t_3 . Such set containment between two clusters is called *cluster containment relation*, denoted by \subseteq_c . Thus, we have $c_1 \subseteq_c c_3$ & $c_2 \subseteq_c c_3$ in Fig. 1(a). By joining these two cluster containment relations, we can construct a containment tree to model converging behaviors of moving objects, as shown in Fig.

1(b). To realistically model converging behaviors, a converging requires to have enough participators who appear in the most snapshot clusters during the event lifetime. As shown in Fig. 1(c), the group of participators $\langle o_1, o_2, o_3, o_4, o_5 \rangle$ satisfies the above requirements because they appear in two clusters (i.e., c_1 & c_2) at time t_2 and t_3 . But, the group excludes o_6 , since o_6 only appears in one snapshot cluster, which is less than the given threshold $k_p = 2$.

Figure 1: Example of a converging

3 FRAMEWORK OF GEDETECTOR

Fig. 2 shows the framework of GEDetector, which consists of three major modules: (1) **snapshot cluster discovery (SCD)**: we perform density-based clustering on the moving objects to discover a set of snapshot clusters at each timestamp; (2) **cluster containment join (CCJ)**: we perform a cluster containment join on any two snapshot cluster sets at consecutive timestamps, and return a collection of cluster containment relations; and (3) **converging detection (CD)**: we construct cluster containment trees through joining all cluster containment relations, and further derive the qualifying results from the candidates of cluster containment trees according to the aforementioned requirements of converging concepts.

The detection procedure of GEDetector is as follows. The initial input of GEDetector is a trajectory data stream that is periodically collected at timestamp t_i . When the latest batch of trajectory data is appended to the trajectory database, GEDetector will trigger the detection process in an incremental manner, as shown in Fig. 2. At t_i , the snapshot clusters are first discovered from the new trajectory data by clustering algorithms. Then, the CCJ is performed between the snapshot cluster sets of t_{i-1} and t_i . Correspondingly, the new convergings may be generated, and some existing convergings may be also updated. The procedures of the first two modules (i.e., SCD & CCJ) can be repeated until no new trajectory data is given. Finally, the qualified converging patterns are derived by the third module (CD).

The efficient discovery of convergings in trajectory streams is a challenging task. First, it is hard to discover all moving objects

attending a gathering event in the same way as many state-of-the-art trajectory clustering methods since they do not stay close together most of the time. Second, to achieve early detection, converging algorithms need to detect gathering events in an incremental manner. Third, identifying cluster containment relations between any consecutive timestamps may face huge search space and hence incur high cost. Fourth, the system has to ensure the effectiveness of mining converging patterns from trajectory streams.

To tackle these issues, the GEDetector employs a general framework for effective and efficient discovery of convergings. Specially, To boost the performance of CCJ, which is a fundamental part of mining converging patterns, we develop a signature quad-tree based index, called SQT, to organize clusters hierarchically and spatially, and correspondingly propose an SQT based CCJ (SQTCCJ) approximate algorithm, which enables us to rapidly filter unqualified candidates and efficiently identify matches by considering cluster containment relationship and spatial proximity simultaneously. In addition, to facilitate evaluating set containment, we approximate the sets of moving objects by means of a signature technique, and use a bloom filter method [8] to generate signatures in this work.

The SQTCCJ consists of two phases: (1) SQT construction; and (2) SQT probing and verification. Firstly, we construct an SQT structure to organize all candidate clusters. Then, SQTCCJ performs a cluster query on SQT for each query cluster to obtain all cluster containment matches.

SQT Construction. An SQT is constructed in the following manner. We start with a set of candidate clusters, and insert representative points of these clusters into a spatial region according to their positions. Then we partition the whole spatial region by recursively subdividing it into four square quadrant cells (i.e., NE, NW, SE, and SW), until the number of points in it meets a certain threshold, ρ . Otherwise, the quadrant cell continues splitting into four small ones. The tree structure of SQT follows the above spatial decomposition. Although the SQT is organized in the same way as the traditional quad-tree, the difference is that each node is assigned a signature consisting of m bits, which represents a set of moving objects of all clusters in the corresponding cell. In the next phase, we will utilize signature comparisons to support membership query.

EXAMPLE 1. We use the data in Fig. 3(a)(b) to illustrate the construction of SQT. Based on these clusters, we build an SQT for searching clusters, and its nodes are organized as Fig. 3(c)(d) shows.

SQT Probing and Verification. The search process based on SQT works in a top-down manner instead of in a recursive manner. And its goal is to find the nearest quadrant cell to the query point. Specifically, when a query cluster q comes, the search starts at the root node and utilize the query signature and its coordinates to probe the index structure. When it visits a internal node p with signature $p.sig$, we need to check it to see if $q.sig \vee p.sig = p.sig$. If yes, it immediately performs a four-way comparison operation at the node, and then chooses the subtree where the centroid of its corresponding MBR is nearest to the query point. Otherwise, it visits the sibling nodes. When it reaches a leaf node, we need to verify all clusters to check if there exists a super-cluster in the leaf node. If yes, we can obtain a cluster containment match; otherwise, we get a mismatch.

EXAMPLE 2. Continuing with Example 1, we illustrate how to perform the query process based on SQT. For a given query

Figure 2: Framework of GEDetector

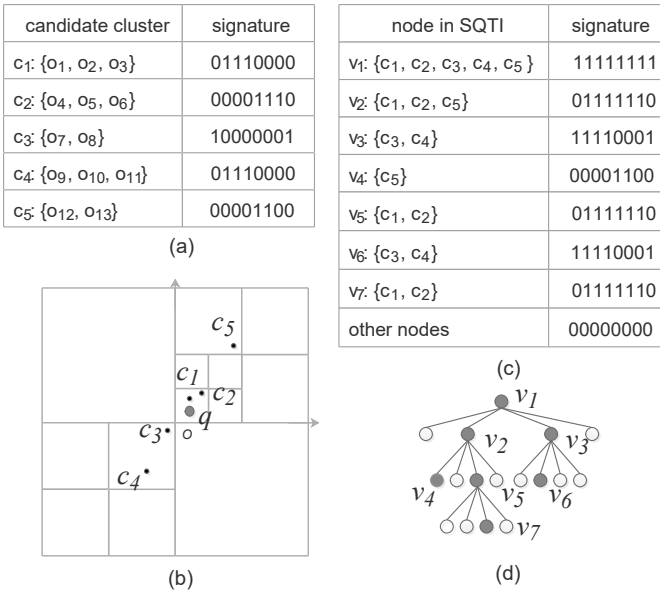

Figure 3: Illustration of SQTI construction

$q = \{o_1, o_2\}$ with the signature 01110000, the search starts at the root node v_1 . Then it need to check the nodes v_2 and v_3 to see if the query signature is contained. Unfortunately, both v_2 and v_3 satisfy the above condition. In this case, the search algorithm in the traditional tree will suffer from a backtracking problem incurred by a recursive paradigm. But, the search in *SQTCJ* can avoid this since it only takes the nearest quadrant cell to the query position. As a consequence, the search chooses the sub-tree rooted at the node v_2 . It reaches the leaf node v_7 along the path $v_1 v_2 v_5 v_7$ after signature comparisons. At the leaf node, we still need to verify all clusters in it because of false positive. Finally, we can obtain a match $q \subseteq c_1$.

4 DEMONSTRATION

4.1 Demo Interface

In the demo of GEDetector, we provide a monitoring map interface for users to visualize and monitor gathering events dynamically. A screenshot of the demo is shown in Fig. 4. This demo interface allows users to investigate gathering events from various views, including spatial view, temporal view, and detail view. The map on the upper left pane of the GUI visualizes the discovered gathering events using map markers, which represent the location points of all gathering events. The bar chart on the bottom left pane of the GUI represents the basic characteristics

Figure 4: Screenshot of main interface

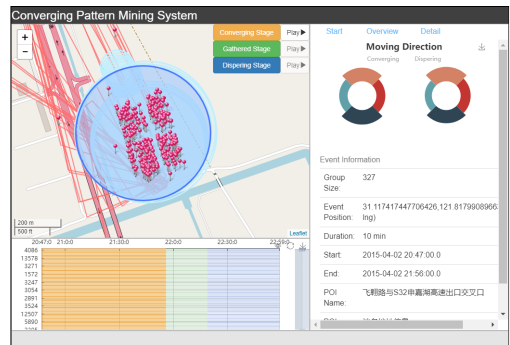

Figure 5: Visualization of a taxi gathering event at Shanghai Pudong international airport

of gathering events, such as scale, start time, durability, and point of interest (POI) type. When the user clicks on any map marker, the interface switches to the display mode of the corresponding gathering event. The user can obtain more detailed information of the gathering event, including the routes of all participators, direction statistics of all routes (represented by a wind rose diagram), the event timeline, and other properties. As shown in Fig. 5 and 6, our system has detected a typical gathering event at Shanghai Pudong international airport, where a large number of taxis converge together for waiting guests.

In summary, the GEDetection system can allow users to interactively monitor and visualize gathering behaviours in various ways, and also help users gain insights of the identified gathering events from both spatial and temporal aspects.

Figure 6: Satpic of a cabstand at Shanghai Pudong international airport

5 PERFORMANCE OF GEDETECTOR

To evaluate the performance of our system, we conduct all experiments based on a real trajectory dataset, namely Shanghai taxi cab traces (BigTaxi), which is sourced from the one generated by 13,000 taxis of Shanghai in a period of 30 days (from April 1st to April 30th in 2015). In this section, we investigate the efficiency of the SQTCCJ algorithm, which is the essential part of our system.

The SQTCCJ algorithm may generate approximate results due to missing some cluster containment matches, only when a result cluster does not share the same cell with the query. Therefore, we use an accuracy rate metric, which is the fraction of matches obtained by SQTCCJ over the total amount of those of NLCCJ, to evaluate the result of SQTCCJ algorithm. In Fig. 7(a), we show accuracy rates of SQTCCJ. We can find that SQTCCJ can find almost all candidate clusters when the parameter ρ is greater than 20.

Next, in Fig. 7(b)(c), we show another nice property of SQTCCJ, namely insensitivity to key parameters including the signature length m and the number threshold ρ . In addition, we note that we can tackle the problem of CCJ using set containment join methods if we treat a cluster as a set. Thus, we compare our algorithm with TT-Join [9], which is the state-of-the-art method evaluating set containment join. As we can see from Fig. 7(d), SQTCCJ significantly outperforms TT-Join especially as the dataset size increases.

1 INTRODUCTION

When Alice goes trekking in the French Alps with friends, she is equipped with a pedometer to measure her efforts, takes pictures using her smartphone and uses a mobile coach app to monitor her trip and GPS trail. But how could Alice have a transversal view of the personal data she generates and how could she share -part of- her data with her friends?

The Personal Cloud paradigm emerges[1] (e.g., Cozy Cloud, ownCloud, Databox to cite a few) and holds the promise of a Privacy-by-Design storage and computing platform where each individual could gather her complete digital environment in one place and share it under control. Conjointly, smart disclosure initiatives pushed by legislators (e.g., EU General Data Protection Regulation) and industry-led consortiums (e.g., Blue Button for medical records in the US, Midata in the UK, MesInfos in France) give shape to this paradigm by letting individuals getting their personal data back from the applications that collected them. Hence, Alice could link her personal devices to the personal cloud platform of her choice and then manage the personal data she generates when trekking and regulate data sharing at will. However, the personal cloud paradigm causes a gravity shift of data management and data security from organizations to individuals, who are usually not database administrators nor security experts. Unfortunately, the main existing access control models (e.g., RBAC, ABAC or TBAC [2]) are geared towards central authorities and require a deep expertise to define users, roles and privileges. Some decentralized models have been proposed to let individuals manually define their own sharing preferences, often based on Web of Trust-like approaches [8] or on the owner's social graph [3], but offer limited expressive power and poorly cope with the versatile nature of the personal cloud. To tackle this issue, several works aim to ease the sharing administration. For example, [5, 12] give the possibility for the owner to share any kind of personal data through the use of attribute-based sharing rules, while [4, 7] explore machine learning techniques to automatically infer the best sharing policies. However, they provide little means for individuals to control the actual effects of their policies and could actually result in unexpected data leakage. This contradicts a founding principle of the Personal Cloud paradigm, namely enabling individuals making sovereign decisions about the sharing of their data [1]. The problem is exacerbated in a ubiquitous and smart surrounding producing continuous flow of daily activity events.

We derive from these statements a new sharing paradigm dedicated to the personal cloud context, called SWYSWYK (Share What You See with Who You Know). SWYSWYK relies on two founding principles: (1) provide intuitive means to derive sharing rules directly from the personal cloud content and help the personal cloud owner administer the resulting sharing policy by

visualizing and sanitizing its net effects and (2) provide a secure personal cloud architecture giving tangible guarantees that the sharing policy will be properly enforced, whatever the security expertise of the owner.

In [11], we investigated point (2) and proposed a secure architecture combining untrusted, isolated and secure execution environments. [10] presented a practical instantiation of this architecture where the reference monitor runs into a secure hardware device. In [9], we focus on point (1) and introduce the semantics of the SWYSWYK sharing paradigm and discuss the specificities of its administration.

This demonstration focuses on point (1) with the goal to assess the practical interest of our paradigm. To this end, we have integrated SWYSWYK in a real personal cloud platform, namely Cozy, and apply it to a smart surrounding scenario inspired by Alice's one. A video of the demonstration is available online¹. We refer to [10] for a demonstration focused on the security and scalability of the platform in a constrained environment.

In this paper, Section 2 presents the SWYSWYK baseline, Section 3 gives the scenario and Section 4 concludes.

2 SWYSWYK PARADIGM

2.1 Baseline

SWYSWYK is not yet-another access control model. It is rather a new sharing paradigm, helping the derivation of expressive access control rules directly from the personal cloud content and providing convenient tools to administrate the resulting policies. The originality of SWYSWYK relies on two core principles helping circumventing the aforementioned difficulties of data sharing in the Personal Cloud context:

Documents are rules. The personal cloud content on its own conveys intuitive sharing rules, e.g., share pictures and related events of a trek with people who appear on these pictures and as such are identified as participants in that trek. Such rules should be straightforward to express, as the related permissions could be derived from the documents' content. The subjects targeted by the document, called identifyees [6], should be extracted from the document content and enter in the rule definition. We call *reflexive sharing rules* the rules based on this principle.

Subjects and objects are documents. The content of a personal cloud also intrinsically describes the individual's acquaintances under different forms (e.g., contact files, identity picture.) and conversely, acquaintances are associated with pieces of information in the owner's space (e.g., agenda entries, photos on which a friend appears). A corollary is that for each permission granted to a subject *s* on an object *o*, viewable documents should represent *s* and *o*. More generally, the result of a sharing policy (sets of sharing rules) must be viewable by the personal cloud owner, who can thus precisely understand what is the net effect of this policy. For example, a stream of GPS tracks may be represented

¹http://wanda.inria.fr/demos/videos/swyswyk_model.org

as trajectories on a map and time series of activities logs could be represented in graphs.

The combination of these principles gives substance to the *Share What You See with Who You Know* (SWYSWYK) paradigm. This is in direct opposition with existing approaches that are either very limited and manual, or based on complex and opaque computations that cannot be easily understood by the end user.

2.2 Sharing Paradigm Semantics

SWYSWYK aims at providing simple expressions for sharing rules and make the sharing policy self-administrated when the personal cloud content evolves. We show here how this can be captured within simple semantics, combined with a set of simplifying assumptions. First, our sharing paradigm relies on a closed policy, i.e. every action not explicitly granted is denied. Actions are CRUD operations on documents in the personal cloud. The paradigm supports only authorizations (positive rules) but allows the owner to post-filter the produced Access Control List (ACL) when exceptions need to be declared. Consequently, there is a direct translation between sharing rules and sets of ACLs: an action a is granted to subject s on document d iff $(s, d, a) \in ACL$ and is denied otherwise. The sharing is by construction consistent (the decision is unique), complete (the decision always exists) and can be evaluated in logarithmic time.

For the sake of conciseness, we do not formally define here all the notations and operators of SWYSWYK. Rather, we illustrate the paradigm through a single type of sharing rules, namely the reflexive sharing rules, and refer to [9] for a complete description.

Reflexive sharing rules. These rules express the sharing of documents with subjects appearing on it. They implement the documents are rules principle and are thus considered as first-class citizen rules:

$$ACL \leftarrow \{(s, d, a) \in S \times D \times A / Filter(d, Q) \wedge MatchS(DI(d), SI(s))\}$$

$Filter$ and DI are user-defined, platform dependent, functions. $Filter$ returns true if a document d of the personal cloud satisfies the qualification Q , that can be expressed on the metadata or on the content of d . DI extracts identification traits of individuals, denoted next by IT , from d . IT must uniquely represent a subject in the personal cloud and can combine simple attributes (e.g., email, phone number) or complex representation (e.g., facial features, fingerprint). SI and $MatchS$ are internal SWYSWYK operators. SI returns the IT from a registered subject s and $MatchS$ returns true if the compared IT s are equivalent. Below are various illustrations of reflexive sharing rules.

Example 1. Share the pictures taken during my trekking sessions with the people appearing on it:

$Q: docType='photo' \wedge tagGallery='trek'$

$DI: face\ detection\ algorithm$

$MatchS$: here, compares the facial features extracted from DI with the ones returned by SI from known subjects.

Example 2. Share the minutes of meetings with the attendees:

$Q: docName\ like\ 'minutes-\%.doc'$

$DI: extract\ attendee\ names\ from\ a\ minute\ document$

These two examples, extracted from two different application contexts, show the generality of the sharing paradigm.

2.3 Sharing Administration

To make the sharing paradigm practical, subject declaration and maintenance should be (quasi) automatic while respecting the owner's privacy. In SWYSWYK, the notion of rule consistency

concretizes the fact that the effects of all rules can be visualized (and then easily controlled by the owner), the notion of exceptions permits customization of these effects according to the owner's preferences, and subject administration can be automatically performed such that the set of subjects grows along document insertions and rule declarations with minimal interactions.

Rules Consistency. A SWYSWYK sharing rule is said well-formed iff it only produces ACLs involving viewable documents shared with recognizable subjects: $\forall sr \in SR, \forall acl \in ACL, acl.d \in DV \wedge acl.s \in DS$, where SR is the set of sharing rules, DV the set of viewable documents and DS the subset of viewable documents characterizing a unique subject. Any acl which does not satisfy this condition is filtered out.

Rules Exceptions. Instead of introducing interdiction rules to capture exceptions, which makes the net effects of the resulting policy complex to apprehend, we simply give the owner the ability to filter out the permissions which hurt her privacy (considered as suspicious ACLs). We introduce three types of watchdog triggers to highlight suspicious permissions:

$$What(Q_s, A) \rightarrow \{(s, \{(d, a)\}) / (s, d, a) \in ACL^* \wedge s \in Q_s(S) \wedge a = A\}$$

$$Who(Q_d, A) \rightarrow \{(d, \{(s, a)\}) / (s, d, a) \in ACL^* \wedge d \in Q_d(D) \wedge a = A\}$$

$$Which(Q_s, Q_d, A) \rightarrow \{(s, d, a) / (s, d, a) \in ACL^* \wedge s \in Q_s(S) \wedge d \in Q_d(D) \wedge a = A\}$$

ACL^* corresponds to the set of newly created/updated ACLs. $What$ identifies, for each sensitive subject, the new set of (document, action) she is granted to (e.g., *which new documents can be seen by my boss?*). Who identifies, for each sensitive document, the new set of subjects s with granted action a on them (e.g., *which new subjects have a read access to my medical records?*). Finally, $Which$ identifies new ACLs combining a selection of (sensitive) subjects and documents (e.g., *which new authorizations my colleagues have on my family photos?*).

Subjects Administration. New subjects can automatically be created while inserting new contact files or address book entries. The IsS operator is invoked each time (1) documents are created or updated in the personal cloud and (2) a new rule invoking IsS is defined, thus enriching the set of subject S along document insertions and rule declarations as side-effects of the function. Each $s \in S$ is made of the extracted identification traits and at least one generated credential for the authentication.

2.4 Sharing Enforcement

General principle. The creation, maintenance and evaluation of a set of SWYSWYK permissions are as follows: (1) the owner creates sharing rules and watchdog triggers to be applied on her personal cloud; (2) a *rule translator* translates the selected rules into candidate (ACL^*) and suspicious ($ACL^?$) ACLs and materialize them; (3) the owner checks the suspicious ACLs at will and accepts (ACL^+) or rejects (ACL^-) them using the *administration GUI*; (4) the *reference monitor* authenticates subjects and evaluates *Allowed* (i.e., $Allowed(s, d, a) = true$ iff $(s, d, a) \in ACL^+$) and delivers the requested documents accordingly.

ACL production and maintenance. Five operators are required to translate any sharing rule into ACLs, namely $Filter$, DI , SI , IsS and $MatchS$. The data flow between the operators to translate a reflexive sharing rule into ACLs is shown in Figure 1. At declaration time, the rule tree is evaluated over all documents of the personal cloud. First, $Filter$ operators are evaluated at the leaf of each branch to select the targeted subjects documents (right

branch) and the targeted objects documents containing identifiers (left branch). Then *DI* operators extract the list of *ITs* from the targeted subject documents (left branch) and from the objects documents (*ITs* of the identifiers). In the right branch, *IsS* tries to match the extracted *ITs* with the subjects already registered in *S*, then *SI* appends the identified *ITs* to each subject. Finally, *MatchS* joins the left and right branches on subject *ITs* and produces the (candidate) ACLs. At insertion of a new document *d* in the personal cloud, the *Filters* of all rules are evaluated against *d* to check whether new candidate ACLs can be produced.

Figure 1: ACL production

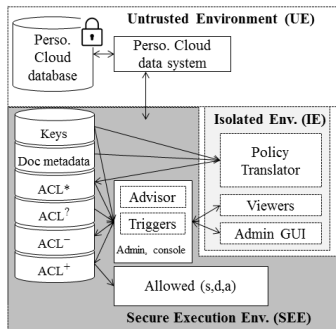

Figure 2: Reference architecture

Secure enforcement of sharing policies. The enforcement issue is exacerbated when the personal cloud platform runs on the owner’s side, the security of which can be questioned. In [10], we proposed a reference architecture tackling this issue, displayed in Figure 2. It consists of three environments: (i) an *untrusted environment (UE)* on which no security assumption is made for the code nor for the data, (ii) an *isolated environment (IE)* on which general purpose code can be run with the guarantee that it cannot leak any information but with no guarantee about the soundness and honesty of its output and (iii) a *Secure Execution Environment (SEE)* which runs only certified core programs and protects data and code against snooping and tampering. In Figure 1, the light grey operators (*DI* and *Filter*) are run in the *IE*, as they are made of untrusted third parties code, while the ones in dark grey are executed in the *SEE*. Administrative tools helping the owner to control and sanitize the ACLs are partly hosted in *SEE* (e.g., watchdog triggers) and in *IE* (e.g., document viewers).

3 DEMONSTRATION

The objective of this demonstration is to show that the SWYSWYK paradigm makes sense in concrete environments. Hence, it considers a ubiquitous surrounding scenario with connected smart devices producing continuous data streams that are gathered and stored in the Cozy personal cloud platform. SWYSWYK has been partially integrated in Cozy, a simplified version being part of the server stack².

3.1 Demonstration platform

The platform consists of an Android smartphone, a Withings smart watch and a local Cozy instance running on a laptop with Ubuntu 16.04. Additionally, several Cozy instances running on a remote server are used to simulate other subject’ personal clouds. Pictures and GPS tracks are synced with the local Cozy instance thanks to the Android Cozy app. Pedometer data from the smartwatch is retrieved through the Withings’ API. The Cozy stack running on the laptop is implemented in Go and stores documents in a CouchDB database. The Cozy apps are developed in JavaScript, with the React framework.

3.2 Demonstration scenario

The demonstration focuses on the usage of the SWYSWYK paradigm. The scenario is composed of four steps, as summarized in Figure 3 and described in the video accessible online:

Step 1 - Data collection: this step illustrates how surrounding data produced by smart devices can be collected by the Cozy platform to be further exploited. A Cozy instance is populated with a set of predefined documents and timely integrates data produced by Paul’s smartphone and pedometer. A Sharowalky application developed on Cozy (for illustration purpose) manages Paul’s trekking data, namely his photos, GPS trails and physical activity. The attendees are invited to connect to Cozy as Paul (the personal cloud owner and incidentally co-author of this paper), open the Sharowalky app and browse days of trekking.

Step 2 - Sharing definition: the Sharowalky app proposes the attendee to share the photos of a trekking day with Paul’s friends appearing on them (among which Riad). The GUI presents the semantics of the underlying sharing rule, that is a typical SWYSWYK reflexive rule represented as logic-based predicates on Cozy metadata. The GUI allows the attendee to identify that Riad has been granted access to certain pictures of the circle, confirmed when connecting to Riad’s personal cloud. The attendee can also share the GPS and activity trails of the circle with Riad very easily.

Step 3 - Sharing administration: the access control console allows the attendee (playing Paul’s role) to visualize and control the net effect of the current access control policy (set of all existing sharing rules). All resulting permissions are shown as viewable ACLs, i.e., triples $\langle \text{subject}, \text{object}, \text{permission} \rangle$ where each *subject* and *object* are personal cloud documents which can in turn be visualized. The GUI brings to light a suspicious permission that the attendee is invited to remove (or confirm according to her will).

Step 4 - Dynamicity: the demo operator finally selects from the Cozy the set of pictures taken during the conference, showing groups of people. Then, he takes a selfie with a demo attendee and creates her contact based on the photo, triggering her registration as a subject. This automatically grants her a read access on all the

²<https://cozy.github.io/cozy-stack/sharing.html>

conference pictures on which she appears, including the selfie and forthcoming ones, thanks to a pre-trained face recognition model.

3.3 Demonstration results

The demonstration shows an implementation of the SWYSWYK model in the Cozy platform. The semantics of the model and its administration principles, based on the combination of *the documents are rules and subjects and objects are documents* motto, opens to a set of benefits:

Ease-of-use. The content of a personal cloud, which describes Alice’s acquaintances, and conversely, acquaintances which are associated with pieces of information of Alice, are used to express sharing rules. Most interesting rules could also be easily shared via the Cozy marketplace, and reused among interested users.

Self-administration. The sharing rules are self-administrated while the personal cloud content evolves. Typically, new subjects (attendees) are automatically created while inserting new contact files or address book entries and a search of correspondences with potential content to share with them is automatically triggered.

Visualization. Subjects and objects are all viewable documents of the personal cloud. Hence the net effect of any sharing policy can be visualized and precisely apprehended by Alice (e.g., the GPS tracks pictured in a map that she is ready to share with a subject represented by her identity picture).

Control. Administration tools are provided to ease the detection of suspicious permissions and sanitize the access control policy. Pursuing this objective, watchdog triggers highlight newly generated ACLs involving sensitive subjects, documents and the associations of presumed incompatible subject/object pairs.

4 CONCLUSION

Finding new ways for the individual to intuitively share personal data and apprehend the real effects of their sharing policies is paramount. This is particularly true in a ubiquitous context where highly sensitive personal data (e.g., well-being data, daily activity logs) are produced at an increasing rate by smart appliances. Gathering these data in a personal cloud allows the definition

of new transversal services of great value for the individual and holds the promise of a better privacy than storing them in a central cloud. However, appropriate sharing tools are needed to regulate data sharing and prevent individuals from exposing their digital life because of too permissive sharing policies. This demonstration shows how the SWYSWYK model tackles this challenge. We hope that this work contributes to a new step in the privacy preservation of personal data.

ABSTRACT

In this paper, we demonstrate Hermes@Neo4j¹, an extension of Neo4j graph DBMS for semantic trajectories of moving objects, on the so-called Spatio-Temporal-Keyword Pattern queries. For this purpose, our engine exploits on hybrid Spatio-Temporal-Keyword (STK) index structures, also boosted by an appropriate selectivity estimation model. Hermes@Neo4j functionality is demonstrated over synthetic and real semantic trajectory datasets.

1 INTRODUCTION

The efficient management and analysis of the spatio-temporal evolution of a moving object (the so-called object's trajectory) has led to the development of plenty of appropriate index structures and algorithms, and even extensions over DBMS during the last two decades [1-5]. Recently, the research community has turned its interest to semantic trajectories [6], where spatio-temporal information is enriched with related annotations about the what, how, and why of movement [6-8].

The paradigm of Location-based Social Networking (LBSN) services, such as Twitter, Instagram and Foursquare, is indicative of this shift: the management and analytics over large amounts of spatio-temporal-textual data may result in useful conclusions about the users' behaviour.

Our motivation in this work is to demonstrate how a

Semantic Trajectory Database (STD), built on top of an extensible DBMS, can efficiently support queries where constraints are set over the triple (spatial, temporal, textual) nature of semantic trajectories. In particular, we aim to demonstrate the functionality of our Hermes@Neo4j STD engine over Spatio-Temporal-Keyword Pattern (STKP) queries [9].

According to [9], an STKP query is defined as follows: Let E_i be a semantic trajectory episode abstraction, which is defined as a partially or completely defined episode. An episode abstraction therefore is an episode where some of its properties – spatial, temporal, textual information – may be missing. An STKP query over a STD takes as input a sequence Q of episode abstractions or the * wildcard (more formally, $Q := \langle p^* \mid p \text{ is either an episode abstraction } E_i \text{ or the } * \text{ wildcard} \rangle$) and gives as output the semantic trajectories in STD that are compatible with Q .

An example of STKP query follows in Fig. 1 [9].

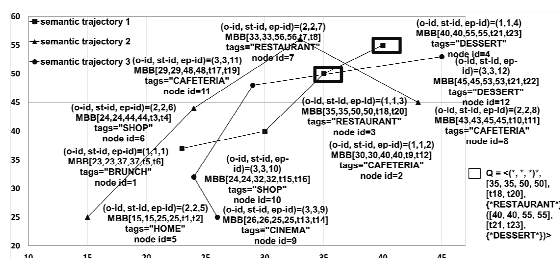

Figure 1: Graph representation of an STD consisting of 3 trajectories along with a STKP query.

In Fig. 1, we depict a STD consisting of 3 semantic trajectories; each trajectory consists of four episodes. An example STKP query Q is also illustrated at the bottom right corner. In particular, Q consists of a number of episode abstractions; with notation E_i^* corresponding to a number of

¹More information regarding Hermes@Oracle and Hermes@Postgres are available at www.datastories.org/hermes.

zero or more episode abstractions of the form E_i . For clarity of presentation the episode abstractions in Q distinguish the temporal from the spatial information, which is not the case in reality where both are organized together in a Minimum Bounding Box (MBB). Actually, Q searches for trajectories starting with zero or more episodes of any kind (see notation $(*, *, *)^*$ in Q), followed by an episode in a spatial [35, 35, 50, 50] and temporal $[t_{18}, t_{20}]$ range with keyword 'RESTAURANT' and ending with an episode in a spatial [40, 40, 55, 55] and temporal $[t_{21}, t_{23}]$ range with keyword 'DESSERT'. The output set includes semantic trajectory 1, which fulfills the above constraints.

The practical contribution of this work is that we present a framework that utilizes recently introduced (a) state-of-the-art hybrid indexes and (b) query processing algorithms on (c) a new STD engine, coined Hermes@Neo4j STD engine.

Hermes@Neo4j STD engine provides efficient and effective storage, indexing mechanisms and a library of utilities that facilitate spatio-temporal and textual operations on data, able to support STDs. More specifically, the merits and contributions of Hermes@Neo4j STD engine are summarized below:

1. Following the successful MOD engine paradigm of Hermes@Oracle [7,8], we designed a new datatype system for the representation and management of Semantic Trajectories into the extensible DBMS architecture of Neo4j [10], an ACID-compliant transactional NoSQL DBMS with native graph storage and processing, implemented in Java. The datatype system is formulated in the context of the graph database, that provides an intuitive model in our case.
2. Neo4j Spatial library [11], which is a library of utilities for Neo4j that facilitates spatial operations on data, is extended for processing the spatio-temporal and textual information of semantic trajectories.
3. We designed efficient access methods for semantic trajectories, called TSR-tree and TSR-tree indexes, for the hybrid indexing of both the spatio-temporal and the textual component. The hybrid indexes combine a spatiotemporal and text index tightly, such that both types of information can be used to prune the search space simultaneously during the spatiotemporal keyword query algorithm processing in STDs.
4. We developed efficient query processing algorithms upon the proposed indices in order to support a useful query type at the STD level, called STKP, as well as algorithms for efficiently importing semantic trajectories into STDs.

Employing separate indexes is weaker in comparison with the tightly integrated proposed state-of-the-art approach, since an efficient resolution of the STKP requires repetitive invocation of spatio-temporal-keyword matching queries.

The paper is organized as follows: in Section 2 we provide a brief presentation of the system architecture, the underlying indexes, etc. (the interested reader is referred to [9] for more details). Section 3 provides more information about system implementation details. Finally, Section 4 outlines the flow of the demonstration.

2 SYSTEM ARCHITECTURE

In this section, we present the core information about the architecture of our framework, illustrated in Fig. 2.

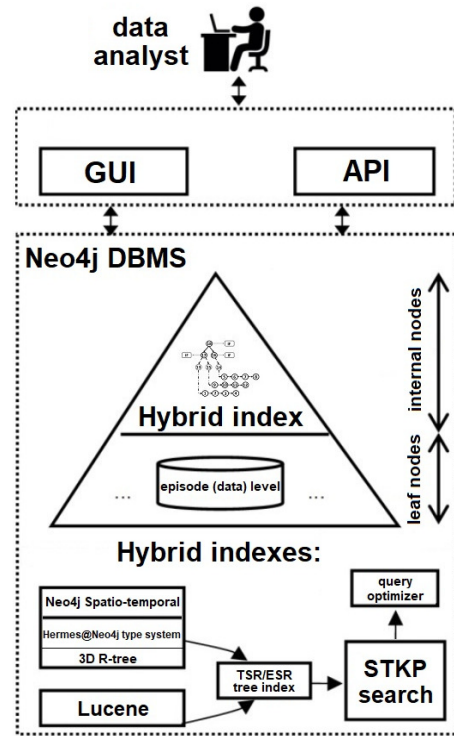

Figure 2: Hermes@Neo4j STD engine architecture.

2.1 Hybrid indexes

Neo4j Spatial R-tree index is extended to support spatio-temporal and classical trajectory-based queries (3D R-Tree) and is also used in order to enable effective spatiotemporal-keyword operations on semantic trajectories. There are two alternative indexing structures to support efficient STKP query processing. The proposed hybrid indices combine tightly a spatial and a text index (i.e. a 3D-Rtree and inverted file, respectively), so that both types of information can be used simultaneously for pruning the search space.

TSR-tree index. In this index, a semantic trajectory is considered as an individual unit for the tree construction. More specifically, for each semantic trajectory we compute its MBB and a list of tags related to the semantics of the episodes, sorted by time. MBB is the minimum bounding box that encloses a specific sub-trajectory of a moving object, along with the start and end times of the movement. At the end, the tags in the list are concatenated to a single string. Specifically, a pseudo-word for each semantic trajectory is created with all the concatenated tags of each trajectory's episode to a single string in order to use it for the keyword query search criteria. The leaves of the TSR-tree index are the above-described approximation of the whole semantic trajectories. For the exploitation of the graph database where our index resides, these leaf nodes are the starting nodes

of the sequence of the episodes of the approximated semantic trajectory. Moreover, inverted files (IFs) are created for all the internal nodes of the tree.

ESR-tree index. As an alternative, we build a tree using as its structural unit the episodes of the semantic trajectories rather than the semantic trajectories themselves. In other words, ESR-tree index takes into account as structural unit for the creation of the 3D-Rtree the episodes of the semantic trajectories. The leaves of the ESR-tree index are the base for the creation of the episode MBBs. Accordingly, the MBBs of the entries of the internal nodes represent the spatio-temporal union of the MBBs of the children nodes. Additionally, for each internal node there exists a pointer to an IF that organizes all the tags of its children nodes. The IFs for each internal node of the tree contain the keywords of the episodes of its child nodes.

2.2 STKP query processing

STKP queries can be processed in Hermes@Neo4j using either TSR-tree or ESR-tree index. In the former (latter) approach, STKP search algorithm takes into account that TSR-tree (ESR-tree, respectively) is built using entire semantic trajectories (episodes of semantic trajectories, respectively) as building blocks [9]. It is noteworthy that STKP search is boosted by an optimization method.

STKP query optimizer. Given a STKP query $Q := \langle E_1, \dots, E_k \rangle$, where E_1, \dots, E_k is a sequence of spatio-temporal-textual constraints over episode abstractions, the STKP query optimizer identifies the most selective episode abstraction E^* in Q , in order to start the execution of the ESR-tree search algorithm from there, thereby pruning candidate results the earliest possible. The cost model that the query optimizer implements decomposes the computation of selectivity of an episode abstraction in two parts, one for the spatio-temporal and another for the textual component of the episode abstraction [9].

Regardless of the query length, it turns out that the search based on the ESR-tree and boosted by the query optimizer, is considerably faster, with the penalty of the higher index creation time and size compared with the TSR-tree approach.

3 SYSTEM IMPLEMENTATION

Our framework provides a robust API with the necessary tools for STD creation, querying, etc. Toward the realization of the concepts of semantic trajectories and STDs presented in the previous section, we followed the object relational (OR) approach for the datatype system of Hermes@Neo4j STD engine. In detail, we follow the abstract datatype (ADT) paradigm and define the episodes and semantic trajectory datatypes that support the definitions in [9]. Upon these datatypes, we register a rich palette of object methods; some indicative examples appear in Table 1. More details are available at Hermes@Neo4j web page².

Table 1: Methods over episodes and semantic trajectories

² <http://infolab.cs.unipi.gr/HermesNeo4j/>

Object	Method	Definition
Episode	duration()	Returns the episode duration.
Semantic Trajectory	num_of_episodes (String tag, String distinct), where “tag” is a set of substrings and a boolean string.	Returns the number of episodes (distinct or not, depending on distinct string) that includes tags LIKE the given ones (pattern-matching per input tag).
LayerST (object with the episodes and semantic trajectories of an STD)	confined_in (LayerST layer, MBB envelope, String tag), where tag is a concatenated set of substrings.	Returns semantic trajectories, whose episodes are overlapping spatiotemporally with the MBB and textually with the “tag” parameter.

STD creation. STD construction includes two phases (3D R-tree and IFs), along with segmental options for creating a graph database in steps (separate 3D R-tree and IFs creation routines) in case of size and memory concerns.

Semantic Trajectory Synthesizer. In case of trajectory datasets lacking textual annotations, our synthesizer is able to augment raw trajectories with textual annotations using a customized text generator that chooses terms from a lexicon of V keywords. The number of keywords for each episode follows a Zipfian distribution, in order to simulate the skewness present in real-life textual datasets.

STD search. Several functions are available for a wide range of queries like intersection, overlapping or union, with the emphasis, of course, in STKP queries (details for the appropriate search methods appear in Table 2).

Table 2: STKP query methods

Method	Parameters	Index
SpatialTemporalKeywordTrajectoryQuery	LayerST, list of MBBs,	TSR-tree index
SpatialTemporalKeywordTrajectoryEpisodesQuery	list of String tags	ESR-tree index

Hermes@Neo4j STD engine utilizes Apache Lucene [12] indexes that use inverted indexes for search and retrieval from text collections. For the implementation of interactive visualizations of the semantic trajectories over a 3D model of the globe and different types of 2D maps, the NASA WorldWind API [13] is utilized. The library has been extended in order to display the spatio-temporal and textual information of a semantic trajectory. Visual representation of search results is performed through different 3D / 2D map services, such as Open Street Map, Bing, MS Virtual Earth, NASA Blue Marble and i-cubed Landsat (Fig. 3).

The interface has the required parameters for spatio-temporal

and textual constraints that are used as query arguments. The interface also includes necessary options for importing a dataset to a new STD. Apart from setting spatio-temporal and textual constraints, in order to perform a STKP query over the selected STD, the user decides the index and search algorithm of his/her choice. The semantic trajectories that are the results of the STKP query are displayed through a proper animation zoom at the selected map service and reference system by displaying the geographical area that covers the specific semantic trajectories. Correspondingly, information about the search results and the number of trajectories that meet the search criteria are displayed in a relevant result box.

4 ABOUT THE DEMONSTRATION

Throughout the demonstration, Hermes@Neo4j users will be able to test the system by using the real “Foursquare New York” dataset [14] and the synthetic “Hermes Attica” dataset³ generated by the Hermoupolis generator [15]. The real dataset includes long-term (about 10 months - from Apr.12, 2012 to Feb.16, 2013) check-in data (227,428 check-ins) in New York City collected from Foursquare social network and the synthetic dataset consists of a total of 1,450,738 records that represent semantic trajectories.

Figure 3: Interactive visual exploration of a semantic trajectory that is the result of an STKP query through a 2D map representation.

The demonstration captures the following phases: (i) preparatory phase, where users have the opportunity to comprehend the internals of our framework, and (ii) our Hermes@Neo4j engine in action, where users experience various scenarios of STKP search. In particular:

Preparatory phase (background knowledge). During this phase, we show off the different datatypes and operands that can be utilized in the Hermes@Neo4j engine. In addition, we demonstrate how the user can use our framework to run legacy operands, and even more interestingly, focus on the two STKP query indexing and searching approaches.

Hermes@Neo4j engine in action. Having gained the necessary background knowledge, the user experiences a scenario of STKP search and index creation, based on the TSR-tree search algorithm. For instance, Fig. 3 present an example of

an STKP query result, which is a semantic trajectory from the “Hermes Attica” dataset. The user can display the results with a selected 3D/2D map representation and reference system of his/her choice. In addition, the user can interactively switch on and off the visibility of the results. In turn, we present a scenario of STKP search and index creation, based on the ESR-tree search algorithm. The goal of this scenario is to effectively demonstrate that the STKP search based on the ESR-tree, is more efficient in comparison with the STKP search based on the TSR-tree index, with the penalty of the higher index creation time and size compared with the TSR-index.

For a deeper comprehension of the demonstrated functionality, a related video is available at Hermes@Neo4j web page⁴.

ABSTRACT

On-demand integration of multiple data sources is a critical requirement in many Big Data settings. This has been coined as the data variety challenge, which refers to the complexity of dealing with an heterogeneous set of data sources to enable their integrated analysis. In Big Data settings, data sources are commonly represented by external REST APIs, which provide data in their original format and continuously apply changes in their structure (i.e., schema). Thus, data analysts face the challenge to integrate such multiple sources, and then continuously adapt their analytical processes to changes in the schema. To address this challenges, in this paper, we present the Metadata Management System, shortly MDM, a tool that supports data stewards and analysts to manage the integration and analysis of multiple heterogeneous sources under schema evolution. MDM adopts a vocabulary-based integration-oriented ontology to conceptualize the domain of interest and relies on *local-as-view* mappings to link it with the sources. MDM provides user-friendly mechanisms to manage the ontology and mappings. Finally, a query rewriting algorithm ensures that queries posed to the ontology are correctly resolved to the sources in the presence of multiple schema versions, a transparent process to data analysts. On-site, we will showcase using real-world examples how MDM facilitates the management of multiple evolving data sources and enables its integrated analysis.

1 INTRODUCTION

In recent years, a vast number of organizations have adopted data-driven approaches that align their business strategy with advanced data analysis. Such organizations leverage Big Data architectures that support the definition of complex data pipelines in order to process heterogeneous data, from multiple sources, in their original format. External data (i.e., neither generated nor under control of the organization) are commonly ingested from third party data providers (e.g., social networks) via REST APIs with a fixed schema. This requires data analysts to tailor their processes to the imposed schema for each source. A second challenge that data analysts face is the adaptation of such processes upon schema changes (i.e., a release of a new version of the API), a cumbersome task that needs to be manually dealt with. For instance, in the last year Facebook’s Graph API¹ released four major versions

affecting more than twenty endpoints each, many of them breaking changes. The maintenance of such data analysis processes is critical in scenarios integrating tenths of sources and exploiting them in hundreds of analytical processes, thus its automation is badly needed.

The definition of an integrated view over an heterogeneous set of sources is a challenging task that Semantic Web technologies are well-suited for to overcome the *data variety* challenge [3]. Given the simplicity and flexibility of ontologies, they constitute an ideal tool to define a unified interface (i.e., global vocabulary or schema) for such heterogeneous environments. This family of systems, that perform data integration using ontologies, propose to define a global conceptual schema (i.e., by means of an ontology) over the sources (i.e., by means of mappings) in order to rewrite ontology-mediated queries (OMQs) to the sources. The state of the art approaches for such integration-oriented ontologies are based on generic reasoning algorithms, that rely on certain families of description logics (DLs). Such approaches rewrite an OMQ, first to an expression in first-order logic and then to SQL. This approach, commonly referred as *ontology-based data access* (OBDA) [8], does not consider the management of changes in the sources, and thus such variability in their schema would cause OMQs either crash or return partial results. This issue, which is magnified in Big Data settings, is caused because OBDA approaches represent schema mappings following the *global-as-view* (GAV) approach, where elements of the ontology are characterized in terms of a query over the source schemata. GAV ensures that the process of query rewriting is tractable and yields a first-order logic expression, by just unfolding the queries to the sources, but faulty upon source schema changes [2]. To overcome this issues a desiderata is to adopt the *local-as-view* (LAV) approach. Oppositely to GAV, LAV characterizes elements of the source schemata in terms of a query over the ontology, making it inherently more suitable for dynamic environments [4]. LAV flexibility, however, comes at the expense of computational complexity in the query answering process.

To address these challenges, we adopt a vocabulary-based approach for data integration. These approaches are not necessarily restricted to the expressiveness of a DL and its generic reasoning algorithms. Such settings rely on rich metamodels for specific integration tasks, here focused on schema evolution. Under certain constraints when instantiating the metamodel, it is possible to define specific efficient algorithms that resolve LAV mappings without ambiguity. To this end, we created the Metadata Management System, or shortly MDM², an end-to-end solution to assist data stewards and data analysts during the Big Data integration lifecycle. Data stewards are provided with mechanisms to

²<http://www.essi.upc.edu/~snadal/mdm.html>

semi-automatically integrate new sources and accommodate schema evolution into a global schema. In turn, data analysts have means to pose OMQs to such global schema by making transparent the underlying mechanisms to query the sources with LAV mappings.

MDM implements a vocabulary-based integration-oriented ontology, represented by means of two RDF graphs, specifically the global graph and the source graph [5]. The former representing the domain of interest (also known as domain ontology) and the latter the schema of the sources. The key concepts are *releases*, which represent a new source or changes in existing sources. A relevant element of releases are *wrappers* (from the well-known mediator/wrapper architecture in data integration), the mechanism enabling access to the sources (e.g., an API request or a database query). Upon new releases the schemata of wrappers are extracted and their RDF-based representation stored in the source graph. Afterwards, the data steward is aided on the process of linking such new schemata to the global graph (i.e., define the LAV mapping). Orthogonally, data analysts pose OMQs to the global graph. The current de-facto standard to query ontologies is the SPARQL query language, however to enable non-expert analysts to query the sources MDM offers an interface where OMQs are graphically posed as subgraph patterns of the global graph, which are automatically translated to SPARQL. A specific query rewriting algorithm takes care of how to properly resolve LAV mappings, a process that consists on the discovery of joins amongst wrappers and their attributes, regardless of the number of wrappers per source.

Motivational use case. As motivational use case, and for the sake of understandability, we will analyse information related to European football teams. This represents the simple use case that will be demoed on-site amongst others with higher complexity (i.e., the SUPERSEDE project). Precisely, we aim to ingest data from four data sources, in the form of REST APIs, respectively providing information about players, teams, leagues and countries. The integrated schema of this scenario is conceptualized in the UML depicted in Figure 1, which we use as a starting point to provide a high-level representation of the domain of interest, used to generate the ontological knowledge captured in the global graph.

Figure 1: UML of the motivational use case

Each of the APIs is independent from each other, and thus they differ in terms of schema and format. Thus, for instance, the *Players API* provides data in JSON format while the *Teams API* in XML. An excerpt of the content provided by such two APIs is depicted in Figure 2. Next, the goal is to enable data analysts to pose OMQ to the ontology-based representation of the UML diagram (i.e., global graph) by navigating over the classes. Specifically, we aim the sources to be automatically accessed under multiple schema versions. An exemplary query would be, “*who are the players that play in a league of their nationality?*”.

Outline. In the rest of the paper, we will introduce the demonstrable features to resolve the motivational and other exploratory

queries. We first provide an overview of MDM and then, we present its core features to be demonstrated. Lastly, we outline our on-site presentation, involving the motivational use case and a complex real-world use case.

2 DEMONSTRABLE FEATURES

MDM presents an end-to-end solution to integrate and query a set of continuously evolving data sources. Figure 4 depicts a high-level overview of the approach. Its pillar is the Big Data integration (BDI) ontology [7], the metadata model (i.e., set of design guidelines) that allow data stewards to semantically annotate the integration constructs that enable automating the evolution process and unambiguously resolve query answering.

Figure 4: High-level overview of our approach

We devise four kinds of interaction with the system, which are in turn the offered functionalities: (a) *definition of the global graph*, where data stewards define the domain of interest for analysts to query; (b) *registration of wrappers*, either in the presence of a new source or the evolution of an existing one; (c) *definition of LAV mappings*, where LAV mappings between the source and the global graphs are defined; and (d) *querying the global graph*, where data analysts pose OMQs to the global graph which are automatically rewritten over the wrappers. In the following subsections, we describe how MDM assists on each of them.

2.1 Definition of the global graph

The global graph, whose elements are prefixed with G, reflects the main domain concepts, relationships among them and features of analysis. To this end, we distinguish between two main constructs *concepts* and *features*. Concepts (i.e., instances of $G:Concept$) are elements that group features (i.e., $G:Feature$) and do not take concrete values from the sources. Only concepts can be related to each other using any user-defined property, we also allow to define taxonomies for them (i.e., $rdfs:subClassOf$). It is possible to reuse existing vocabularies to semantically annotate the data at the global graph, and thus follow the principles of Linked Data. This, enables data to be self-descriptive as well as it opens the door to publish it on the Web [1]. Furthermore, we restrict features to belong to only one concept.

MDM supports the definition of the global graph avoiding the need to use external ontology modeling tools (e.g., *Protégé*). Figure 5 depicts an excerpt of the global graph for the demo use case, focusing on the concepts *Player* and *Team*. Like we said, we reuse vocabularies as much as possible, hence the concept *Team* is reused from <http://schema.org/SportsTeam>. When no reuse is possible, we define the example’s custom prefix *ex*. As data stewards interact with MDM to define the global graph, the corresponding RDF triples are being generated automatically.

Figure 5: Global graph for the motivational use case. Blue and yellow nodes denote concepts and features

2.2 Registration of new data sources

New wrappers are introduced either because we want to consider data from a new data source, or because the schema of an existing source has evolved. Nevertheless, in both cases the procedure to incorporate them to the source level, whose elements are prefixed with *S*, is the same. To this end, we define the data source (i.e., *S:DataSource*) and wrapper (i.e., *S:Wrapper*) metaconcepts. Data stewards must provide the definition of the wrapper, as well as its signature. We work under the assumption that wrappers provide a flat structure in first normal form, thus the signature is an expression of the form $w(a_1, \dots, a_n)$ where w is the wrapper name and a_1, \dots, a_n the set of attributes. With such information, MDM extracts the RDF-based representation of the wrapper’s schema (i.e., creates elements of type *S:Attribute*) which are incorporated to the existing source level. In the case of a wrapper for an existing data source, MDM will try to reuse as many attributes as possible from the previous wrappers for that data source. However, this is not possible among different data sources as the semantics of attributes might differ. In the case of attributes in the source graph, as they are not meant to be shared, oppositely to features in the global graph, there is no need to reuse external vocabularies.

Figure 6 depicts an excerpt of the source graph for the sources related to players and teams, the former with a wrapper’s signature $w_1(id, pName, height, weight, score, foot, teamId)$ and the latter $w_2(id, name, , shortName)$. Note that, for w_1 , some attribute names differ from the data stored in the source (see Figure 2), this is due to the fact that the query contained in the wrapper might rename (e.g., *foot*) or add new attributes (e.g., *teamId*). The definition of a wrapper (e.g., a MongoDB query, a Spark job, etc.) is out of the scope of MDM and should be carried out by the data steward.

2.3 Definition of LAV mappings

LAV mappings are encoded as part of the ontology. We represent them as two components, (a) a subgraph of the global graph, one per wrapper, and (b) a function linking attributes from the source graph to features in the global. The former are achieved thanks to RDF named graphs, which allow to identify subsets of other RDF

Figure 6: Source graph for the motivational use case. Red, orange and blue denote data sources, wrappers and attributes

graphs identified by an URI. In this case, the URI will be the one for the wrapper. The latter are achieved via the `owl:sameAs` property. Note that, traditionally, the definition of LAV mappings was a difficult task even for IT people. However, in MDM LAV mappings can be easily asserted through the interface: each wrapper must map to a named graph (i.e., a subset of the global graph), and a set of `owl:sameAs` from attributes to features. The task consists on first selecting a wrapper, and then, with the mouse, drawing a contour around the set of elements in the global graph that this wrapper is populating (including concept relations).

Figure 7 depicts the LAV mappings for wrappers w_1 and w_2 , respectively in red and green. Note the intersection in the concept `sc:SportsTeam` and its identifier, this will be later used when querying in order to enable joining such concepts. However, this joins are only restricted to elements that inherit from `sc:identifier`.

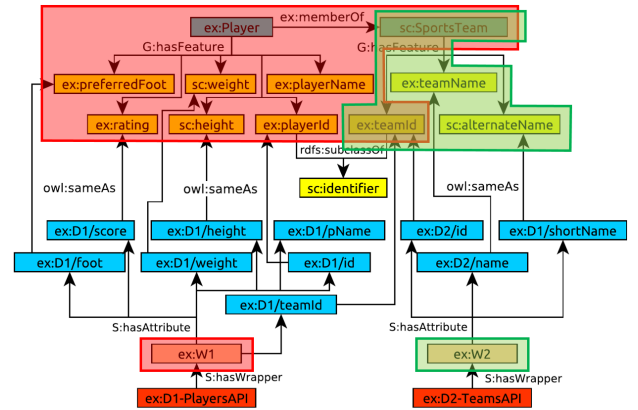

Figure 7: LAV mappings for the motivational use case

2.4 Querying the global graph

To overcome the complexity of writing SPARQL queries over the global graph, MDM adopts a graph pattern matching approach to enable non-technical data analysts perform their OMQs. Recall that the *WHERE* clause of a SPARQL query consists of a graph pattern. To this end, the analyst can graphically select a set of nodes of the global graph representing such pattern, we refer to it as a *walk*. Then, a specific query rewriting algorithm takes as input a walk and generates as a result an equivalent union of conjunctive queries over the wrappers resolving the LAV mappings [7]. Such process consists of three phases: (a) *query expansion*, where the walk is automatically expanded to include concept identifiers that have not been explicitly stated; (b) *intra-concept generation*, that generates partial walks per concept indicating how to query the wrappers in order to obtain the requested features for the concept at hand; and (c) *inter-concept generation*, where all partial walks are joined to obtain a union of conjunctive queries.

Using the excerpt of the ontology depicted in Figure 7, we could graphically pose an OMQ fetching the name of the players and their teams. Figure 8 shows how such query can be defined in MDM by drawing a contour (in red) around the concepts and features of interest in the global graph. On the right hand side, it is depicted the equivalent SPARQL query, as well as the generated relational algebra expression over the wrappers. Table 1 depicts a sample of the output resulting of the execution of the query.

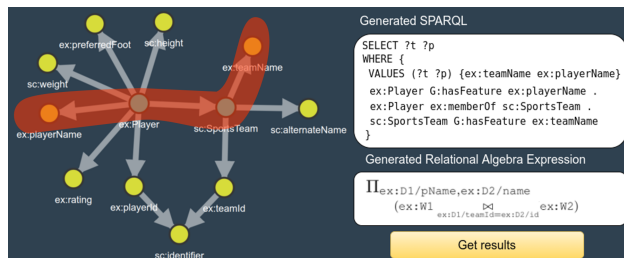

Figure 8: Posing an OMQ in MDM

ex:teamName	ex:playerName

Table 1: Sample output for the exemplary query.

2.5 Implementation details

MDM has been developed at UPC BarcelonaTech in the context of the SUPERSEDE³ project using a service-oriented architecture. It is the cornerstone of the Big Data architecture supporting the project, and a central component of its Semantic Layer [6]. On the frontend, MDM provides the web-based component to assist the management of the Big Data evolution lifecycle. This component is implemented in *JavaScript* and resides in a *Node.JS* web server. The interface makes heavy use of the *D3.js* library to render graphs and enables the user to interact with them. Web interfaces are defined using the *Pug* template engine, and a number of external libraries are additionally used. The backend is implemented as a set of REST APIs defined with *Jersey* for *Java*, thus the frontend interacts with the backend by means of HTTP REST calls. This enables extensibility of the system and a separation of concerns in such big system. The backend makes heavy use of *Jena* to deal with RDF graphs, as well as its persistence engine *Jena TDB*. Additionally, a *MongoDB* document store is responsible of storing the system’s metadata. Concerning the execution of queries, the fragment of data provided by wrappers is loaded into temporal SQLite tables in order to execute the federated query.

3 DEMONSTRATION OVERVIEW

In the on-site demonstration, we will present the functionality of MDM relying based on two use cases. First, we will focus on the paper’s motivational scenario, in order to comprehensively show the functionalities offered by MDM. Next we will focus on the SUPERSEDE use case, a real-world scenario of Big Data integration under schema evolution in order to show the full potential and benefits of MDM. We will cover the four possible kinds of interactions with MDM, taking the role of both data steward (definition of the global graph, registration of new wrappers, definition of LAV mappings) and data analyst (querying the global graph). We

³<https://www.supersede.eu>

will showcase how MDM aids on each of the processes, considering as well the input from participants. Precisely, the following scenarios will be covered:

System setup. In the first scenario we will take the role of a data steward that has been given a UML diagram (likewise Figure 1), and assigned the task of setting up a global schema to enable integrated querying of a disparate set of sources. Thus, we will show how MDM supports the definition of its equivalent global graph (likewise Figure 5) within the interface. Once finished, we will introduce the four sources (i.e., the players API, teams API, etc.) and a wrapper for each. We will show how MDM automatically extracts the schemata of wrappers to automatically generate the source graph (likewise Figure 6). Finally, we will show how MDM supports the graphical definition of named graphs, which are the basis for LAV mappings, and thus properly maps the source and global graphs (likewise Figure 7).

Ontology-mediated queries. With the global graph set up and a set of data sources and wrappers in place, now we can act as data analysts in order to pose OMQs to the system. We will encourage participants to propose their queries of interest, this is possible because MDM presents the global graph and allows to graphically draw a walk around its nodes. This is later automatically translated to its SPARQL form (likewise Figure 8), and to a relational algebra expression derived from the query rewriting process. MDM presents the execution of the query in tabular form.

Governance of evolution. In Big Data ecosystems, changes in the structure of the data sources will frequently occur. In this scenario, we will release a new version of one of the APIs including breaking changes that would cause the previously defined queries to crash. First, we will showcase how MDM easily supports the inclusion of this new source into the existing global graph and the definition of its LAV mappings. Next, we will execute again the queries that were supposed to crash showing how MDM has adapted the generated relational algebra expressions, where the two schema versions are now fetched and yield correct results.

ABSTRACT

Tools for *visual data exploration* allow users to visually browse through and analyze datasets to possibly reveal interesting information hidden in the data that users are a priori unaware of. Such tools rely on both *query recommendations* to select data to be visualized and *visualization recommendations* for these data to best support users in their visual data exploration process.

EVLIN (exploring visually with lineage) is a system that assists users in visually exploring relational data stored in a data warehouse. EVLIN implements novel techniques for recommending both queries and their result visualization in an integrated and interactive way [3]. Recommendations rely on *provenance* (aka lineage) that describes the production process of *displayed data*.

The demonstration of EVLIN includes an introduction to its features and functionality through sample exploration sessions. Conference attendees will then have the opportunity to gain hands-on experience of provenance-based visual data exploration by performing their own exploration sessions. These sessions will explore real-world data from several domains. While exploration sessions use a Web-based visual interface, the demonstration also features a researcher console, where attendees may have a look behind the scenes to get a more in-depth understanding of the underlying recommendation algorithms.

1 VISUAL DATA EXPLORATION

Data exploration [8] helps users in finding interesting information in data sets when they do not know beforehand what useful information hides in their data. It thus supports humans in understanding and interpreting data in an investigative way. As manual data exploration is tedious, time-consuming, and it is easy to overlook interesting information, there is a need for tools supporting data exploration. These tools typically rely on different kinds of recommendations. Essentially, *query recommendation* guides users in their investigation of a data set D by suggesting queries as next exploration steps, given an initial query Q . Opposed to that, *visualization recommendation* commonly determines suited visualizations given a data set as input.

State-of-the-art. Most data and visualization recommendation techniques work independently from one another, meaning that the result of query recommendation, i.e., the data set $Q'(D)$ returned by executing a recommended query Q' over D , has no impact on the visualization recommendation process, and vice versa. This becomes apparent in Tab. 1 that summarizes works most closely related to ours. For each approach, it describes (i) the expressiveness of input queries (e.g., select-project-join (SPJ) queries, select-project-aggregate (SPA) queries, or cube queries

corresponding to SPJA queries), (ii) the type of recommended output queries, (iii) the information used to compute query recommendations, (iv) the type of recommended visualization, and (v) the information used to compute visualization recommendations. This summary clearly shows that there is a gap between query recommendation systems such as YmalDB [5], SeeDB [12], or REACT [10] for expressive data exploration on the one hand, and visualization recommendation systems such as Voyager [14, 15] and Tableau’s Show Me [9] on the other hand. Indeed, whereas the former may support the full range of typical OLAP queries, they do not offer any visualization recommendation. Typically, there is a one to one mapping between the result relation and a displayed table [5, 10] or bar chart [12]. Opposed to that, visualization recommendation solutions typically offer no or very limited support for query recommendation.

System	input query	recom. query	input for query recom.	recom. vis.	input for vis. recom.
YmalDB [5]	SPJ	SPJ	$D, Q(D)$	-	-
SeeDB [12]	cube	sub-cube	$D, Q(D)$	-	-
REACT [10]	cube	OLAP queries	previous exploration sessions’ query history	-	-
Show Me [9]	SPA	-	-	diverse	data types
Voyager [14, 15]	SPA	Changed SELECT-clause	D, Q , metadata of D (schema, statistics)	diverse	data types, visual encoding channels
EVLIN	cube	OLAP queries	$D, Q, \text{data \& evolution provenance}$	diverse	$Q(D)$, evolution provenance

Table 1: Summary of data exploration systems leveraging query recommendation or visualization recommendation

Contribution. EVLIN bridges the gap between query and visualization recommendation, seamlessly integrating both query and visualization recommendation for a streamlined, interactive user-experience. It relies on a novel recommendation strategy that leverages provenance to recommend queries and interactive visualizations in relation to each other [3]. The underlying techniques as well as the implementation focus on visually exploring relational data stored in a data warehouse. That is, we assume an input data set to conform to a snowflake schema. This demonstration focuses on the usability and interactivity of EVLIN in letting users explore these data. Through various real-world scenarios, we showcase that provenance-based recommendations for visual data exploration allow to effectively reveal interesting information. An example exploration session showing the functionality of EVLIN is available as an online video in [1].

Structure. Sec. 2 highlights the innovative aspects of EVLIN. The audience experience is first addressed in Sec. 3 where we discuss an exploration session in detail. On-site details such as the intended audience, sample scenarios, and a summary of the audience experience beyond the sample exploration session of Sec. 3 are then covered in Sec. 4.

2 EVLIN CONTRIBUTIONS

This section briefly summarizes the scientific contributions of EVLIN. We refer interested readers to [3] for more technical details, which we leave out here due to space constraints.

Leveraging data and evolution provenance. EVLIN captures two types of provenance: *data provenance* (more specifically why-provenance) and *evolution provenance* [7]. Data provenance records which data in the database D was used to derive the query result $Q(D)$ of a given query Q . In our context, evolution provenance [3] captures the explored dataset history as well as user interactions and visual encoding parameters of corresponding visualizations, thus tracking how a current visualization was derived. Thus, our model of evolution provenance extends the query history model used for query recommendation in REACT [10].

Provenance-based recommendation. We have developed a novel query recommendation algorithm that takes into account data provenance of data that has been explored and interacted with during an exploration session via the visual front-end. For an input SPJA SQL query, the computed recommendations follow typical data warehouse operations such as drill-down, roll-up, or slice. To identify adequate visualizations for the results of recommended queries, we have further developed a recommendation strategy that takes into account both interactions and visualizations captured as evolution provenance. While our query recommendation is similar in spirit to REACT [10], which records query histories from exploration sessions, our system leverages a richer provenance model and recommends not only queries but also their result visualizations.

Recommendation data space coverage and conciseness. To the best of our knowledge, EVLIN is the first system that recommends visualizations of query results for all queries typical in data warehouse navigation. Indeed, recommendations include roll-up, slice/dice, and drill-down queries, including drill-down queries that navigate to dimensions not considered by previous queries. In addition, data can be clustered by different characteristics or measures to zoom-in to more detailed distributions. To reduce the number of recommendations that are ultimately presented to the user (both for efficiency and usability reasons) while avoiding the loss of potentially relevant recommendations, we have explored how to leverage integrity constraints such as functional dependencies to prune redundant recommendations [3].

Visualization of quantified recommendation quality. Given the high diversity and possibly large number of recommended queries (and associated visualizations) produced by EVLIN, we propose to support users to navigate through the exploration space by quantifying the “interestingness” of recommended next exploration steps. The computed scores are then visualized in an interactive impact matrix, pointing users to potentially interesting data visualizations for different data warehouse operations.

3 SYSTEM FUNCTIONALITY

The above contributions are implemented as part of the EVLIN Web application that supports the exploration of multidimensional relational data stored in a data warehouse D with schema $schema(D)$, given an initial SQL query Q . EVLIN users are expected to have initial basic knowledge about the schema and dimensions of the data warehouse. The query Q , as well as all queries subsequently recommended take the form

`SELECT $f(m)$, A FROM $rel(Q)$ WHERE $cond$ GROUP BY A`

where m is a measure in the fact table, $A = \{a_1, \dots, a_n\}$ is a set of attributes, f is an aggregation function, $rel(Q)$ refers to one or more relations in $schema(D)$, and $cond$ is a conjunction of predicates.

Figure 1: EVLIN system overview

Fig. 1 depicts the general processing EVLIN implements: (i) A user triggers an exploration session by issuing Q . (ii) The *query processor* executes the query and returns its result, denoted $Q(D)$. (iii) $Q(D)$ is then input to *rendering recommendation* that determines an adequate visualization to render the query result. (iv) The user can interact with the data via the graphical user interface, selecting a data-subset of interest, denoted R . (v) Based on this interaction, *data recommendation* identifies which attributes and values within their domain may be of interest to the user at the next step of his data exploration session. (vi) For each data recommendation, *query reformulation* determines variations Q' of the query Q that correspond to different exploration queries over a data cube in a data warehouse (slice, drill-down, roll-up, etc.). The interestingness of these queries is quantified based on the data underlying Q and Q' and the consistency of possible visualizations for $Q'(D)$ wrt evolution provenance. The result of this step is a set of recommended queries and respective visualizations for each recommended attribute of step (v) with associated interestingness scores. This information is visualized as an impact matrix to the user. The user then chooses one particular query to explore next. Upon selection of this query Q' , the next iteration of the exploration process starts.

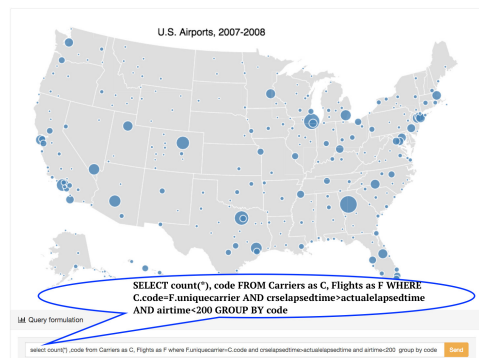

Figure 2: Initial input interface and sample query Q

In what follows, we detail functionalities, interfaces, and interactions that the audience will experience, focusing on the rendering recommendation, data recommendation, and query reformulation components. Due to space constraints, an in-depth discussion of the underlying algorithms is out of the scope of this paper, and we refer interested readers to [3] for details.

An initial user-specified query Q is input via a graphical user interface, as illustrated in Fig. 2. While our current implementation requires full-text SQL (loaded from a file or typed in a text field), a more user-friendly interaction similar to Voyager is planned. Our sample scenario considers a database D of domestic US flights

(a) Example of recommended visualization for $Q(D)$

(b) Visualization of recommended query result $Q'(D)$

Figure 3: Sample visualizations rendered using EVLIN

and Q that determines the number of short flights per airline which arrive ahead of schedule (a possible indicator for airline quality). Using the same scenario, a more extensive exploration session than the one described in the following is showcased in an online video in [1]. It includes for instance visualizations other than bar charts and further data warehouse operations.

3.1 Rendering recommendation

The rendering recommendation component takes as input a query result $Q_i(D)$ and evolution provenance P_e to determine a suited visualization of $Q_i(D)$. As described in [3], evolution provenance encompasses information about (i) past queries, (ii) the set of visualization resources used to render results of these queries, and (iii) information of past user interactions such as the selected data regions or specific sub-results. Essentially, this information are collected for each exploration step of an exploration session, where steps are delimited by transitioning from visualizing a query Q to visualizing a query Q' . This results in evolution provenance being a directed graph where nodes represent individual exploration steps and edges represent transitions from one step to the next. For a given $Q_i(D)$, its corresponding evolution provenance P_e includes all meta-data associated to graph nodes on the path from the initial query Q to the node representing the query Q_i .

Using this input, rendering recommendation aims at maximizing the visual similarity of a recommended visualization with those seen and interacted with previously for similar queries (intuitively, such that users easily recognize the same information as seen previously and thus understand the meaning of visualizations faster). This first requires determining similar queries among those in P_e . We quantify this similarity using a token-based similarity function between Q_i and a query $Q_p \in P_e$, weighted by the inverse of the shortest distance from Q_i to the previously seen Q_p on the path defining P_e . Among all queries of P_e with a similarity to Q_i above a predefined threshold θ_V , we now take the most frequent encoding parameters used to visualize information that is also selected by Q_i . These define a preliminary skeleton for the recommended visualization of $Q_i(D)$. In case no prior visualizations can be used, we resort to the effectiveness metrics adopted by Voyager [14, 15] to construct the visualization. Finally, the visualization skeleton is possibly updated based on the set of constraints defined in [11], that reduce conflict between visualizations.

As an example, Fig. 3a displays the recommended bar-chart visualization for our sample query Q that counts short flights

arriving ahead of schedule for each airline. For this initial rendering, $P_e = \emptyset$, thus, the recommendation is solely based on the effectiveness metrics.

The user can inspect (by mouse hovering) the data and select a region R of interest by clicking to pursue the exploration. In Fig. 3a, the user has selected the highest bar that designates the overly punctual flights of the airline with code WN. The selected region is highlighted in a different color. At this point, P_e is updated to include the initial query Q in its query history, the user interaction event (selection of bar with code=WN) as well as visual encoding parameters of the displayed chart.

Recommending the visualization of Fig. 3b (explained later) relies on the updated P_e to generate a similar visualization of same features, e.g., same axis scale for the y-axis, same order of airline codes on the x-axis, or choice of a stacked bar chart to maintain same heights as seen previously (e.g., in the bar-chart of Fig. 3a).

3.2 Data recommendation

Figure 4: Impact matrix for running example

Selecting a particular sub-result $R \subseteq Q(D)$ of the data via the graphical user interface triggers the data recommendation component. It takes as input R , D , and Q to determine a set of attribute-value pairs $P = \{(a_1, v_1), \dots, (a_n, v_n)\}$. Before passing these to query reformulation, the attribute-value pairs in P are grouped by attribute, resulting in the final output $G = \{(a_1, V_1), \dots, (a_k, V_k)\}$. Essentially, data recommendation determines which data to explore next while query reformulation determines how these data will be explored.

To compute P , we leverage the data provenance of R , denoted $P_d(R)$, using the Perm provenance management system [6]. This provenance corresponds to all tuples in D that have contributed to producing R (i.e., why-provenance [4]). An attribute-value pair is then recommended if it satisfies one of the two following conditions: (i) it is widely present in $P_d(R)$ and more massively present in the database D or (ii) it is widely present in $P_d(R)$ but rarely present in D . We verify these conditions by first requiring a minimum frequency $f_{a,v}$ for an attribute-value pair in $P_d(R)$, i.e., $f_{a,v}(P_d(R)) \geq \theta_L$, where θ_L is a predefined threshold. We then compare this frequency to the frequency of the same attribute-value pair in the whole database D using the support measure defined by $support_{a,v}(R) = \left\lfloor \log_e \left(\frac{f_{a,v}(P_d(R))}{f_{a,v}(D)} \right) \right\rfloor$. Finally, only those attribute-value pairs with a lineage-based support above a given threshold θ_{supp} are retained for recommendation. In our prototype, threshold values of θ_L and θ_{supp} have been set to 0.1 and 0.7 respectively, which proved to be practical for the use cases we considered. However, setting these in general is an interesting avenue for future research. Using the method described above, it is possible that two distinct entries in P , i.e., (a, v) and (a', v') yield redundant query reformulations.

This is for instance the case when functional dependencies exist between attributes. To avoid redundant recommendations, we employ data profiling algorithms to determine functional dependencies [2] of the form $a \rightarrow a'$ and prune a' . The row labels of Fig. 4 show the set G , including for instance $(cancelled, \{1\})$ or $(dest, \{LAS, MDW, PHX\})$ that result from relevant attribute pairs $(cancelled, 1)$ and $\{(dest, LAS), (dest, MDW), (dest, PHX)\} \subseteq P$, respectively.

3.3 Query reformulation

The data recommendations are input to the query reformulation component that produces, for each $(a, V) \in G$, a set of queries corresponding to variations of the original query Q . Each variation reflects an operation typical when querying data warehouses. Our system supports variations implementing slice (and dice), drill-down, including the navigation to dimensions not considered in the initial query Q (which we call extension afterward), roll-up, and grouping or clustering the original results of Q by further attributes (zoom-in). The variations are systematically constructed based on Q , (a, V) , and the specific data warehouse operation. For instance, the query reformulation for slice will add conditions of the form $AND a = v_1 OR \dots OR a = v_n$ to the initial WHERE clause of Q , where $\{v_1, \dots, v_n\} = V$, whereas a roll-up, drill-down changes the attribute set A in the SELECT and GROUP BY clauses of Q to a higher or lower granularity.

To assist users in choosing the next query for the next exploration step, we assign a utility score s to each query variation. Developing and evaluating suited scoring functions to quantify the interestingness of query variations based on their result data and candidate visualization properties is currently actively researched. As a proof-of-concept for our visual data exploration, we have currently implemented Kullback-Leibler divergence function [13] as a utility function. It quantifies the divergence of a 's value distribution in $Q'(D)$ from its distribution in D .

The mapping of (a, V) -pairs to sets of scored recommended queries is visualized as an impact matrix. Fig. 4 shows the impact matrix that results from the query and interaction depicted in Fig. 2 and Fig. 3a. Each line of the matrix corresponds to an (a, V) -pair and each column corresponds to a type of query variation. The cell colors encode the divergence score. From this example, we see for instance that the zoom-in query for $(airtime, 0)$ obtains a high interestingness score. Upon clicking this interesting cell, the corresponding query variation is set to be the new query Q , which is then executed before its result is visualized as recommended by the rendering recommendation component (see Fig. 3b).

The visualization of Fig. 3b shows that a significant number of flights satisfying the initially intended quality criteria for airlines, i.e., arrival ahead of schedule, has a flight duration equal to zero. Based on this insight, users may decide to revise or refine the airline quality criteria.

4 SCENARIOS AND USER EXPERIENCE

The demonstration will rely on scenarios from different domains. The domains are chosen so that some basic knowledge about database schemas and attributes can be assumed. Possible supported scenarios could leverage for instance the following datasets.

Flights. The first dataset describes US domestic flights¹. It contains information about two million flights done by more than 1500 airline companies between 2007 and 2008. It includes further information about 3300 airports and almost 4500 plane types

used for the covered flights. The facts recorded for each flight include various numerical attributes such delays, cancellation, arrival and departure time etc.

Movies. The second dataset describes one million ratings made by 6000 users of the MovieLens platform² on 4000 movies. This database stores various information about users and movies.

Soccer. The third dataset is the European soccer league database³. It contains detailed information about more than 25,000 fixtures between 2008 and 2016 in 11 European championships.

We expect the demonstration to attract a broad audience, generally interested in interactive data analysis or visual data exploration. Having some proficiency in SQL is crucial to be able to follow and express SQL queries that trigger an exploration session.

The audience experience will be similar to the sample scenario used throughout Sec. 3. However, whereas the example limits to one exploration step, attendees will have the opportunity to run exploration sessions spanning multiple exploration steps similarly to the user experience shown in [1].

In addition to experiencing the system's main functionality, the demonstration provides a tour "behind the scenes". This includes seeing how user interaction translates to a provenance query, which scores are computed for data recommendation, which attribute-values are pruned along the way, and which queries (with associated scores) are recommended. Ultimately, after hands-on data exploration experience using EVLIN, the audience will have gained a better understanding of the explored data set and possibly even discovered new insights on the underlying data set.

Acknowledgments. We thank the German Research Foundation (DFG) for supporting projects A03 and D03 of SFB-TRR 161.

Interactive Visualization of Large Similarity Graphs and Entity Resolution Clusters

Demonstration Paper

M. Ali Rostami, Alieh Saeedi, Eric Peukert, and Erhard Rahm

Database group and ScaDS Dresden/Leipzig, University of Leipzig

{rostami,saeedi,peukert,rahm}@informatik.uni-leipzig.de

ABSTRACT

Entity Resolution (ER) identifies semantically equivalent entities, e.g. describing the same product or customer. It is a crucial and challenging step when integrating heterogeneous (big) data sources. ER approaches typically compute a similarity graph where vertices represent entities and edges (links) connect similar entities. Different clustering algorithms can be applied on such similarity graphs to finally determine groups of matching entities. In this demonstration paper, we introduce a new interactive tool to visualize and thus help to analyze large similarity graphs and large sets of ER clusters. Users can intuitively investigate the link and cluster structure to identify potential problems such as overly large clusters, cluster overlaps or singletons that might indicate the need for repair activities on the ER result. To support large graphs, computation-intensive tasks like layouting and sampling are executed on the server side as parallel or serial processes. The demo walks through different matching and clustering tasks and allows users to interactively explore the results.

1 INTRODUCTION

In the era of big data, one of the challenging data integration tasks is to identify semantically equivalent entities (e.g., describing the same product or customer) in large and heterogeneous data sources. This task is referred to as Entity Resolution (ER) or record linkage [6]. ER typically computes a similarity graph where vertices represent entities and edges (links) connect similar entities with a pair-wise similarity above a predefined threshold. Matching entities can directly be derived from such a similarity graph or from groups of matching entities determined with subsequent clustering algorithms [9]. Our recently introduced framework FAMER (Framework for Multi-source Entity Resolution) supports a parallel computation of such similarity graphs and ER clusters for multiple (≥ 2) data sources [12].

During the continuous development of FAMER, it is difficult to investigate the correctness and efficiency of the certain algorithms and to understand the problems. Such an investigation may lead to introduce better match and cluster algorithms or even an extra postprocessing step of repair (for more details see [13]). However, to identify (or debug) such issues with limited effort and time we see the need for a comprehensive and powerful approach to visually analyze similarity graphs and ER clusterings. Unfortunately, general purpose graph visualization tools like Gephi¹ or Graphviz² have only limited capabilities to

¹<https://gephi.org>

²<http://www.graphviz.org>

Figure 1: The software architecture

analyze ER clusterings and also have problems to visualize large (big data) similarity graphs with vertex and edge properties.

In this demo paper we introduce SIMG-VIZ, a new visualization system for entity resolution and clustering that allows us to investigate different match and clustering techniques for multi-source entity resolution. SIMG-VIZ offers the following key features:

- SIMG-VIZ allows a user to analyze precomputed similarity graphs and clusterings from existing ER tools and also supports executing and analyzing ER match tasks directly with FAMER.
- Different graph and ER cluster visualization techniques and layouts can be applied to choose the best visualizations.
- To increase performance, some layouts can be precomputed on the server with either parallel or serial computation. This provides a significant optimization potential in particular for force-directed layouts [3].
- To support visualization of large graphs, preprocessing techniques such as sampling (also executed in parallel on the server) can be selected to obtain a fast overview of large similarity graphs and their clustering results.
- Clusters and their overlaps as well as edges annotated with their type and similarity are visualized by using a simple but useful cake-like visual metaphor. Users can interact with clusters and select individual clusters for investigation.

2 SIMG-VIZ OVERVIEW

The SIMG-VIZ system consists of three modules: (1) the FAMER server, (2) a visualization server in JAVA and (3) a web-based UI-client written in JavaScript (see Fig. 1).

The FAMER server is used to link several sources and executes defined matching tasks. However, SIMG-VIZ also allows a user to load similarity graphs and clustering results that were computed by other frameworks and tools. The visualization server offers several preprocessing (e.g. for sampling) and layouting algorithms. The preprocessing algorithms are implemented in distributed fashion based on Gradoop and Apache Flink whereas

graph layouts are currently only implemented as non-distributed algorithms. The web-based client, provides an interactive visualization of similarity graphs and ER-clusterings. Node and edge properties can be investigated and server-side components like matching, clustering, preprocessing and layouting can be triggered. Through the client a user selects options and triggers server based REST-interfaces. The visualization server and the FAMER server both respond with JSON results. In the following paragraphs each of the components is described in detail.

2.1 FAMER Tool

FAMER offers parallel entity resolution for multiple data sources. It supports different match and clustering schemes that are executed on top of a distributed data processing engine (Apache Flink [4]) and the graph analytics framework Gradoop [10]. Its execution has two main phases: (1) computation of a similarity graph based on pairwise matching and (2) clustering. The first phase consists of several steps, namely blocking, pairwise comparisons, and match classification. Blocking reduces the number of necessary comparisons which otherwise would require to compare each entity of a data source to all entities of any other source. Different blocking techniques can be applied in FAMER such as Standard Blocking (SB), Sorted Neighborhood as well as single- and multi-pass blocking. In the matching step all entities of the computed blocks are compared by computing and combining similarities between their attributes, e.g. based on similarity measures such as Edit-Distance or Jaro Winkler. For matching, match rules can specify the required minimal similarity for the considered attribute-comparisons. The output of this step is the set of matching entity pairs (links) together with a combined similarity value per link. In the following match classification step entity pairs are classified as match or no-match based on the computed similarity values. This output is stored as a similarity graph where entities are represented as vertices and match links as edges. The clustering phase of FAMER aims at grouping together all matching vertices of the similarity graph based on the link structure and similarity values. Clustering algorithms typically try to maximize the similarity between entities within a cluster while the similarity between entities of different clusters should be minimized. FAMER supports several clustering algorithms for ER such as Connected Components, Correlation Clustering (CCPivot) [2, 5], Center [9], Merge Center [1], and Star [1].

With SIMG-VIZ, all components of FAMER can be configured and parameterized which allows users to run and compare different ER match tasks.

2.2 Client (Web-based HTML/JS Frontend)

Fig. 2 shows an overview of the web-based client of SIMG-VIZ. At the top part of the client, several options can be selected. The user can choose between different clustering and match configurations which are stored after executing FAMER. Before visualizing the similarity graph some available preprocessing algorithms such as sampling can be applied. Moreover, the user can select layouting options, i.e. which layout to use and where the computation should take place. In particular for large graphs, computing the layout on the server gives significant improvements. Finally, SIMG-VIZ offers a list of actions (see Table 1) that support different drawing tasks of the graph and some statistics computations can be triggered. On the right side of the client a number of parameters for visualization can be set. To improve interactivity,

styling tasks are performed on the client, for example changing vertex or edge sizes.

Table 1: Actions in SIMG-VIZ

Action	Description
Draw graph (Cytoscape)	Draws a sim-graph in Cytoscape ³ .
Draw graph (WebGL)	Draws a sim-graph in WebGL based on VivaGraph.
Compute only	Executes preprocessing and sampling without visualization.
Compute labels/keys	Computes all labels and property-keys of the vertices and edges for filtering in the left part of the UI.
Save as image	Exports an image of the drawn graph.
Remove selected node	Removes a selected node.
Degree Distribution	Computes the degree distribution of the graph.
Graph Statistics	Computes additional basic statistics of a graph.

2.3 Visualization Server

The visualization server offers preprocessing and layouting services. The preprocessing algorithms are implemented in a distributed fashion based on Gradoop and Apache Flink. Table 2 lists currently implemented preprocessing components. All layouting

Table 2: Preprocessing algorithms in SIMG-VIZ

Preprocessing	Description
Graph sampling	Computes a statistical sampling of a graph. Currently SIMG-VIZ implements vertex, edge and page rank sampling.
Graph summary	Computes a graph summary by grouping dense subgraphs of a graph to generate a compact overview of a large graph [11]. In SIMG-VIZ the Flink implementation is used.
Cluster neighbor filtering	In particular for ER-Clustering a filtering to neighbors of clusters is needed. The user specifies a cluster ID (at the right part of UI) and that cluster together with its neighbor clusters is visualized.
Cluster sizes filtering	Only the clusters with specific sizes are visualized.
Cluster Aggregation	It visualizes a graph in which the cluster vertices are grouped together.

algorithms are available both for the client and the server as non-distributed algorithms. We observed that executing layouting algorithms that need iterations like the force directed layout [8] should not be executed on the client within a browser. Executing it on a server brings significant run-time improvements, even without distributing the computation to multiple nodes. After a layout computation finishes on the server, the positions of nodes are send to the client together with the graph. As future work we plan to implement parallel versions of layouting to be run on top of Flink or Gradoop.

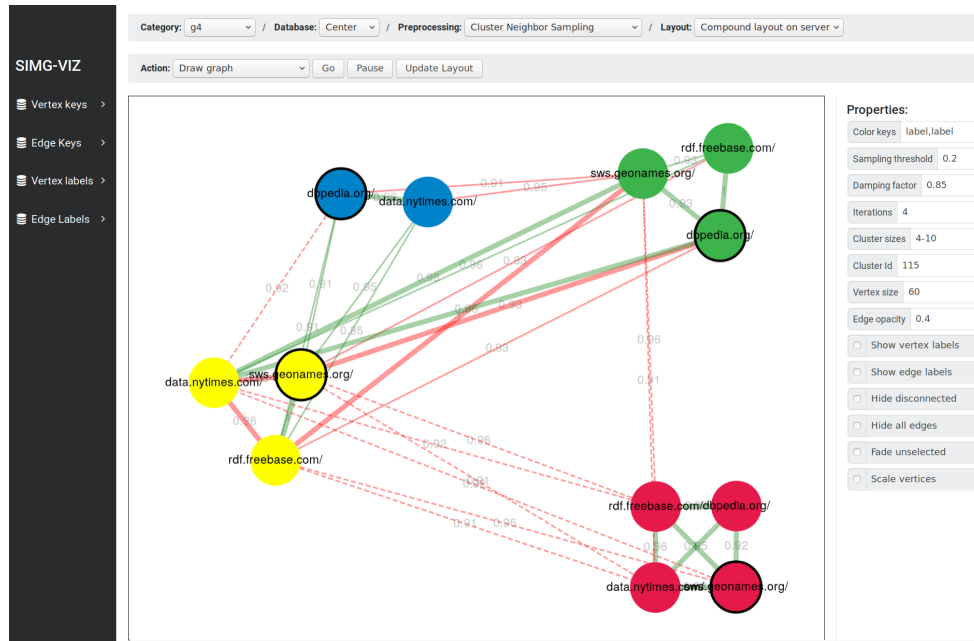

Figure 2: An overview of SIMG-VIZ

2.4 Cluster Visualization

In this section, we describe some specific features of SIMG-VIZ which are designed particularly for the visualization of ER clusters.

These features are explained along a real world ER-example of integrating four duplicate-free data sources namely Freebase (Fb), New York Times (nyt), DBpedia (db), and Geonames (geo). We initially compute a similarity graph and apply different clustering techniques with FAMER. A result cluster includes only vertices from these four sources which are most probably the same real world entities. An edge connects two vertices which have a high value of computed similarity measure. In Fig. 3 we initially visualize the complete clustering result. Clusters are given different colors to indicate cluster membership. Users can identify clusters that may warrant a closer inspection, e.g., clusters with more than 4 vertices or singleton clusters. A user can zoom in and inspect the properties of each vertex. Since generic graph layouting algorithms often have problems in visualizing large similarity graphs (e.g., problem of edge cluttering) we applied a compound layout for cluster visualization. Such compound layouts of graphs like CoSE-Bilkent [7] visualize vertices in a cluster (referred to as compound in the paper) close to each other while the whole graph is visualized by using a modified force-directed algorithm. Fig. 4(middle) shows a visualization of such a compound layout which we also compute on the server side. Vertices of a cluster share the same color and are closely grouped together to form a compound.

To get a cleaner picture, a user can interactively select a specific cluster or enter a cluster ID to only visualize a specific cluster for closer inspection. Often we also need to visualize a cluster together with its neighboring clusters (see Fig. 4 (top)). The vertex labels here refer to the corresponding data source for that entity. The scenario illustrates a problem case since there are more than four cluster members with some data sources having two entities in the same cluster which should not be possible for duplicate-free sources. There is also a singleton cluster that might have

Figure 3: A visualization of all clusters.

to be merged with another cluster. Based on such observations we are now able to re-assess the used cluster algorithms and investigate new approaches for cluster repair.

We also provide support for visualizing clustering result of specific clustering algorithms like Star[9]. The Star clustering computes cluster representatives and all neighbors of those representatives are assigned to the corresponding cluster. In SIMG-VIZ those cluster representatives are highlighted with a black outline (see Figure 4). It happens that a vertex is a neighbor of several cluster representatives so that such vertex will belong to multiple clusters. These multi-assignments are represented as pie-charts on nodes. Each piece of a pie chart which has a specific color specifies a cluster assignment. For example, Fig. 4 (Middle) contains a

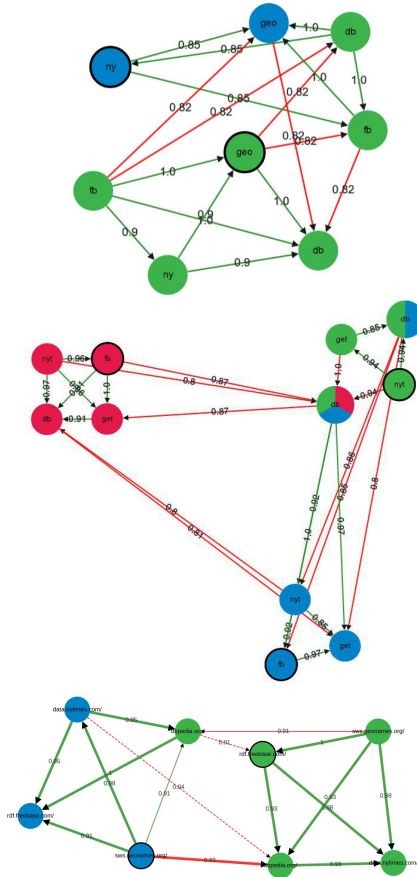

Figure 4: visualizations of (top) clusters with different colors, (Middle) vertices can belong to more than one cluster - drawn in compound layout, (Bottom) different styles for edges indicating how strong connections between entities are.

pie chart with three pieces which means that node (entity) is assigned to three clusters. Obviously some cluster post-processing is needed to select the best cluster for each entity that have been assigned to several clusters.

SIMG-VIZ provides special visualization support for evaluating clusters when the perfect cluster result is available for comparison. As shown in Fig. 4 (Bottom) there are different edge colors: green for edges within correct clusters and red for (wrong) edges between such clusters. Hence, clusters containing red edges should be investigated more closely. Finally we implemented a map-visualization of geo-referenced data so that entities can be plotted onto a map. With the help of this map-visualization we are able to identify false matches within a given data set.

2.5 Web-based Visualization Libraries

Drawing large graphs within a browser is problematic. We investigated several different Javascript-based visualization libraries and observed that there are significant performance differences. Three groups of libraries can be found: (1) SVG-based libraries compute SVG-nodes and tags. They are often feature rich but do not scale well due to many generated SVG-Elements. (2) The second group relies on HTML-Canvas. These libraries are typically

faster but interactivity is harder to realize. Still they mostly do not scale well for larger graphs. (3) WebGL-based libraries offer the best scalability but are still not as feature rich as existing libraries in the other two categories. We finally decided to use the Canvas-based Cytoscape⁴ library for small graphs up to 2000 vertices since it gives more flexibility regarding the style of edges and vertices. For example, the feature of drawing a pie chart on vertices is already available in Cytoscape. For large graphs, we use VivaGraph⁵, which is a WebGL-based library with less support for vertex and edge attributes, styling and coloring. However for larger graphs the user won't be able to see those details anyway.

3 DEMONSTRATION

In the demonstration, we walk through a complete workflow of entity resolution using matching and clustering for small and large ER match problems. A user could select data sources and the corresponding properties, similarity measures and match classifiers that are used by FAMER. The resulting clusters from FAMER are loaded into the visualization server. We then allow a user to compare different preprocessing algorithms as well as different layouts. We consider small data sources as well as large ones.

ACKNOWLEDGEMENT

This work was partly funded by the German Federal Ministry of Education and Research within the projects Competence Center for Scalable Data Services and Solutions (ScaDS) Dresden/Leipzig (BMBF 01IS14014B) and BIGGR (BMBF 01IS16030B).

ABSTRACT

Functional Dependencies (FDs) define attribute relationships based on syntactic equality. As a result, FD-based data cleaning systems incorrectly label syntactically different but semantically equivalent values as errors. To address this problem, we demonstrate FastOFD: a system for discovering Ontology Functional Dependencies (OFDs) which express semantic attribute relationships such as synonyms and is-a hierarchies defined by an ontology. In addition to discovering OFDs, FastOFD generates suggestions for repairing erroneous data, and we demonstrate that FastOFD significantly reduces the number of false positive errors compared to FD-based data cleaning techniques.

1 INTRODUCTION

In constraint-based data cleaning, tuples that violate the given integrity constraints are identified as erroneous. Candidate repairs are then generated to suggest how erroneous tuples could be modified to eliminate inconsistencies. The most popular integrity constraint considered in the data cleaning literature has been the Functional Dependency (FD) [2] and its extensions such as conditional FDs [3]. However, FDs are limited to identifying attribute relationships based on syntactic equivalence or syntactic similarity in case of metric FDs [5]. As a result, data cleaning systems that are based on FDs have a common flaw: they incorrectly label syntactically different but semantically equivalent values as errors. This leads to an increased number of reported “errors” and a larger search space of candidate data repairs.

Example: Table 1 shows a sample of clinical records containing patient country codes (CC), country (CTRY), symptoms (SYMP), diagnosis (DIAG), and the prescribed medication (MED). Consider two FDs: $F_1: [CC] \rightarrow [CTRY]$ and $F_2: [SYMP, DIAG] \rightarrow [MED]$. The tuples (t_1, t_5, t_6) violate F_1 as ‘United States’, ‘America’, and ‘USA’ are *not syntactically equivalent* (the same is true for (t_2, t_4, t_7)). However, ‘United States’ is synonymous with ‘America’ and ‘USA’, and (t_1, t_5, t_6) all refer to the same country. Similarly, ‘Bharat’ in t_4 is synonymous with ‘India’ as it is the country’s original Sanskrit name. For F_2 , (t_1, t_2, t_3) and (t_4, t_5, t_6) do not satisfy the dependency as the consequent values all refer to different medications. However, with domain knowledge from a medical ontology shown in Figure 2, we see that the values participate in an inheritance relationship. Both ‘ibuprofen’ and ‘naproxen’ are non-steroidal anti-inflammatory drugs (NSAID), and ‘tylenol’ is an ‘acetaminophen’ drug, which in turn is an ‘analgesic’.

id	CC	CTRY	SYMP	DIAG	MED
t_1	US	United States	joint pain	osteoarthritis	ibuprofen
t_2	IN	India	joint pain	osteoarthritis	NSAID
t_3	CA	Canada	joint pain	osteoarthritis	naproxen
t_4	IN	Bharat	nausea	migrane	analgesic
t_5	US	America	nausea	migrane	tylenol
t_6	US	USA	nausea	migrane	acetaminophen
t_7	IN	India	chest pain	hypertension	morphine

Table 1: Sample clinical trials data

To address these problems, we demonstrate FastOFD¹, a tool for *contextual* data cleaning with a novel class of dependencies called Ontology Functional Dependencies (OFDs) which take synonyms and inheritance relationships into account. In the above example, if F_1 and F_2 were specified as OFDs then no tuples would be falsely reported as erroneous. Our demonstration focuses on the following novel features of FastOFD:

- (1) **Automatic discovery of OFDs to show how prevalent they are in real data.** We have recently proposed an efficient algorithm for discovering OFDs from data [1]. The FastOFD system uses this algorithm, and conference participants will be able to run it on several real datasets and ontologies, and visualize the results. Furthermore, conference participants will learn, through real examples, about an interesting aspect of OFDs that does not arise in standard FDs: the notion of senses or interpretations with respect to a given ontology. For example, the value “jaguar” can be interpreted as an animal or as a vehicle.
- (2) **Data cleaning with OFDs.** FastOFD discovers OFDs that mostly hold but may be violated by a bounded number of tuples. Once such OFDs are discovered, FastOFD identifies erroneous tuples and suggests how to modify them in order to remove inconsistencies. Conference participants will be able to apply the suggested modifications (or propose different modifications) in real-time.
- (3) **Comparison with FD-based data cleaning methods.** We demonstrate that FastOFD is practically as fast as existing algorithms for discovering traditional FDs, yet OFDs are more expressive. We also show that FastOFD significantly reduces the number of false positive errors compared to FD-based data cleaning techniques. This reduces the computational effort of data cleaning and the manual burden for users to identify falsely categorized data errors.

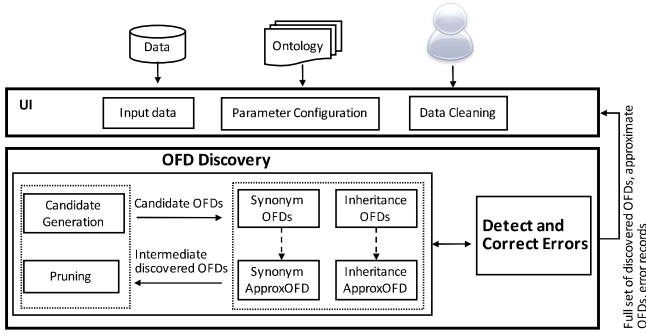

Figure 1: FastOFD Architecture.

2 SYSTEM OVERVIEW

2.1 Ontology Functional Dependencies

A functional dependency (FD) F over a relation R is represented as $X \rightarrow A$, where X is a set of attributes and A is a single attribute in R . An instance I of R satisfies F if for every pair of tuples $t_1, t_2 \in I$, if $t_1[X] = t_2[X]$, then $t_1[A] = t_2[A]$. A partition of X , Π_X , is the set of equivalence classes containing tuples with equal values in X . For example, in Table 1, $\Pi_{CC} = \{\{t_1, t_5, t_6\}\{t_2, t_4, t_7\}\{t_3\}\}$.

An ontology S is a specification of a domain that includes concepts, entities, properties, and relationships among them. The meaning of these constructs can be modeled according to different senses leading to different ontological interpretations.

Figure 2: A medical ontology

For example, the value ‘jaguar’ can be interpreted as an animal or as a vehicle. As an animal, ‘jaguar’ is synonymous with ‘panthera onca’, but not with the value ‘jaguar land rover’ which is an automotive company.

We define classes E to capture the senses defined in S . Let $synonyms(E)$ be the set of all synonyms for a class E . For instance, $synonyms(E1) = \{\text{‘car’}, \text{‘auto’}, \text{‘vehicle’}\}$, $synonyms(E2) = \{\text{‘jaguar’}, \text{‘jaguar land rover’}\}$ and $synonyms(E3) = \{\text{‘jaguar’}, \text{‘panthera onca’}\}$. Let $names(C)$ be the set of all classes, i.e., interpretations or senses, for a given value C . For example, $names(jaguar) = \{E2, E3\}$ as jaguar can be an animal or a vehicle. Let $descendants(E)$ be a set of all string representations for the class E or any of its descendants, i.e., $descendants(E) = \{s \mid s \in synonyms(E) \text{ or } s \in synonyms(E_i), \text{ where } E_i \text{ is-a } E_{i-1}, \dots, E_1 \text{ is-a } E\}$. For instance, $descendants(E3) = \{\text{‘jaguar’}, \text{‘peruvian jaguar’}, \text{‘mexican jaguar’}\}$.

We consider two ontological relationships in the right-hand-side of a dependency, synonyms and inheritance, leading to the following definitions for synonym OFDs and inheritance OFDs:

Definition 2.1. A relation instance I satisfies a *synonym OFD* $X \rightarrow_{syn} A$, if for each equivalence class $x \in \Pi_X(I)$, there exists an interpretation in S under which all the A -values of tuples in x are synonyms. That is, $X \rightarrow_{syn} A$ holds if for each class x ,

$$\bigcap_{names(a), a \in \{t[A] \mid t \in x\}} \neq \emptyset.$$

Definition 2.2. Let θ be a threshold representing the allowed path length between two nodes in S over an attribute A (each attribute can have a different θ). A relation instance I satisfies an *inheritance OFD* $X \rightarrow_{inh} A$ if for each equivalence class $x \in \Pi_X(I)$, the A -values of all tuples in x are descendants of

a Least Common Ancestor (LCA) which is within a distance of θ in S . That is, $X \rightarrow_{inh} A$ holds if for each equivalence class x ,

$$\bigcap_{descendants(names(a), a \in \{t[A] \mid t \in x\})} \neq \emptyset$$

and the resulting LCA is within a distance of θ in S to each a .

Example: Consider the OFD $\phi_1: [CC] \rightarrow_{syn} [CTRY]$ from Table 1. We have $\Pi_{CC} = \{\{t_1, t_5, t_6\}\{t_2, t_4, t_7\}\{t_3\}\}$. The first equivalence class, $\{t_1, t_5, t_6\}$, representing the value ‘US’, corresponds to three distinct values of CTRY. According to a geographical ontology, $names(\text{‘United States’}) \cap names(\text{‘America’}) \cap names(\text{‘USA’}) = \text{‘United States of America’}$. Similarly, the second class $\{t_2, t_4, t_7\}$ gives names(‘India’) \cap names(‘Bharat’) = ‘India’. The last equivalence class $\{t_3\}$ contains a single tuple, so there is no conflict. Since all references to CTRY in each equivalence class resolve to some common interpretation, ϕ_1 holds over Table 1. Now consider the OFD $\phi_2: [SYMP, DIAG] \rightarrow_{inh} [MED]$, and the ontology in Figure 2. For the first equivalence class, $\{t_1, t_2, t_3\}$, the LCA is ‘NSAID’ which is within a distance of one to each MED value in this class. For the second equivalence class, $\{t_4, t_5, t_6\}$, the LCA is ‘analgesic’, which is within a distance of two to each MED value in this class. The third equivalence class consists of a single tuple (t_7) so there is no conflict. Thus, ϕ_2 holds with $\theta = 2$ over MED.

Synonym OFDs subsume traditional FDs, where all values are assumed to have a single canonical name (i.e., for all classes E , $|synonyms(E)| = 1$). Furthermore, inheritance OFDs subsume synonym OFDs since we can recover synonym OFDs by setting $\theta = 0$ for each attribute. For example, the inheritance OFD $[SYMP, DIAG] \rightarrow_{inh} [MED]$ allows synonyms such as ‘ibuprofen’ and ‘advil’ to appear in tuples having the same SYMP and DIAG values; however, different medications under the same LCA such as ‘ibuprofen’ and ‘naproxen’ are not allowed.

OFDs *cannot* be reduced to traditional FDs or Metric FDs [5] (which assert that two tuples whose left-hand side attribute values are equal must have syntactically similar righthand side attribute values according to some distance metric). Since values may have multiple senses (e.g., jaguar the animal and jaguar the car), it is not possible to create a normalized relation instance by replacing each value with a unique canonical name. Furthermore, ontological similarity is not a metric since it does not satisfy the identity of indiscernibles (e.g., for synonyms).

2.2 OFD Discovery

The notion of senses makes OFDs non-trivial and has important implications on their discovery. While checking pairs of tuples is sufficient to identify violations and therefore verify traditional FDs (or metric FDs), this is not the case for OFDs. To verify an OFD, we must find a common interpretation of the Y -values for each equivalence class, as shown in Definitions 2.1 and 2.2. As a result, existing dependency discovery algorithms that validate dependencies via pairwise tuple comparisons (e.g., FastFD [6]) cannot be easily extended to OFDs.

Instead, we use our OFD discovery algorithm [1] which uses an Apriori-like approach, similar to the TANE FD discovery algorithm [4]. In this approach, the set of possible antecedent and consequent values considered by FastOFD is modeled as a set containment lattice. OFD candidates are considered by traversing the lattice in a breadth-first search manner. We consider all X consisting of single attribute sets, followed by all 2-attribute sets, and continue level by level to multi-attribute sets until (potentially) level $k = n$, where n is the number of attributes. When the

algorithm processes an attribute set X , it verifies candidate OFDs of the form $(X \setminus A) \rightarrow A$, where $A \in X$. This guarantees that only non-trivial OFDs are considered. For each candidate, we check if it is a valid synonym or inheritance OFD as per Definition 2.1 and Definition 2.2. This small-to-large search strategy guarantees that only minimal OFDs are discovered, and we develop novel optimizations to prune the search space effectively [1]. In our evaluation, we found that FastOFD incurred an average overhead of 5% to 10% over TANE [4] while discovering a larger set of (synonym, inheritance and approximate) dependencies.

2.3 Data Cleaning with Approximate OFDs

In addition to OFDs that hold over the entire data instance, FastOFD can discover approximate OFDs that hold with some exceptions. We define a minimum support level, τ , that specifies the minimum number of tuples that must satisfy an OFD ϕ . Given a relational instance I , and a minimum support threshold τ , $0 \leq \tau \leq 1$, FastOFD can find all minimal OFDs ϕ such that $s(\phi) \geq \tau$ where $s(\phi) = \max\{|r| \mid r \subseteq I, r \models \phi\}$. Since approximate OFDs are satisfied by most of the relation, violating tuples may be considered erroneous. These are records involving syntactically different but semantically equivalent attribute values that would otherwise be identified as errors using traditional FDs.

Furthermore, unlike previous dependency discovery algorithms, FastOFD discovers OFDs that hold under a given sense, which provides context for data cleaning. For a given ontology, we assume a sense is provided that defines the ontological context under which we identify the exceptions and the corresponding fixes (based on satisfying record values). For synonym OFDs, the set of potential clean values includes all synonyms defined in the ontology. For inheritance OFDs, we identify the highest ancestor a of the frequent (clean) values in the data, and record the set of ontology values from the sub-tree with a as the root. We ensure that the height of the sub-tree does not exceed θ .

2.4 FastOFD Architecture

FastOFD is an interactive web application running on Flask + uWSGI using Python and JavaScript libraries. The backend is implemented using Java v1.8, running on an Intel Xeon CPU E7-LL8867 2.13GHz with 32GB of memory. Figure 1 shows the FastOFD architecture, consisting of a user-interface (UI) layer, the OFD discovery engine, and a data cleaning module that identifies and corrects error values by interactively engaging with a user. The user interface (UI) layer provides the input specifications for the data instance, parameter configuration, and ontology RDF files along with the corresponding attributes and senses. Configuration settings include specifying the path length threshold (θ), the desired type of OFDs to be discovered (synonym or inheritance, or both), whether approximate OFDs are desired, and if so, the minimum support level. Discovered OFDs are returned to the user along with approximate OFDs for interactive cleaning.

The discovery algorithm generates candidate OFDs by traversing the attribute lattice in a level-wise manner. FastOFD checks whether a candidate $\phi : X \rightarrow A$ satisfies a synonym or inheritance OFD relative to the given parameter settings. If so, then candidate OFDs that are supersets of X are pruned from the lattice, and ϕ is added to the list of discovered OFDs. If ϕ is an approximate OFD (i.e., with support greater than τ), we record the satisfying (clean) values along with the exceptions, and continue the search by evaluating candidate OFDs containing supersets of X . The efficiency of our algorithm relies on pruning candidates

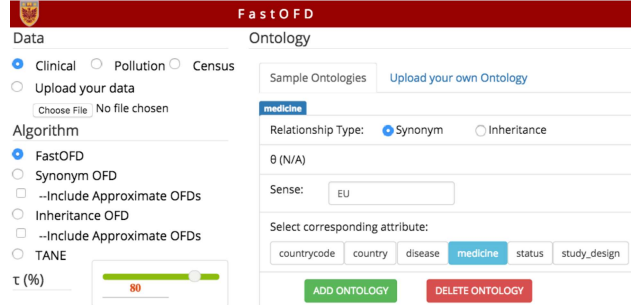

Figure 3: Input and parameter configurations.

through our axioms from the lattice that are supersets of discovered OFDs, keys, and FDs. We also disqualify approximate OFD candidates that do not have a minimum τ support. That is, for a candidate $X \rightarrow A$, adding a new attribute B to X only fragments the equivalence classes, and does not increase the support level.

3 DEMONSTRATION OVERVIEW

In this demo, conference participants will interact with FastOFD to: (1) discover OFDs and see first-hand how prevalent they are in real data. We show examples from both synonym and inheritance OFDs, and cases where similar OFDs exist under different senses; (2) interactively clean the data using approximate OFDs where candidate repairs are provided, and users can apply these changes in real-time with immediate feedback on the impact to support levels; and (3) experience the effectiveness of FastOFD to reduce the number of false positive errors while achieving comparable runtimes to traditional FD discovery algorithms.

Input Interface. Figure 3 shows the input interface where users can select a sample dataset among clinical trials data from LinkedCT.org, pollution data from the Canadian Pollutant Release Inventory, and census-income data from <https://archive.ics.uci.edu/ml/>. In this paper, we use the clinical data to demonstrate example scenarios. Users can then select the type of dependencies, configure τ to return approximate OFDs with minimum τ support, and inheritance OFDs containing IS-A relationships within a distance of θ in the ontology. For each input ontology, users can define the corresponding synonym or inheritance relationship, the applicable attribute, and the sense interpretation. For example, in Figure 3, we add an ontology containing synonyms for attribute ‘medicine’ to be interpreted under the sense ‘EU’ for European Union.

3.1 Automatic Discovery of OFDs

Figure 4 shows an example output of two discovered synonym OFDs, and four approximate synonym OFDs ranked according to decreasing support. Each dependency shows the corresponding sense under which it holds over the data. The inclusion of senses is unique to FastOFD (in contrast to other dependency discovery systems) as it provides a specific interpretation under which an OFD holds. For example, Figure 4 shows that the synonym OFD [disease] \rightarrow [medicine] holds over the clinical data under two senses: (i) as an OFD under sense ‘EU’ (for the ‘European Union’), and (ii) as an approximate (synonym) OFD under sense ‘US’ (for the ‘United States’) with 93.4% support. This example shows that the same medication may be used to treat different diseases, and is referred to by different names, in different regions of the world (i.e., in different geographical senses). Senses help to differentiate semantically equivalent entities under different contexts. Similarly, the OFD [country] \rightarrow [countryCode] holds

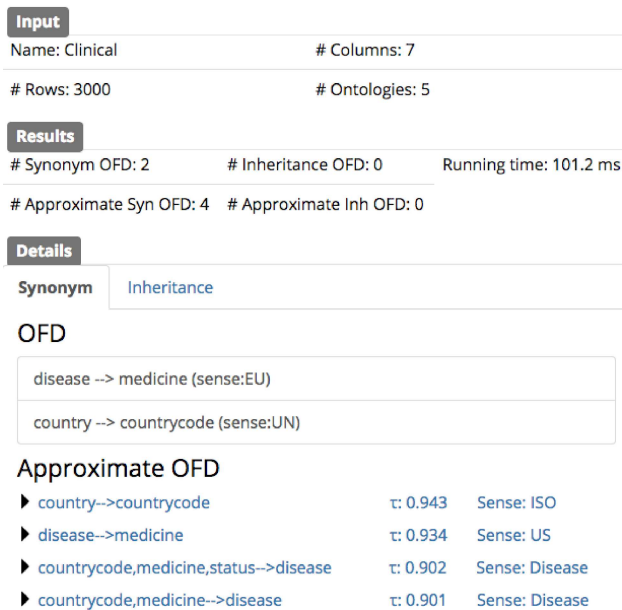

Figure 4: Viewing discovered OFDs.

under the sense ‘UN’ denoting country name abbreviations published by the United Nations, but holds approximately under the sense ‘ISO’ denoting the abbreviations used by the International Organization for Standardization. Conference participants will be able to delve deeper (by clicking on each OFD) to explore these distinctions between similar dependencies. Unlike previous dependency discovery algorithms that assume equivalence classes, FastOFD provides a contextual view for discovered OFDs that can be customized with interpretations according to a user’s domain or application requirements.

3.2 Contextual Data Cleaning

Given a set of approximate OFDs, we now show how users can interact with FastOFD to correct these exceptions. Figure 5 shows a data cleaning example w.r.t. the OFD ϕ : [disease] \rightarrow [medicine], that states a given disease is treated by prescribed medications. However, while ϕ holds over the clinical data under the sense ‘EU’, it holds only approximately under the ‘US’ sense as medication names vary between the two regions. An example of this semantic data quality issue is shown in Figure 5 by expanding the approximate OFD version of ϕ . Users can view the positive (supporting) examples highlighted in green, while the exceptions are highlighted in red. In this example, ‘asthma’ is treated by medications {‘Advicor’, ‘Advair’, ‘Seretide’}, which are all synonymous in the ‘EU’ sense. However, in the ‘US’, ‘Seretide’ is not recognized as a synonym, and is flagged as an exception. The frequency levels for each tuple pattern are shown such that users can correct exceptions directly, and receive immediate feedback. By clicking ‘Apply’, if the entered value(s) are correct, the corresponding τ support level for the OFD is updated, and the tuple pattern changes from red to green. Conference participants will be able to perform hands-on exploration and cleaning, and observe how prevalent these OFDs are in real data.

3.3 Effectiveness of FastOFD

Finally, we show that FastOFD significantly reduces the number of ‘false positive’ errors that are found in FD-based data cleaning solutions, with comparable running times to FD discovery algorithms even though OFDs have greater expressiveness and

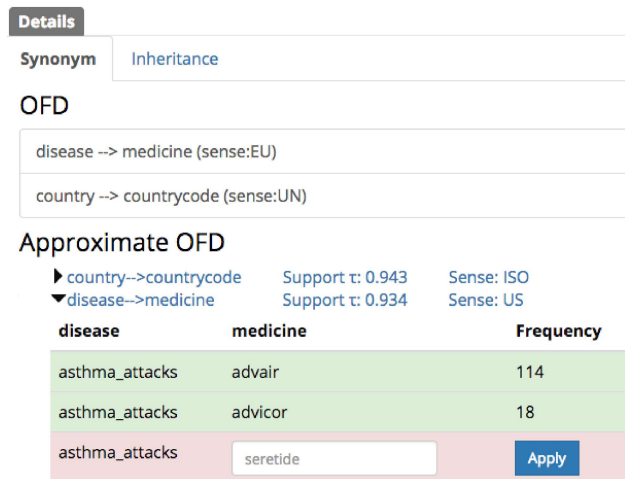

Figure 5: Data cleaning with approximate OFDs.

larger result sets [1]. Figure 6 shows the comparative performance between FastOFD and TANE, and more importantly, the distinctions between the two sets of approximate dependencies. While the same set of dependencies are discovered, the support level τ is higher for approximate OFDs than approximate FDs. Upon closer inspection, users will be able to drill down and notice that these differences are caused not only due to true errors (highlighted in red), but also the false positive errors (highlighted in blue). These false positive values represent values that are *syntactically* different than the clean (green highlighted) values, but are *semantically* equivalent. For example, the medication ‘Celexa’ is synonymous with ‘Celebrex’ in treating ‘osteoarthritis’. These values are identified as clean in FastOFD but as exceptions in TANE. Our case studies show that an average 33% of errors found in traditional FD-based data cleaning solutions are false positive errors that can be eliminated. This reduces the manual burden of having users validate these ‘errors’, and also reduces the space of possible repairs, thereby improving the overall data cleaning runtime. In addition to the synonym examples described here, conference participants will be able to explore examples involving inheritance properties that are present in real data.

Figure 6: Reducing the number of false positives.

ABSTRACT

Cities worldwide aim to reduce their greenhouse gas emissions and improve air quality for their citizens. Therefore, there is a need to implement smart city approaches to monitor, model, and understand local emissions to better guide these actions. We present our approach that deploys a number of low-cost sensors through a wireless Internet of Things (IoT) backbone and is thus capable of collecting high-granular data. Based on a flexible architecture, we built an ecosystem of data management and data analytics including processing, integration, analysis, and visualization as well as decision-support systems for cities to better understand their emissions. Our prototype system has so far been tested in two Scandinavian cities. We present this system and demonstrate how to collect, integrate, analyze, and visualize real-time air quality data.

1 INTRODUCTION

Urban emissions contribute over 60% to global greenhouse gas emissions. Cities aim at reducing their emissions through tailored policy and integration to Smart City approaches. Smart City approaches facilitate easier integration of emission sensing into city systems and fulfill city requirements through novel and low-cost approaches [5, 6, 8, 10, 11].

The overall aim of our project¹ is to fulfill the information needs of cities that need specific data for emission reduction actions by providing complementary on-the-ground emission data for improved understanding and decision making [2]. In short, the need based on future challenges faced by cities will be better and more high-granularity measurements to complement existing official measurement stations.

Some Nordic cities have specific challenges in that they have already implemented a range of climate actions, which means that future impact on a certain class of emissions can only be achieved by a more detailed and granular understanding and analysis of emissions, since many broad measures are already in place. The next step then is to get better insight into more

difficult to measure components, also to be able to adapt policy in fast feedback loops and at varying scales. This includes impact assessment of measures ranging from small-scale such as closing down certain streets (and being able to observe spillover and evasion effects in surrounding parts of the city) to large-scale such as changes in public transport or denser urban development.

A high spatial granularity of sensor deployments is obviously not possible with the existing expensive high-quality measurement stations that are often provided nationally. Our approach, in contrast, is to use low-cost sensors to cover a city's spatial footprint with a much higher sensor density. This enables a trade-off of high number and high granularity of low-cost sensors that can compensate for their relatively lower accuracy.

Existing official measurement stations are equipped with high-quality sensors that cost up to \$500,000. Our low-cost approach could provide a very dense coverage of a city with 250 additional sensors for the price of one additional station by using sensor units of around \$2,000 each. For ease of installation, this requires standalone sensor units that do not need cabling for electricity or connectivity. We achieve that by deploying solar-powered sensor nodes with a wireless data link over the LoRaWAN standard for Smart City IoT applications, which also enables us to quickly scale up the sensor deployment. The approach allows to quickly prototype system components on the hardware and software side for the overall goal of linking the measurement data to the information needs of the cities for emission reduction both for baseline and continuous data collection.

After having built and deployed the general IoT sensor network before [2], we focus here on the integration of data sources and the data analysis infrastructure for Smart City applications.

2 APPROACH

Our approach is to build an ecosystem of relevant tools and methods to better understand city emissions and work with data, such as analytics [9, 12], visualizations [7], and decision support systems [5, 6, 11] around local emission measurements and the integration of external data sources. This is an important aspect of Smart Cities [9], and can also be used as a case study to understand and build similar systems. Our system is piloted in the two cities of Trondheim, Norway, and Vejle, Denmark.

In this paper, we describe key aspects of this ecosystem of data analysis and visualization that strongly relates to challenges and

¹Carbon Track & Trace – CTT: <https://www.ntnu.edu/ad/ctt>

Figure 1: Overall system architecture

requirements of the cities. We further demonstrate the integration and aggregation of data sources for a smart city.

2.1 Architecture

The system architecture and data flow is sketched in Fig. 1, which consists of four components: a city-wide IoT sensor network, cloud-based systems for data collection and storage, integration of external data, and analysis and visualization platforms for stakeholders. The architecture is flexible through an ecosystem approach and accommodates different components for a range of related tasks. Our technology stack follows common concepts for IoT and Smart City systems [10] with project-specific adaptations.

The sensor network is composed of sensor nodes deployed within the city, which measure emissions and air parameters: CO₂, NO₂, PM_x (particulate matter); temperature, pressure, and humidity. The data is transmitted to the IoT backbone, which forwards collected data to the cloud storage, from where it is available for analysis and visualization, using relevant external data sources. The backbone uses LoRaWAN as a radio-based urban sensor networks through a number of gateways covering the pilot regions [2]. Data forwarding and cloud sensor management was built through the event-driven MQTT communication protocol.

Visualizations and analyses are connected to all stages of the data processing. Examples are network monitoring and early data validation close to the sensors, stream processing on measurement data, up to C&C centers, satellite measurement grounding, integration into GML-based 3D city models, and other forms of mapping and integration that we describe in the following.

2.2 Data Integration

Apart from the direct sensor data, there is a range of municipal and national data sets available as well as other external data sources that need to be included in the data analytics and visualization to support analyses and improve data quality. Table 1 gives an overview of these sources and how they can be utilized. They range from direct measurements of air quality that can be used to validate and calibrate the sensor network to other data sources that help to understand emissions in the context of a city, for example through traffic patterns [12] or integration into city tools and systems.

The sensor network has the usual issues of missing data that is dealt with on a technical monitoring level and being handled by standard methods in the analyses, as well as the aggregation of data from multiple sensor units. More interesting are the challenges posed in the data integration. The sources contain highly heterogeneous data, with different timescales, measurement frequencies, spatial distributions and granularities, measurement technologies, and a complex set of related uncertainties and inaccuracies in the data.

Figure 2: Dataport Protocol Diagram

2.3 Network Metadata Analysis and System Status Monitoring

The network, server components, gateways and sensors are subject to transient and permanent failures, which can ultimately result in missing data. Although the later analysis tasks can detect such losses of data, they do not analyze the cause for the error, or prevent further losses. Instead, failures in the system should be detected as quickly as possible, so that data loss is kept at a minimum. We therefore built a monitoring application (the *dataport*) to monitor the status of all sensors, gateways and the network [3]. It is built with the Akka framework, which facilitates the creation of fault-tolerant applications based on the actor model [4]. Actors are independent, supervised processes that encapsulate data and control logic and communicate via messages. Each device in the real world corresponds to a dedicated actor that acts as its digital twin, which is a virtual model of the sensor or gateway. It keeps track of its state in real-time, monitors all communication and triggers alarms if data is not received as expected. Incoming data contains meta-data that identifies the originating sensor and the gateway from which it was received. In this way, the digital twin for a gateway can detect if a gateway operates as expected.

Faults of a more complex nature, such as decaying sensors, erroneous behavior of sensor nodes, or missing data patterns need specific analysis. For example, a single missing measurement is expected occasionally. Based on the measurement frequency of individual sensors, it takes some cycles to determine a failure with certainty. As sensors nodes can adapt their frequency based on battery levels, a complex model of the sensor node and its status is needed for detection. Actors are organized hierarchically. On higher levels, failures can be grouped so that for example a distinction can be drawn between sensor failures versus a gateway outage that would make a set of sensors invisible.

The dataport also monitors the larger system, such as the The Things Network (TTN) cloud backend and the MQTT connection. If any of the components on the data path from the sensors to the data storage fails, the dataport generates a notification. If the dataport itself fails, it is detected by an external watchdog service, in this case AppBeat. The dataport further drives a visualization of the network itself, shown in Fig. 3, of the structure of digital twins for sensors and gateways, their location, the connections and live data transmission between sensors and gateways. Apart from the practical value of monitoring the network, it is also a useful illustration of the spatial and measurement characteristics.

2.4 Data Analyses and Visualizations

A range of analyses work on the collected data streams as illustrated in Fig. 1 apart from the more operational network analysis. Examples are ongoing data collection and analysis, understanding of patterns, as well as comparison of sensor measurements to air quality measurement stations to ground the network and calibrate the sensors. There are very few official stations; to

Table 1: Examples of external data integration

Type	Example	Description
Official air quality measurements	NILU data (Norwegian Air Quality Institute)	Ground truth for certain pollution types, grounding and calibrating measurements to high-quality reference stations
Remote sensing	NASA OCO-2 satellite CO ₂ measurements	Ground truth top-down measurements for certain emission types, large-scale coverage, low spatial resolution, coupling to large-scale modeling and validation
Traffic data	Traffic density from here.com	Estimate traffic emissions by correlating continuous external traffic density to emission measurements
3D city models	Municipal traffic counts Municipal 3D model of Vejle	Validate traffic estimations, but only available for short periods Integration into existing visualization tools. Use of city geometry in future emission modeling
National statistics	GHG emission estimates from national statistics office	down-scaled national GHG emission data, often with high uncertainties
Other municipal data and tools	GIS, statistics, decision support, etc.	Understanding emissions in the context of the city

Figure 3: Visualization of sensors, gateways, and links

support the grounding and calibration, we have co-located one of our sensor units to the only station in the pilot area. This allows to compare both absolute and relative accuracy and calibrate the local sensor and, through larger-scale correlated trends, the network, but with lower certainty. In connection with the network monitoring, it also allows the identification of outliers and malfunctioning sensors. Main ongoing work is modeling dependencies of NO₂, PM_x, and CO₂, especially from transport emissions, which therefore also looks at linking to traffic patterns [12]. We discuss some analytics around this data in the following.

Battery levels depend on the charging of the autonomous sensor units through their solar panels. Charged occurs during daytime, and is affected by weather conditions. It is important to monitor the battery level to keep the nodes running. Fig. 4 shows the battery level as a function of time (left), and the difference in battery-level from previous sent package versus time of day, and where red indicates whether the nodes could have been charged by sunlight since the previous package (right). This allows to estimate battery depletion.

Dynamics of CO₂ emissions and possible links to traffic in the form of a traffic jam factor (from here.com data) is shown in Fig. 5. According to the plots, we can conclude for this sensor location that traffic is not the only factor that accounts for the dynamics of the CO₂ emission as they exhibit different patterns, and have no apparent correlation. In fact, CO₂ emission dynamic is a more complex issue that may be affected by many factors, including traffic, wind speed, temperature, humidity and other weather conditions, as well as daily and seasonal patterns, which we will further investigate in our future work.

Figure 4: Battery level analysis

Figure 5: A study of CO₂ dynamics

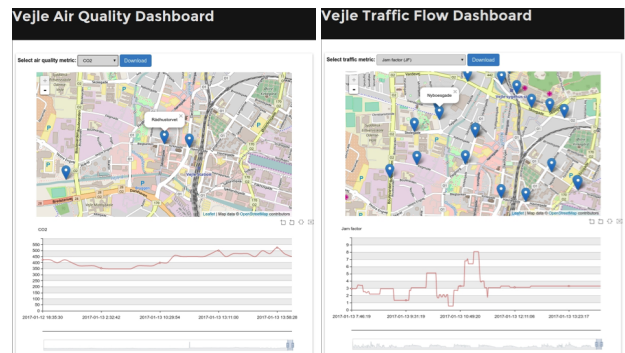

Figure 6: Example of dashboards for air quality and traffic

Visualizations and Dashboards for real-time monitoring. Fig. 6 shows the air quality and traffic flow dashboard, respectively. The dashboard is implemented using Apache Zeppelin as the visualization platform and accesses the data from the OpenTSDB time series database. The mapped sensors show the real-time data and analytic results for each location. Examples are the the air quality and traffic indicators in Fig. 6. This was further integrated into a 3D CityGML model as seen in Fig. 7 and also into a full network and data overview wall display shown in Fig. 8.

3 DEMONSTRATION

In this first full demonstration of the CTT air quality system, we show the architecture and implementations of IoT and analytics

Figure 7: Integration of sensor data into 3D city model

Figure 8: Network monitoring and data visualization dashboards

technologies in air quality monitoring and explore insights. We use two use cases of deploying our systems in Vejle, Denmark and Trondheim, Norway, where two and twelve sensors were deployed respectively to collect air quality data. We demonstrate our system from the perspective of developers, city policymakers, and citizens. For developers, we explore the system in detail, demonstrate the building blocks of the system, and show how to build similar IoT systems; for policymakers, we aim to assist them in decision making for smart cities with the proposed IoT technologies, e.g., urban planning; for citizens, we aim to raise the awareness of environment protection and greenhouse gas reduction for better city life.

We use real-time data collected from the deployed sensors from both cities, as well as traffic data sets streamed from the third-party traffic flow monitoring operator, here.com. The sensor data consist of the CO₂, NO₂, and PM_x, and weather data including humidity and temperature. The sensor data is collected at a five-minute interval. The demo also uses historic data saved in our time-series database, collected since January 2017.

Developers' point of view: We show the architecture and components used by our air quality monitoring system, including sensors, IoT sensor network, cloud storage for sensor data and external traffic data, analytics, and dashboards. We demonstrate how to collect, process and visualize high-frequent sensor data in our system developed on the Zeppelin platform; and how to streamline the whole data flow, including segmentation, chaining, and automation. Finally, we demonstrate how to generate dashboards and integrate analysis algorithms in the web interface. Attendees can vary system and analysis properties, and observe the reflection on the dashboard; and change the dependency of the data flow to evaluate the flexibility of the data stream analysis.

City officials' point of view: We show an interactive dashboard to analyze CO₂ dynamics using real-time and historic measurement data, and demonstrate the pattern and its correlation to the traffic flow (see Fig. 5–6). In addition, we demonstrate the 3D CityGML model integrating different measuring points of air quality (see Fig. 7). In this demo scenario, we can inject synthetic data showing different pollution levels. We interact with attendees by discussing urban planning issues such as construction

sites of roads, buildings or factories, and see how different pollution levels will affect their decision makings. Also, we consult with attendees about choosing the sites of air quality monitoring, e.g., according to the road network and building density.

Citizens' point of view: We demonstrate air quality and traffic flow on the dashboard using the real-time data. Similarly, we use synthetic data with different pollution levels, and discuss the influence on routing planning, and citizens' approaches for emission reduction. Attendees can browse historic data in the system to investigate anomalous emission levels.

4 CONCLUSION

We have described the possibilities for urban emission monitoring and our approach and the prototype system we have developed together with the approaches to data flows and analysis. The flexible and scalable solution allows to quickly prototype different analysis approaches on top of the sensor streams to link measured data to cities' information needs for emission reduction.

In future work, we plan to improve the measurement network and the real-time and aggregate dashboards. Further, with more data collected, we will be able to tune models for emission distribution and dispersion to overcome some of the issues and provide improved analysis with better models. Integration into decision support systems is a far goal. Urban emission monitoring needs a range of heterogeneous data and we are continuing to build useful urban systems around it.

ACKNOWLEDGEMENTS

This paper is part of the Carbon Track & Trace (CTT) project. Funding for this project was in part provided by the LoCaL² Climate-KIC flagship programme. We thank all our project partners and specifically VCS³ for the 3D city model demo. Parts of this article are based on project deliverables [1].

Pharos: Privacy Hazards of Replicating ORAM Stores

Victor Zakhary, Cetin Sahin, Amr El Abbadi, Huijia (Rachel) Lin, Stefano Tessaro

 [victorzakhary,cetin,amr,rachel.lin,tessaro]@cs.ucsb.edu

ABSTRACT

Although outsourcing data to cloud storage has become popular, the increasing concerns about data security and privacy in the cloud blocks broader cloud adoption. Recent efforts have developed oblivious storage systems to hide both the data content and the data access patterns from an untrusted cloud provider. These systems have shown great progress in improving the efficiency of oblivious accesses. However, these systems mainly focus on privacy without considering fault-tolerance of different system components. This makes prior proposals impractical for cloud applications that require 24/7 availability. In this demonstration, we propose **Pharos**, the **Privacy Hazards of Replicating ORAM Stores**. We aim to highlight the data access pattern privacy hazards of naively applying common database replication and operation execution techniques such as locking and asymmetric quorums.

1 INTRODUCTION

Outsourcing data to cloud storage has become increasingly popular due to its promise of better scalability and availability. However, existing confidentiality concerns [6] make potential users often skeptical about joining the cloud. While necessary, encryption alone is not sufficient to solve all privacy challenges posed by outsourcing private data. Although encryption hides the data content, the cloud provider can monitor the *access patterns* of each data block. This includes the recency and frequency of access in addition to the type of access such as reads and writes of each data block. Revealing data access patterns presents a real threat to the privacy of the outsourced data. Data access patterns can leak sensitive information using prior knowledge. For example, Islam et al. [11] show a concrete inference attack against an encrypted e-mail repository exploiting only access patterns.

Oblivious RAM (ORAM) – a cryptographic primitive originally proposed by Goldreich and Ostrovsky [9] as a solution for software protection – is the standard approach to hide access patterns. ORAM aims to hide the *target block of each access operation* and the *access operation type*. To achieve these *two* goals, each logical access is translated to a sequence of random looking accesses. In addition, ORAM shuffles and re-encrypts the data content in each data access, making access patterns of any two equally long sequences of read/write operations completely indistinguishable.

Hiding access patterns was initially considered in the context of memory access [9]. While classical ORAM schemes with small client memory apply directly to the memory access setting, in cloud applications a client has more storage space and is capable of storing more data locally and more importantly can outsource the storage of a large dataset to the cloud. The benefits, as well as, the fast adoption of the cloud encouraged the research community in the past several years to develop new secure data services. Many ORAM schemes have been constructed for secure cloud

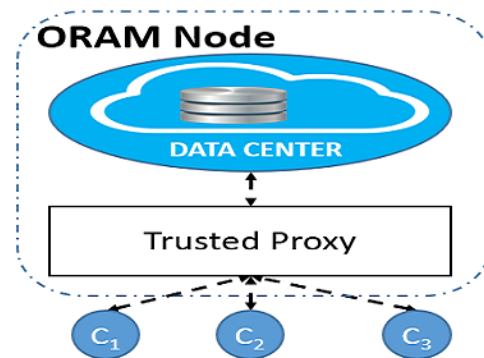

Figure 1: An ORAM node and clients.

storage systems [3, 4, 12–15, 17]. The initial ORAM proposals focused on developing ORAM constructions for a single client setting. These systems do not fit the requirements of cloud deployments, since accesses to the storage are performed sequentially (e.g. [9, 16]). To overcome the limitations of single client ORAM constructions, recent proposals develop new constructions that adopt real-world storage requirements by enabling multi-client concurrent and asynchronous accesses while preserving access privacy [3, 13, 14]. Figure 1 shows the typical architecture of an ORAM node in a cloud setting. The data is outsourced to the cloud and clients communicate with a trusted proxy to serve their requests. The trust proxy is responsible for data retrieval from the cloud storage in an oblivious manner.

Although these systems have shown great improvements in terms of efficiency and throughput, to the best of our knowledge, none of the earlier oblivious cloud storage systems were designed to tolerate the failure of different system components. Designing systems that run on commodity machines should consider failures of different system components as the norm such as machine crashes and network partitioning [7]. By ignoring fault tolerance as an important design principle, existing oblivious cloud storage solutions do not fit the requirements of real-world applications.

Figure 2: Replicated Cloud ORAM Node.

This demonstration, Pharos, is an initial attempt to illustrate the hazards of ignoring privacy when blindly applying standard database techniques to ensure fault-tolerance. The standard database approach for handling concurrency is locking. The standard

© 2018 Copyright held by the owner/author(s). Published in Proceedings of the 21st International Conference on Extending Database Technology (EDBT), March 26-29, 2018, ISBN 978-3-89318-078-3 on OpenProceedings.org. Distribution of this paper is permitted under the terms of the Creative Commons license CC-by-nc-nd 4.0.

approach to ensure fault-tolerance is replication, and typically quorums are used, where quorums of sets of replicas are chosen so that any two quorums have a non-empty intersection. In a database system, read operations are expected to be much more frequent than write operations, hence in a typical database system read operations acquire shared read locks while write operations acquire exclusive write locks. Furthermore, in a replicated fault-tolerant setting, asymmetric quorums are typically used, i.e., read operations use read quorums and write operations use write quorums, where read quorums do not need to intersect, but should intersect with write quorums. Since read operations dominate database workloads, read quorums are typically much smaller than the write ones. In fact, if write availability is not critical, a read quorum of one replica and a write quorum of all replicas is often recommended (or to increase write fault-tolerance, a read quorum of two replicas and a write of all replicas minus one).

Pharos supports oblivious access to replicated cloud ORAM nodes. Figure 2 shows an example of a replicated cloud ORAM node. The trusted proxy and the cloud storage are replicated to tolerate the failure of different system components (the cloud or the trusted proxy). Clients independently communicate with different trusted proxies to serve their read and write operations. During the demo, the attendees will be challenged to support a concurrency control and replication scheme. The traditional approaches of locking and asymmetric quorums will be proposed and contrasted with lock-free and symmetric quorums. Either the attendee or the system will propose an attack to illustrate the possible data access privacy violations in the chosen solutions. Pharos is a demonstration that will help bridge the gap between the database community and the security and privacy community by highlighting the privacy hazards in standard database solutions. Pharos presents attendees different attacks, thus giving them a real sense of the potential hazards of using a replication technique or an operation execution technique on the privacy of data access patterns.

2 DATA MODEL

We give a brief overview of oblivious storage systems that depend on a trusted proxy [3, 13, 14]. As shown in Figure 1, an **ORAM node** consists of a *storage* service that is outsourced to the cloud and a *trusted proxy* that is deployed in between to mediate client server communication as well as to execute the oblivious algorithm. Data is stored in a key-value store, which is encrypted and outsourced to the storage and the meta-data used to locate objects in the storage is maintained in the trusted proxy. Clients submit single operations: object lookups, $get(k)$, and object updates, $put(k, v)$, to the trusted proxy, where k is a key, and v is a value. The trusted proxy translates these requests into oblivious retrievals (OR) and oblivious evictions (OE). An **oblivious retrieval** translates a client get or put of an object O into fetching multiple objects where accessing O is obfuscated among the fetched objects. The trusted proxy has to write-back the retrieved objects by performing an oblivious eviction. An **oblivious eviction** hides the type of client access, (get or put), and the access frequency of different objects by shuffling and re-encrypting all the fetched objects at the trusted proxy before writing them back to the storage. Also, the trusted proxy has to update its meta-data to be able to locate these objects in the storage for later accesses.

3 THREAT MODEL

We consider the threat model for asynchronous ORAM that is introduced in [13]. The threat model assumes an honest-but-curious adversary which can see the raw storage and network communication of the server. It controls the asynchronous links where arbitrary delays can be added to different communication messages. Additionally, an adversary can adaptively schedule access, read and write operations and learn the timing of the responses. This security definition is called *aaob-security*. It formalizes the obliviousness in asynchronous and concurrent multiple access deployment scenarios and ensures that two timing consistent executions should be indistinguishable in the described threat model.

4 PRIVACY HAZARDS OF TYPICAL DATABASE TECHNIQUES

Replication has always been used to provide fault tolerance to database systems. Many of the database replication techniques were developed to focus on performance and data consistency assuming that all the data replicas are trusted. Designing systems where privacy is considered a first class requirement narrows the design choices. Many common design alternatives that enhance the performance might lead to a data access pattern privacy violation. We first illustrate the privacy hazards of using *asymmetric read and write quorums*. Then we demonstrate the problems of using *lock-based concurrency control* solutions.

4.1 Asymmetric Quorums Hazard

Database replication is commonly used to tolerate server failures. Once data is replicated, consistency becomes an important challenge. We assume linearizability [10] as a correctness condition for object accesses. Reading an object should always return the most recent committed update to this object. Although replicas can have different versions of the same object, client reads should always return the latest value of an object. This behavior is defined as operation consistency [2]. Operation consistency requires that clients receive the correct expected results regardless of the state consistency of replicas.

Different replication strategies introduce a trade off between fault tolerance, *the number of replica failures f that the system can tolerate before it stops completely*, and performance, *the number of replicas that should be accessed per read and update operations* for a given consistency requirement. We present the trade offs of different replication strategies.

Linearizability and operation consistency on the object level are achieved using quorums and version numbers [8]. A read quorum (q_r) is the minimum number of replicas that need to be accessed to retrieve the latest value of an object. A write quorum (q_w) is the minimum number of replicas that need to be updated to guarantee consistent reads. To achieve operation consistency, any read quorum should intersect with all write quorums $q_r \cap q_w \neq \emptyset$. This intersection guarantees that a read will always access the latest value of an object. To achieve total order on updates, a centralized sequencer can be used to assign total order version numbers for updates. In this case, write quorums do not have to intersect (e.g. write one read all). However, a total order can be achieved in a distributed way using quorums. In this case, any two write quorum q_{w_1} and q_{w_2} should intersect in at least one replica $q_{w_1} \cap q_{w_2} \neq \emptyset$. This intersection guarantees that objects will be updated in the same order in all the quorum replicas.

Table 1: Summary of different replication strategies, their requirements, and their guarantees.

Replication Strategy	$ q_r $	$ q_w $	f	Hazardous?
Master/Slave (read optimized)	1	N	0	Yes
Master/Slave (write optimized)	N	1	0	Yes
Majority quorums	N/2	N/2	N/2 - 1	No
Grid quorums [5]	\sqrt{N}	$2\sqrt{N}$	$\sqrt{N} - 1$	Yes
Tree quorums [1]	$\log(N)$	$\log(N)$	$\log(N) - 1$	No

Table 1 summarizes the commonly used quorum sizes and their degree of fault tolerance in the worst case. Majority quorums tolerate the failure of any number of replicas less than a majority. It executes read and write operations from majority quorums. Master/slave (read optimized) requires write quorums of size N. If updates are sent to all the replicas, reading from any single replica returns the most up to date version of an object. Similarly, master/slave(write optimized) requires read quorums of size N and write quorums of size 1. Reading all the replicas of an object guarantees freshness given that updates are applied to at least one replica. In a master/slave model, the failure of one replica halts any update(read optimized) or read(write optimized) and hence stops the whole system. Many proposals are based on the notion of logical structures that are imposed on the replicas and used to reduce the cost of quorums, while maintaining the intersection property. As a result, usually, one operation, eg. read operations, requires smaller quorums and hence is cheaper, but then write operations are more expensive. Cheung et al. [5] proposed the grid protocol to maintain replicated data. Replicas are ordered in a grid and a read quorum is any row **or** any column in the grid and a write quorum is any row **together with** any column in the grid. The failure of a full row or a full column halts the system and prevents any updates. Agrawal and El Abbadi [1] present tree quorums where read quorums and write quorums are paths in the tree from the root to a leaf. The failure of a full path stops the system.

The last column of Table 1 indicates if a replication strategy could introduce any privacy hazards on the data access patterns. As shown, all replication strategies that use *symmetric* read and write quorums are safe while others that use *asymmetric* read and write quorums are hazardous.

Recall that in the threat model of Section 3, an adversary monitors all the communication links between the clients and the trusted proxies. When asymmetric read and write quorums are used, the adversary can easily distinguish between read and write accesses by observing the number of messages sent per access. This allows the adversary to identify the type of access for every legitimate client request. Although asymmetric quorums can benefit the system performance, they can easily be used to leak the access type which represents a privacy hazard on the data access patterns.

4.2 Locking Hazards

All trusted-proxy-based ORAM systems assume a single trusted proxy that serves all the client requests. This single trusted proxy is responsible for hiding the access patterns of all client requests and achieving linearizability of access for every data object. Upon

replicating the ORAM nodes and their trusted proxies, the problem of consistently updating the data replicas occurs. In particular, concurrent updates on the same object need to be serialized across the different data replicas. A widely used approach to tackle this problem is *locking*. When a client updates a data object, she first acquires an exclusive lock on this object from a write quorum. Upon receiving the lock response from a write quorum, the client updates the data object and releases the locks. This prevents any inconsistencies that may occur from concurrent updates on the same object. Any concurrent access on the same object that is issued by another client has to wait until the locks are released. However, this concurrent access would not block if it updates a different object.

Recall that in the threat model of Section 3, an adversary can adaptively schedule read and write accesses while trying to understand the objects that are being accessed by other clients. When locks are used, the adversary can concurrently schedule write accesses on all the objects immediately after a legitimate client's access. The adversary should receive the requested locks on all the objects except the one that is being accessed by the legitimate client. By observing the locking responses, the adversary can identify which object is being accessed by the legitimate client request. This attack illustrates the hazard of using locks on the privacy of data access patterns.

5 PHAROS

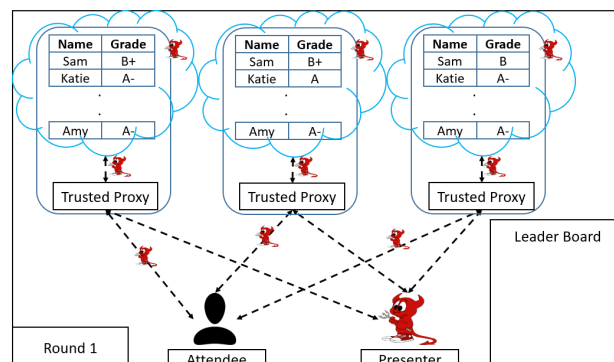

Figure 3: An adversary tries to understand the request types and the data records accessed by a legitimate client.

We propose Pharos to motivate a deeper understanding and appreciation of the privacy hazards that result from the naive application of locks and asymmetric quorums to replicate ORAM stores. Both the attacks on locks and asymmetric quorums result from observing only the communication patterns between the client and the trusted proxy. These attacks are independent of the ORAM implementation. Therefore, we assume a simplified system implementation to illustrate the attacks without distracting the attendee with the ORAM implementation details.

The setup: we assume a simple dataset of 10 student records stored in the ORAM node. Each record has a student name and a grade. The dataset is replicated into three trusted-proxy-based ORAM nodes for fault tolerance. These ORAM nodes are hosted on three cloud machines. The attendee gets to know that locks are used to ensure the consistency of the updates. Also, asymmetric read one write all quorums are used to optimize the latency of read operations. Recall that in the data model of Section 2,

a client can submit $get(student_name)$ to read the record of a student and $put(student_name, grade)$ to update the grade of a student. There are two types of players in the system: legitimate clients and adversaries. A legitimate client submits requests to read or update a data record. An adversary monitors the network, adds delays to messages, and schedules read and write requests in an attempt to reveal the data record or the type of request submitted by a legitimate client. To simulate adversarial network monitoring, each ORAM node sends the adversary the number of messages it receives and an identification of the source of these messages. The setup and the adversary capabilities are shown in Figure 3.

This demonstration proceeds in multiple rounds where the attendee gets to play one of the two roles and the presenter plays the other role. *In the first round*, the attendee is asked to update some student record and the presenter, on another machine, tries to reveal the data record. *In the second round*, the attendee and the presenter flip roles. The presenter submits a sequence of read and update requests and the attendee tries to reveal the type of request submitted by the presenter. The attendees who are able to explain how the two attacks work will have their names written on the *leader board*.

6 CONCLUSION

Private access of data stores is becoming very relevant in the context of cloud computing. Prior work in the security community focused on the privacy of access. We strongly believe that for the success of the cloud, **both** privacy and fault-tolerance dimensions need to be addressed. The goal of Pharos is twofold. First we propose some simple but effective attacks that reveal significant security leaks when the standard approaches for replication are incorporated in a straightforward manner with the privacy preserving solutions. Second, Pharos is a pedagogical game that educates the attendee on the privacy hazards of replication. Our aim is to make the database practitioner attendee aware of these challenges and hence be motivated to better understand the privacy concerns when designing fault-tolerant database systems.
