Foreword

The International Conference on Extending Database Technology (EDBT) is a leading international forum for database researchers, developers, and users to present and discuss cutting-edge ideas, and to exchange techniques, tools, and experiences related to data management. Data management is an essential enabling technology for scientific, business, and social communities. It is driven by the requirements of applications across many scientific, business and social communities, and runs on diverse technical platforms associated with the web, enterprises, clouds and mobile devices. The database community has a continuing tradition of contributing with models, algorithms and architectures to the set of tools and applications that enable day-to-day functioning of our societies. Faced with the broad challenges of today's applications, data management technology constantly broadens its reach, exploiting new hardware and software to achieve innovative results.

EDBT 2018 solicited submissions of original research contributions, descriptions of industrial solutions and applications, and proposals for tutorials and software demonstrations. We encouraged submissions of research papers related to all aspects of data management. In addition to regular research paper submissions, EDBT 2018 again encouraged the submission of short research papers, which includes visionary papers that provide a forum for the identification and discussion of new or emerging areas, innovative or risky approaches, or emerging applications that require extensions of established techniques. Short papers are presented as posters at plenary poster sessions of the conference. This provides an excellent opportunity to describe significant work in progress or research that is best communicated interactively and fosters discussions.

The program committees of EDBT accepted 35 out of 142 submitted regular research papers, resulting in an acceptance rate of 24.6% for the research track; 23 out of 84 submitted short research papers, resulting in an acceptance rate of 27.4% for short research papers; 16 out of 37 demos, resulting in an acceptance rate of 43.2% for the demonstration track; and 10 out of 28 industrial and application papers, resulting in an acceptance rate of 35.7% for industrial and application papers. The papers will be presented in twelve research paper sessions, three industrial and application sessions, as well as two plenary poster and demonstration sessions. The program additionally features four workshops, one of which is the well-established DOLAP workshop that has successfully been co-located with EDBT since many years. Finally, the conference program includes four tutorials and an EDBT and ICDT joint session on research challenges.

I would like to thank all authors for their contributions: a successful conference crucially depends on high-quality submissions. I also would like to thank all reviewers for serving on the EDBT 2018 program committee, in particular for the high quality and timely handling of all reviews and discussions. This community service requires a lot of work on a tight schedule, and is what makes our research community function and ensures the sustained impact of our research. Thanks to this effort we can look forward to an exciting program and attractive EDBT conference in Vienna from March 26-29, 2018. A warm thanks to Norman Paton and Divesh Srivastava for serving on the Test-of-Time Award committee to select the paper from EDBT 2008 that has had the most lasting influence. The committee selected the paper Social ties and their relevance to churn in mobile telecom networks by Koustuv Dasgupta, Rahul Singh, Balaji Viswanathan, Dipanjan Chakraborty, Sougata Mukherjea, Amit A. Nanavati, and Anupam Josi for the test-of-time award.

Lei Chen, Wolfgang Lehner and Kian-Lee Tan generously accepted to serve on the Best Paper committee. As best paper, the committee selected the paper Temporally-Biased Sampling for Online Model Management by Brian Hentschel from Harvard University, Peter Haas from the University of Massachusetts Amherst, and Yuanyuan Tian from IBM Almaden Research Center. The EDBT best paper runner-up was awarded to the paper GeoAlign: Interpolating Aggregates over Unaligned Partitions by Jie Song from the University of Michigan, Danai Koutra from the University of Michigan, Murali Mani from the University of Michigan, Flint, and H. Jagadish from the University of Michigan. Congratulations to the awardees and a warm thanks to the committee members for their work.

The EDBT 2018 program is the result of the joint effort of many people who shared their experience and time to contribute to the EDBT 2018 program and make the conference a success. Norman May served as PC chair for industrial and application papers; Shan-Hung as PC chair for the demonstration track; Erhard Rahm as tutorial chair; Nikolaus Augsten as workshop chair; and Dan Olteanu as challenge session organizer. My warmest thank to all these people.

The general chair, Reinhard Pichler and the local organizers worked hard to make all necessary arrangements for a successful event. Special thanks to Katja Hose, the proceedings chair; Dimitris Sacharidis, the sponsorship chair; and Shqiponja Ahmetaj, Markus Kröll, and Wolfgang Fischl, the website chairs, for tirelessly finding solutions for all our needs and making things happen. Norman Paton was most helpful in advising and coordinating with the EDBT Executive Board.

I hope that you find EDBT 2018 inspiring, informative, and enjoyable and look forward to meeting you in Vienna.

Test-of-Time Award

Since 2014, the Extended Database Technology (EDBT) Conference awards the EDBT test-of-time award, with the goal of recognizing papers presented at EDBT Conferences that have had the most impact in terms of research, methodology, conceptual contribution, or transfer to practice.

This year the award has been given to a paper from the EDBT 2008 Conference in Nantes, France. The award was bestowed upon the paper:

Social ties and their relevance to churn in mobile telecom networks

by Koustuv Dasgupta, Rahul Singh, Balaji Viswanathan, Dipanjan Chakraborty, Sougata Mukherjea, Amit A. Nanavati and Anupam Josi

published in the EDBT 2008 Proceedings, pp. 668–677, DOI: 10.1145/1353343.1353424.

This industry track paper reports on an analysis of mobile telecoms data, with a view to predicting which customers will leave. The analysis involves commercial mobile telephony data, in which nodes are customers and edges represent calls. The hypothesis tested is that it is possible to predict who will leave a network based on earlier departures among their connections. The main technique investigated is the use of spreading activation, to predict the heat of nodes based on the heat of connected nodes. It is shown how the approach based on connections is more effective than classification techniques based on other properties of the nodes. As a result, the paper provides early and compelling experience on the combination an important real problem (churn in mobile telecom networks) with a powerful technique (social ties) and applies it on large real data (telecom operator network over 4 months). The approach has influenced many subsequent studies, for the same problem, but also for analyses involving different types of network and different hypotheses. Social network analysis continues as an important and active area ten years later, and this paper continues to be widely cited.

The EDBT 2018 Test-of-Time Award Committee consisted of Michael Böhlen, Divesh Srivastava and Norman Paton. The EDBT Test-of-Time award for 2018 will be presented during the EDBT/ICDT 2018 Conference, March 26–29, in Vienna, Austria (<http://edbticdt2018.at>).

Best Paper Award

The best paper award was bestowed upon the paper:

Temporally-Biased Sampling for Online Model Management

by Brian Hentschel from Harvard University, Peter Haas from the University of Massachusetts Amherst, and Yuanyuan Tian from the IBM Almaden Research Center. DOI: 10.5441/002/edbt.2018.11

The paper proposes a temporally-biased sampling method for a stream of batches that weighs recent data items more heavily. The inclusion probabilities of data items decay exponentially over time. The authors introduce a reservoir-based temporally-biased sampling method that asserts an upper bound on the sample size while keeping the decay of the sample predictable. The problem is well motivated and described, and the paper offers an excellent solution that is formalized precisely, is robust in the presence of evolving data, and has been implemented and evaluated for a distributed setting.

The best paper runner-up award was bestowed upon the paper:

GeoAlign: Interpolating Aggregates over Unaligned Partitions

by Jie Song from the University of Michigan, Danai Koutra from the University of Michigan, Murali Mani from the University of Michigan, Flint, and H. Jagadish from the University of Michigan. DOI: 10.5441/002/edbt.2018.32

This paper introduces a novel technique to integrate geographical summaries over unaligned geographical regions, e.g., counties and ZIP codes. While traditional techniques assume that the data in each region is uniformly distributed, the proposed approach infers the distribution based on other datasets. The proposed idea is novel, refreshing, and nicely motivated. The described solutions are practical, have been implemented and evaluated, and there is good potential for follow-up work.

The EDBT 2018 Best Paper Award Committee consisted of Michael Böhlen, Lei Chen, Wolfgang Lehner, and Kian-Lee Tan. The EDBT Best Paper Awards for 2018 will be presented during the EDBT/ICDT 2018 Conference, March 26-29, in Vienna, Austria (<http://edbticdt2018.at>).

Table of Contents

Foreword	i
Program Committee Members	ii
Test-of-Time Award	iv
Best Paper Award	v
Table of Contents	vi
Research Papers	
ID Repair for Trajectories with Transition Graphs <i>Xingcan Cui, Xiaohui Yu, Xiaofang Zhou, Jiong Guo</i>	1
MTBase: Optimizing Cross-Tenant Database Queries <i>Lucas Braun, Renato Marroquin, Ken Tsay, Donald Kossmann</i>	13
Extending In-Memory Relational Database Engines with Native Graph Support <i>Mohamed Hassan, Tatiana Kuznetsova, Hyun Chai Jeong, Walid Aref, Mohammad Sadoghi</i>	25
Sequenced Route Query with Semantic Hierarchy <i>Yuya Sasaki, Yoshiharu Ishikawa, Yasuhiro Fujiwara, Makoto Onizuka</i>	37
On Complexity and Efficiency of Mutual Information Estimation on Static and Dynamic Data <i>Michael Vollmer, Ignaz Rutter, Klemens Böhm</i>	49
Finding All Maximal Connected s-Cliques in Social Networks <i>Rachel Behar, Sara Cohen</i>	61
Summarization Algorithms for Record Linkage <i>Dimitrios Karapiperis, Aris Gkoulalas-Divanis, Vassilios S. Verykios</i>	73
Continuous Monitoring of Pareto Frontiers on Partially Ordered Attributes for Many Users <i>Afroza Sultana, Chengkai Li</i>	85
Optimizing Selection Processing for Encrypted Database using Past Result Knowledge Base <i>Wai Kit Wong, Kwok Wai Wong, Ho-Yin Yue</i>	97
Temporally-Biased Sampling for Online Model Management <i>Brian Hentschel, Peter J. Haas, Yuanyuan Tian</i>	109
Detecting Database File Tampering through Page Carving <i>James Wagner, Alexander Rasin, Tanu Malik, Karen Heart, Jacob Furst, Jonathan Grier</i>	121
User-guided Repairing of Inconsistent Knowledge Bases <i>Abdallah Arioua, Angela Bonifati</i>	133
Synchronous Multi-GPU Training for Deep Learning with Low-Precision Communications: An Empirical Study <i>Demjan Grubic, Leo Tam, Dan Alistarh, Ce Zhang</i>	145
EasyCommit: A Non-blocking Two-phase Commit Protocol <i>Suyash Gupta, Mohammad Sadoghi</i>	157
Beyond Frequencies: Graph Pattern Mining in Multi-weighted Graphs <i>Giulia Preti, Matteo Lissandrini, Davide Mottin, Yannis Velegrakis</i>	169
Scalable Evaluation of k-NN Queries on Large Uncertain Graphs <i>Xiaodong Li, Reynold Cheng, Yixiang Fang, Jiafeng Hu, Silviu Maniu</i>	181

MatchCatcher: A Debugger for Blocking in Entity Matching <i>Han Li, Pradap Konda, Paul Suganthan G C, Anhai Doan, Benjamin Snyder, Youngchoon Park, Ganesh Krishnan, Rohit Deep, Vijay Raghavendra</i>	193
Extracting Statistical Graph Features for Accurate and Efficient Time Series Classification <i>Daoyuan Li, Jessica Lin, Tegawendé Bissyandé, Jacques Klein, Yves Le Traon</i>	205
Counting Edges with Target Labels in Online Social Networks via Random Walk <i>Yang Wu, Cheng Long, Ada Fu, Zitong Chen</i>	217
An Homophily-based Approach for Fast Post Recommendation on Twitter <i>Quentin Grossetti, Camelia Constantin, Cedric du Mouza, Nicolas Travers</i>	229
Online Set Selection with Fairness and Diversity Constraints <i>Julia Stoyanovich, Ke Yang, H. Jagadish</i>	241
Apollo: Learning Query Correlations for Predictive Caching in Geo-Distributed Systems <i>Brad Glasbergen, Michael Abebe, Khuzaima Daudjee, Scott Foggo, Anil Pacaci</i>	253
Interactive Rule Refinement for Fraud Detection <i>Tova Milo, Slava Novgorodov, Wang-Chiew Tan</i>	265
Privacy Preserving Group Nearest Neighbor Search <i>Yuncheng Wu, Ke Wang, Zhilin Zhang, weipeng lin, Hong Chen, Cuiping Li</i>	277
Pattern Search in Temporal Social Networks <i>Andreas Züfle, Matthias Renz, Tobias Emrich, Maximilian Franzke</i>	289
Scalable and Dynamic Regeneration of Big Data Volumes <i>Anupam Sanghi, Raghav Sood, Jayant Haritsa, Srikanta Tirthapura</i>	301
TPStream: Low-Latency Temporal Pattern Matching on Event Streams <i>Michael Körber, Nikolaus Glombiewski, Bernhard Seeger</i>	313
QUASII: QUery-Aware Spatial Incremental Index <i>Mirjana Pavlovic, Darius Sidlauskas, Thomas Heinis, Anastasia Ailamaki</i>	325
Loom: Query-aware Partitioning of Online Graphs <i>Hugo Firth, Paolo Missier, Jack Aiston</i>	337
Kernel-Based Cardinality Estimation on Metric Data <i>Michael Mattig, Thomas Fober, Christian Beilschmidt, Bernhard Seeger</i>	349
GeoAlign: Interpolating Aggregates over Unaligned Partitions <i>Jie Song, Danai Koutra, Murali Mani, H. Jagadish</i>	361
Distributed query-aware quantization for high-dimensional similarity searches <i>Gheorghii Guzun, Guadalupe Canahuate</i>	373
Global-Scale Placement of Transactional Data Stores <i>Victor Zakhary, Faisal Nawab, Divy Agrawal, Amr El Abbadi</i>	385
SlickDeque: High Throughput and Low Latency Incremental Sliding-Window Aggregation <i>Anatoli Shein, Panos Chrysanthis, Alexandros Labrinidis</i>	397
Modeling and Exploiting Goal and Action Associations for Recommendations <i>Dimitra Papadimitriou, Yannis Velegrakis, Georgia Koutrika</i>	409
Short Papers	
Very-Low Random Projection Maps <i>Anastasios Zouzias, Michail Vlachos</i>	421

Interval Count Semi-Joins <i>Panagiotis Bouros, Nikos Mamoulis</i>	425
Notable Characteristics Search through Knowledge Graphs <i>Davide Mottin, Bastian Grasnck, Axel Kroschk, Patrick Siegler, Emmanuel Müller</i>	429
EmbedS: Scalable, Ontology-aware Graph Embeddings <i>Gonzalo Diaz, Achille Fokoue, Mohammad Sadoghi</i>	433
All that Incremental is not Efficient: Towards Recomputation Based Complex Event Processing for Expensive Queries <i>Abderrahmen Kammoun, Syed Gillani, Julien Subercaze, Stephane Frenot, Kamal Singh, Frederique Laforest, Jacques Fayolle</i>	437
DeepEye: Visualizing Your Data by Keyword Search <i>xuedi qin, Yuyu Luo, Nan Tang, Guoliang Li</i>	441
Research Directions in Blockchain Data Management and Analytics <i>Hoang Tam Vo, Ashish Kundu, Mukesh Mohania</i>	445
Scalable Active Temporal Constrained Clustering <i>Son Mai, Sihem Amer-Yahia, Ahlame Douzal Chouakria</i>	449
Global Range Encoding for Efficient Partition Elimination <i>Jeremy Chen, Reza Sherkat, Mihnea ANDREI, Heiko Gerwens</i>	453
NoFTL-KV: Tackling Write-Amplification on KV-Stores with Native Storage Management <i>Tobias Vincon, Sergej Hardock, Christian Riegger, Julian Oppermann, Andreas Koch, Ilia Petrov</i>	457
Towards Hypothetical Reasoning Using Distributed Provenance <i>Daniel Deutch, Yuval Moskovitch, Itay Polak, Noam Rinetzky</i>	461
On Answering Why-Not Queries Against Scientific Workflow Provenance <i>Khalid Belhajjame</i>	465
PRoST: Distributed Execution of SPARQL Queries Using Mixed Partitioning Strategies <i>Matteo Cossu, Michael Färber, Georg Lausen</i>	469
Deep Integration of Machine Learning Into Column Stores <i>Mark Raasveldt, Pedro Holanda, Hannes Mühleisen, Stefan Manegold</i>	473
Scalable Detection of Concept Drifts on Data Streams with Parallel Adaptive Windowing <i>Philipp Marian Grulich, Rene Saitenmacher, Jonas Traub, Sebastian Breß, Tilmann Rabl, Volker Markl</i>	477
Point-of-Interest Recommendation Using Heterogeneous Link Prediction <i>Alireza Pourali, Fattane Zarrinkalam, Ebrahim Bagheri</i>	481
MetisIDX - From Adaptive to Predictive Data Indexing <i>Elvis Teixeira, Paulo Amora, Javam Machado</i>	485
Efficient SIMD Vectorization for Hashing in OpenCL <i>Tobias Behrens, Viktor Rosenfeld, Jonas Traub, Sebastian Breß, Volker Markl</i>	489
Histogram Domain Ordering for Path Selectivity Estimation <i>Nikolay Yakovets, Li Wang, George Fletcher, Craig Taverner, Alexandra Poulouvassilis</i>	493
Nomadic Datacenters at the Network Edge: Data Management Challenges for the Cloud with Mobile Infrastructure <i>Faisal Nawab, Divy Agrawal, Amr El Abbadi</i>	497
Dynamic Resource Routing using Real-Time Information <i>Sebastian Schmoll, Matthias Schubert</i>	501

Data Structures for Efficient Computation of Influence Maximization and Influence Estimation <i>Diana Popova, Akshay Khot, Alex Thomo</i>	505
A Roadmap towards Declarative Similarity Queries <i>Nikolaus Augsten</i>	509
Tutorials	
Interactive Exploration of Composite Items <i>Sihem Amer-Yahia, Senjuti Basu Roy</i>	513

ABSTRACT

In many surveillance applications, capture devices are set on fixed locations to track entities, leading to valuable spatio-temporal trajectories. However, sometimes the IDs of the entities in these trajectories are incorrectly identified due to various reasons (e.g., illumination conditions and partial occlusion). Since very often the movements of the entities are constrained by certain restrictions imposed by the application (e.g., vehicles must move along the given road network), we consider how to repair the erroneous IDs using transition graphs derived from such restrictions. Roughly speaking, the occurrence of erroneous IDs can cause a valid trajectory to be broken into trajectory fragments that violate some movement constraints imposed by the transition graph, and we aim to repair them by rewriting the IDs and merging the fragments. This problem is practically challenging since it is not easy to judge which IDs in the dataset are correct, and also there may be multiple candidates as the correct value for a single error. We formulate the repair process as an optimization problem and propose a two-phase repair paradigm, which includes candidate repair generation and compatible repair selection, to maximize the quality improvement estimated by a designed objective function. Though both phases are intractable, we propose effective algorithms to solve them through exploiting the locality and sparsity of trajectories. We further devise an index structure, as well as a pruning method to make the repair process more efficient. Experiments on both real and synthetic datasets demonstrate the effectiveness and efficiency of the proposed methods.

1 INTRODUCTION

Many surveillance related applications require the continuous tracking of entities over time in a specified area. For example, in maritime transport, surveillance devices can be set on ports to track the ships; in traffic surveillance systems, cameras are placed along city streets to capture images of passing vehicles. One of the main tasks for these applications is to identify the unique ID (which may be an atomic value or a composite one consisting of multiple features, such as name, color and shape) of each recorded entity (e.g., a ship or a vehicle) so that tracking records of those entities can be constituted.

For instance, vision-based algorithms are used to identify both the types [3] and names [15] of ships; similarly, optical character recognition (OCR) techniques are used to distill license plate numbers from the captured vehicle images. Due to various reasons (e.g., illumination conditions, partial occlusion or masking), it is not uncommon for the IDs of some entities to be incorrectly identified. Although much effort has been devoted to developing new techniques for improving the recognition accuracy, such errors are still unavoidable, especially when deliberate efforts are made

to prevent the entities from being recognized (e.g., in the case of smuggling at sea¹). According to recent studies [10, 15], the recognition rates of modern approaches are generally over 90% in lab environments, while in real-world settings, the rates may drop (e.g., to about 83% in the real traffic dataset we examined).

In this paper, we take a different perspective and aim to repair erroneous IDs by exploiting the inherent movement constraints, which are formally represented as *transition graphs*, that each entity must follow. Specifically, a transition graph is a directed graph with each vertex corresponding to a location and each edge a feasible move. Furthermore, some vertices are designated as the entrance/exit locations. In general, the transition graphs are the results of geographical restrictions (e.g., road networks), regulations (e.g., shipping routes), etc., and thus can be easily derived or sometimes even explicitly given.

1.1 A Motivating Example

Figure 1: A Transition Graph Example

Example 1.1. As a running example, consider the transition graph depicted in Figure 1(b) for the road network shown in Figure 1(a) with surveillance cameras installed at locations A, B, \dots, E (where the hollow arrows indicate driving directions). The transition graph implies the following two movement constraints: (1) vehicles can only enter this area at locations A or C and leave from location E ; and (2) the move of a vehicle must match a directed edge in this graph.

Table 1 shows an example of the tracking records captured by the cameras in Figure 1(a). Without loss of generality, we assume that each tracking record contains at least three fields – the ID, the capture location and the capture timestamp. We also assume that errors occur only in the ID field, as the locations are fixed and the timestamps can be synchronized across cameras and are thus much less error-prone. Records with the same ID can be chronologically sorted and concatenated to form a trajectory. For convenience, we denote a trajectory by the ID followed by the sequence of locations, e.g., $GL21348\langle A \rightarrow B \rightarrow D \rightarrow E \rangle$ represents an entity with ID $GL21348$ moving from A to B to D to E .

Suppose that the dataset is complete, i.e., there are no missing records. Then each trajectory must satisfy both of the aforementioned movement constraints.

Example 1.2. Table 2 shows the composed trajectories from the tracking records in Table 1. Among the three trajectories, only the first one satisfies the movement constraints imposed by

¹<https://goo.gl/bKGvhh>

Table 1: Tracking Records

ID	Loc	Time
GL21348	A	08:09:10
GL21348	B	08:13:07
GL03245	C	08:17:23
GL21348	D	08:19:13
GL83248	D	08:19:40
GL21348	E	08:21:29
GL83248	E	08:21:30

Table 2: Trajectories

No.	Trajectory
1	GL21348(A → B → D → E)
2	GL03245(C)
3	GL83248(D → E)

the transition graph in Figure 1(b) and is thus considered valid; the second and third trajectories are invalid as they fail to satisfy the first movement constraint in Example 1.1.

Note that ID misidentification can cause “fracture” of a valid trajectory and therefore may render the trajectory invalid with respect to the given transition graph. The transition graph is distinct from most existing constraints [9, 25, 27], in that even trajectories with correct IDs may violate the constraints imposed by the graph and thus become invalid.

Example 1.3. Assume that the original trajectory for entity with ID GL83248 is GL83248(C → D → E). Unfortunately, its ID is misidentified as GL03245 by the camera at C. The trajectory is thus broken into the second and third trajectories in Table 2, both of which are invalid (though the second trajectory is actually error-free).

Some related approaches [27, 29] try to repair erroneous attributes in temporal events (e.g., logs from manufacturing) by exploiting the structural information or the neighborhood constraints of the activities. They propose efficient methods based on graph structures to detect dirty events and devise heuristic algorithms to repair them based on the *minimum change principle* [4]. However, these approaches fall short in our scenario mainly because (1) they perform isolated label rewritings while in our problem a single repair option may involve multiple ID-rewritings (as an ID may be identified as multiple erroneous values), (2) they do not consider the spatial relationships between the trajectories, which play an important role in our problem, and (3) the minimum change principle they follow may no longer be appropriate in our scenario.

1.2 The Present Work

Figure 2: Two Repair Options for Trajectory GL03245[C]

We propose to repair the erroneous IDs through rewriting the IDs and merging the trajectory fragments to recover the “original” trajectories that are valid with respect to the transition graph.

Example 1.4. Consider the trajectory GL03245(C) in Table 2. As shown in Figure 2, by exploring the inherent location and timestamp relationships, we can rewrite the trajectory’s ID to GL83248 (or, GL21348) and then merge the corresponding tracking records chronologically to form a valid trajectory GL83248(C → D → E) (or GL21348(A → B → C → D → E)).

As shown in Figure 2, there could be multiple options to repair an invalid trajectory, which are mutually exclusive since it is logically inconsistent to repair a single ID to different values at the same time. As such, only one of the options can be used.

Various factors can be considered in evaluating the “goodness” of the two repair options in Example 1.4, e.g., the ID similarity and the number of invalid trajectories eliminated. In this example, the bottom repair option in Figure 2 (i.e., rewriting to GL83248) is more likely to be selected roughly because (1) compared with “GL21348”, the string “GL83248” is more similar to “GL03245” (in terms of edit distance), and (2) applying this option can eliminate all the invalid trajectories in the dataset, while applying the other one (i.e., rewriting to GL21348) will leave a dangling invalid trajectory GL83238(D → E) without other trajectories to merge with.

The examples above represent a simple case where the dataset contains only one misidentified ID. In practice, the problem of trajectory ID repair is much more complex because (1) it is non-trivial to judge which IDs in the dataset are correct, (2) generating the repair options, each of which may involve multiple trajectories, can be time consuming, and (3) there can be a large number of interrelated repair options and we must consider them as a whole to make global decisions.

To address these issues, we propose a repair paradigm that consists of two phases. In the first phase, we generate all potential repair options that meet certain criteria for later consideration; in the second phase, we use an evaluation function to estimate the data quality improvement brought by each repair option, and then search for a set of such options that can be applied in tandem to maximize an overall objective function (which reflects the global quality improvement for the given dataset). Specifically, we extract the core processes in these two phases as a clique generation problem and a weighted independent set problem, which are all NP-hard in general settings. To cope with the first problem, we add some restrictions on the cliques of interest and provide a backtracking algorithm. To solve the second one, we propose an approximate greedy algorithm by exploiting the probability of selecting a correct repair option. Furthermore, we also devise an index structure and a pruning method to make the whole repair approach more efficient.

In repairing the IDs, we do not invent new values and assume the correct IDs can always be found from the dataset, which is in line with most previous work on data repair or data matching in other settings [4, 22, 32]. While the datasets often exhibit another type of error, namely missing records, our focus in this paper is on repairing erroneous IDs, which constitute the main source of error in the datasets we have examined. The reason is that the problem of missing records are often mitigated through the deployment of other supporting or complementary technologies. For example, inductive-loop traffic detectors [2] installed at the same locations as the traffic cameras can detect almost all passing vehicles and trigger shots by the corresponding cameras. Therefore, it is rare for a vehicle not to be captured by the camera and its plate (either correctly or incorrectly) recognized. In general, dealing with missing records is a separate issue worthy of investigation in our future work; in fact, most existing methods on missing value recovery [30, 31] focus on the issue of missing records itself without tackling other data quality problems such as indistinguishable objects. Nonetheless, we conduct experiments in Section 6.3.3 to empirically evaluate the impact of missing records on the performance of the proposed methods.

1.3 Contributions

To the best of our knowledge, we are the first to study the problem of trajectory ID repair facilitated by the moving rules. In summary, we make the following contributions in this paper.

- (1) We propose a novel transition graph based trajectory ID repair problem, as well as a two-phase repair paradigm to solve it.
- (2) By exploiting the locality and sparsity of the spatio-temporal trajectories, we provide practical algorithms that can solve the problem effectively.
- (3) We further devise some optimization methods, which make our approach more efficient.
- (4) Extensive experiments are conducted on both real and synthetic datasets, which demonstrate the effectiveness and efficiency of the proposed methods.

The rest of the paper is organized as follows. In Section 2, we provide the preliminaries and formally define the problem. We present the two-phase repair paradigm and the detailed algorithms in Section 3 and Section 4, respectively. We further propose some optimization methods in Section 5, and show the experimental results in Section 6. We provide an overview of the related work in Section 7, and conclude this paper in Section 8.

2 PROBLEM DESCRIPTION

2.1 Preliminaries

We first define several terms that will be used throughout the paper.

Definition 2.1. Transition Graph, Entrance Location and Exit Location. A transition graph $\mathcal{G}_t = (\mathbf{V}, \mathbf{E})$ is a directed graph that represents the set of movement constraints that the entities must follow. Each vertex $loc \in \mathbf{V}$ represents a location (e.g., where a surveillance device is installed), and an edge $(loc_i, loc_j) \in \mathbf{E}$ indicates that an entity can directly move from location loc_i to location loc_j . Among these vertices (locations), there are some special ones from which the entities can enter or leave the area of interest. We call them the *entrance locations* (the set of which is denoted by \mathbf{I}) and *exit locations* (the set of which is denoted by \mathbf{O}).

For the transition graph shown in Example 1.1, $\mathbf{V} = \{A, B, C, D, E\}$, $\mathbf{E} = \{(A, B), (B, C), (B, D), (C, D), (D, E)\}$, $\mathbf{I} = \{A, C\}$ and $\mathbf{O} = \{E\}$.

Definition 2.2. Valid Path. Given a transition graph $\mathcal{G}_t = (\mathbf{V}, \mathbf{E})$ with the entrance location set \mathbf{I} and the exit location set \mathbf{O} , we call a location sequence $loc_1 \rightarrow loc_2 \cdots \rightarrow loc_q$ a *valid path* if it satisfies the following three conditions: (1) $loc_1 \in \mathbf{I}$, (2) $(loc_i, loc_{i+1}) \in \mathbf{E} (1 \leq i < q)$, and (3) $loc_q \in \mathbf{O}$.

Definition 2.3. Tracking Record. A tracking record r is a triple (id, loc, ts) , where id is the entity's unique identifier (which may be erroneous and is the subject of our study), loc is the location, and ts is the timestamp.

Definition 2.4. Trajectory, Valid Trajectory, and Invalid Trajectory. A trajectory T is a chronologically ordered sequence of tracking records with the same ID (denoted by $T.id$), i.e., $T = r_1 \rightarrow r_2 \cdots \rightarrow r_q$ with $T.id = r_1.id = r_2.id = \cdots = r_q.id$ and $r_1.ts < r_2.ts < \cdots < r_q.ts$. We can represent a trajectory with the ID followed by the location sequence, e.g., $GL12345\langle A \rightarrow B \rightarrow C \rangle$. Given a transition graph \mathcal{G}_t and a trajectory T , we call T a *valid trajectory* (or *VT* for short) if the location sequence $r_1.loc \rightarrow$

$r_2.loc \cdots \rightarrow r_q.loc$ of T is a valid path w.r.t. \mathcal{G}_t . Otherwise we call T an *invalid trajectory* (or *IVT* for short).

In an ideal setting, each trajectory in a dataset is error-free and contains all the tracking records of an entity (e.g., $GL21348\langle A \rightarrow B \rightarrow D \rightarrow E \rangle$ in Example 1.2). Due to ID errors, however, a trajectory may be broken into multiple fragments, each containing tracking records with a different ID (e.g., $GL03245\langle C \rangle$ and $GL83248\langle D \rightarrow E \rangle$ in Example 1.2). Certainly, at most one of the IDs is correct, and the rest are all erroneous. Most of the time, those fragments are invalid trajectories (including the one with the correct ID), but there does exist a slight possibility that each of the fragments coincidentally corresponds to a valid path in the transition graph and is thus deemed valid. Considering its rarity, we ignore this case in our subsequent discussion.

We view the ID repair problem as one of "restoring" the original true trajectory through ID rewriting. That is, we seek to find a subset of trajectories and rewrite their IDs to (hopefully) the correct one, and then merge those trajectories to form a valid trajectory. As such, we introduce the following definitions.

Definition 2.5. Join, Joinable Subset and Target ID. Given a transition graph \mathcal{G}_t , we define *join* on a trajectory set \mathcal{T}' and an existing ID r from \mathcal{T}' as first rewriting the ID for each $T \in \mathcal{T}'$ to r and then merging all tracking records in \mathcal{T}' chronologically to constitute a new trajectory \widehat{T}_r , i.e., $\widehat{T}_r = join(\mathcal{T}', r)$. The join is valid iff the newly formed trajectory \widehat{T}_r is a VT w.r.t. \mathcal{G}_t , and we call r the *target ID* and \mathcal{T}' a *joinable subset* iff such a valid join exists.

Definition 2.6. Candidate Repair. A candidate repair (or *repair* for short) R is a pair (\mathcal{T}', r) consisting of a joinable subset \mathcal{T}' and a target ID r . For a repair R , the corresponding joinable subset and the invalid trajectories contained therein are denoted by $jns(R)$ and $ivt(R)$. With R defined, the join operation can be rephrased as $\widehat{T}_r = join(R)$. If r is the true ID for all trajectories contained in \mathcal{T}' (which implies that they actually come from the same entity), and \widehat{T}_r is the true trajectory for the entity with ID r , we call R a *correct candidate repair* (or *correct repair* for short). For two candidate repairs R_i and R_j , if their joinable subsets are mutually exclusive, i.e., $jns(R_i) \cap jns(R_j) = \emptyset$, we say that R_i and R_j are *compatible*; otherwise *incompatible*. If all pairs of repairs in a set of repairs are compatible, then we call this set a *compatible repair set*.

Figure 2 shows two candidate repairs whose correctness is unknown. They are incompatible due to the sharing of trajectory $GL03245\langle C \rangle$.

Given a trajectory set \mathcal{T} and a compatible repair set \mathcal{R}' , a new trajectory set $\widehat{\mathcal{T}}$ can be produced by joining the trajectories indicated by each $R \in \mathcal{R}'$. As illustrated before, the reason why the repairs must be compatible is that it does not make sense to rewrite a trajectory's ID to more than one target ID at the same time.

2.2 Problem Statement

Given a transition graph \mathcal{G}_t , a set of trajectories \mathcal{T} with ID errors, we use \mathcal{R} to represent the set which contains all the potential candidate repairs. The ID repair problem can be regarded as searching a compatible repair set $\mathcal{R}' \subseteq \mathcal{R}$, and joining trajectories designated by the compatible candidate repairs in \mathcal{R}' to obtain a new trajectory set $\widehat{\mathcal{T}}$.

Note that there may exist various (incompatible) candidate repairs in \mathcal{R} for a single trajectory, and our goal is to find the

most promising one. We thus need a function $\omega(R)$ to evaluate the effectiveness of R , which serves as an estimate of how much quality improvement can be gained by R .

2.2.1 The Evaluation Function for Repair Effectiveness. We first discuss the factors that we have considered in devising a suitable evaluation function for the effectiveness of a repair.

- **The individual fitness of a repair.** In real applications, the erroneous IDs often bear some similarities with their correct values, i.e., the more similar two IDs are, the more likely they correspond to the same entity. In the case of composite IDs, even if attempts are made to camouflage the entities with a fake name, the remaining components of the IDs, such as color and type, are more difficult to conceal and thus the erroneous IDs would still be similar to the true IDs. For that reason, we use ID similarity to evaluate the individual fitness of a repair. This similarity can be measured by the distance between the strings or feature vectors representing the IDs, and there have been dozens of metrics (e.g., edit distance, overlap coefficient, and cosine similarity) proposed in the literature for this purpose [24]. In this paper, we choose edit distance as the similarity metric, but this can be replaced by other metrics for different applications. Specifically, for a repair $R = (\mathcal{T}', r)$, we use the *similarity function* $\text{sim}(R)$, which is based on the minimum similarity from an ID in \mathcal{T}' to the target ID r , to evaluate the individual fitness of R :

$$\text{sim}(R) = \min_{T \in \mathcal{T}'} \left(1 - \frac{\text{dist}(r, T.id)}{\max(|r|, |T.id|)} \right) \quad (1)$$

where $\text{dist}(r, T_i.id)$ is the edit distance between r and $T_i.id$, and $|T_i.id|$ is the length of $T_i.id$. Apparently, the range of the similarity function is $[0, 1]$.

- **The potency of a repair.** As illustrated before, ID errors will cause invalid trajectories. Candidate repairs that fix more IVTs are considered more “powerful” and are expected to bring greater quality improvement to a dataset.
- **The rarity of a repair.** For a set of trajectories \mathcal{T} and a set of corresponding potential candidate repairs \mathcal{R} , each IVT $T' \in \mathcal{T}$ may be covered by multiple repairs in \mathcal{R} . We call the number of those repairs the *degree of T'* (denoted by $d(T')$). A smaller degree implies that the trajectory is more “endangered”, i.e., there are fewer candidate repairs that are able to fix it. On the other hand, each such candidate is considered more precious or rarer and thus should be preferred. We define the *rarity* of a repair R as

$$ra(R) = \min_{T \in \text{ivt}(R)} d(T) \quad (2)$$

The value of $ra(R)$ ranges from 1 to $|\mathcal{R}|$. When $ra(R)$ takes the minimum value of 1, it means that only R can fix a certain IVT in the dataset.

Different effectiveness evaluation functions can be designed based on the factors above. We find the following one performs well in our scenarios:

$$\omega(R) = \begin{cases} 0 & |\text{ivt}(R)| = 0 \\ \text{sim}(R) + \lambda \log_{ra(R)+1} |\text{ivt}(R)| & |\text{ivt}(R)| \geq 1 \end{cases} \quad (3)$$

where $\text{sim}(R)$ and $ra(R)$ are the similarity function and the rarity function respectively, $|\text{ivt}(R)|$ represents the number of invalid trajectories in R , and $\lambda \in (0, 1)$ is a coefficient controlling the trade-off between the two terms.

In Equation (3), the first term $\text{sim}(R)$ acts as assurance on the matching fitness and makes it unlikely for an ID to be rewritten to another arbitrary ID. The second term $\log_{ra(R)+1} |\text{ivt}(R)|$ represents the potency impact scaled by the rarity factor. According to this term, repairs holding more invalid trajectories and being more rare will be more effective. In general, $ra(R) + 1 \gg |\text{ivt}(R)|$ and thus the range for $\log_{ra(R)+1} |\text{ivt}(R)|$ is also $[0, 1]$.

Note that due to the introduction of $ra(R)$, the effectiveness of a repair cannot be evaluated unless a full candidate repair set \mathcal{R} is provided.

2.2.2 The ID Repair Problem. Given a trajectory set \mathcal{T} (with ID errors), a transition graph \mathcal{G}_t , and an evaluation function ω for repair effectiveness, the ID repair problem is to search for a compatible repair set \mathcal{R}' that can maximize the sum of the repair effectiveness. Formally, this can be described as

$$\begin{aligned} & \underset{\mathcal{R}'}{\text{maximize}} && \Omega(\mathcal{R}') = \sum_{R \in \mathcal{R}'} \omega(R) \\ & \text{subject to} && jns(R_i) \cap jns(R_j) = \emptyset, \forall R_i, R_j \in \mathcal{R}'. \end{aligned} \quad (4)$$

2.3 Applicability and Assumptions

The ID repair approach we adopt exploits the locality and sparsity properties of the real world spatio-temporal trajectories:

- **Locality of movement** – a given entity is more likely to move within a local geospatial neighborhood than “jumping” between far-away locations in a relatively short time span. This implies that it is more likely to find the true value of an erroneous ID based on entities that are close in time and space.
- **Sparsity of IDs** – two entities with different but very similar IDs are highly unlikely to appear in the same local neighborhood during a relatively short period of time.

Based on these properties, we make the following assumptions. First, we assume that identical IDs in the data, whether correct or not, belong to the same entity. In other words, we would not break a trajectory into smaller pieces. In exceptional cases, it may so happen that a tracking record with an erroneous ID becomes part of a valid trajectory in place of a missing record with the true ID; but such cases are so rare due to the sparsity of IDs that we could consider them negligible.

Second, we consider all records with the same ID constitute a trajectory with bounded length and time span. The rationale is that despite some entities intending to wander around in the area of interest, the majority should be passing traffic and thus their trajectories should not be too long. Based on this assumption, we set two bounds θ and η , where θ is the maximum possible length of a VT (i.e., the maximum number of tracking records in it) in a dataset, and η is the maximum time span for a VT.

Finally, we assume that the error rate for ID identification is not too high (which is consistent with what we observe from real data), i.e., the number of trajectory fragments caused by erroneous IDs in a trajectory is limited. We use a bound ζ to represent the maximum possible number of trajectories in a joinable subset. Although there may be extraordinary cases where these assumed bounds do not hold, their establishment grants us the opportunity to significantly improve the efficiency of the proposed algorithms, as will be shown in Section 6.2.

3 A TWO-PHASE REPAIR PARADIGM

We now describe a two-phase repair paradigm that serves as the framework for solving the ID repair problem. The detailed

algorithms involved in this paradigm will be presented in Section 4.

3.1 Overview of the Paradigm

The basic idea of the proposed paradigm is to first generate all possible candidate repairs and then select a set of repairs that can maximize the objective function (Equation (4)). Figure 3 depicts the repair paradigm consisting of two phases: *candidate repair generation* and *compatible repair selection*.

Figure 3: The Two-Phase Repair Paradigm

In the candidate repair generation phase, we generate all potential candidate repairs \mathcal{R} (which are not necessarily compatible with each other) from the input trajectory set \mathcal{T} according to the transition graph \mathcal{G}_t . This phase can be accomplished using an undirected graph with each vertex representing a different trajectory and each edge indicating that the two trajectories corresponding to its connected vertices can appear in the same joinable subset. We call this graph the *trajectory graph* (denoted by \mathcal{G}_m).

In the compatible repair selection phase, we perform the actual ID repair by selecting a set of compatible repairs $\mathcal{R}' \subseteq \mathcal{R}$ that have the maximum total effectiveness in terms of Equation (4). This task can be carried out by introducing another undirected graph that reflects the incompatible relationships between different repairs in \mathcal{R} . We call this graph the *repair graph* (denoted by \mathcal{G}_r).

3.2 Candidate Repair Generation

This phase performs two core tasks, namely *joinable subset determination* and *target ID assignment*.

3.2.1 Joinable subset determination. Before delving into the details of joinable subset determination, we first introduce two predicates.

- (1) **The *cex* predicate.** Given a transition graph \mathcal{G}_t , the *cex* predicate works by checking whether two trajectories can coexist in a joinable subset w.r.t. \mathcal{G}_t , i.e., $\{\mathbf{T}_x, \mathbf{T}_y\} | cex(\mathbf{T}_x, \mathbf{T}_y) = \{\mathbf{T}_x, \mathbf{T}_y\} \exists \mathcal{T}' (\mathbf{T}_x, \mathbf{T}_y \in \mathcal{T}')$, and \mathcal{T}' is a joinable subset. Apparently, only if the location sequence for the chronologically merged records of the two trajectories is a subsequence (which does not have to be continuous) of a path in \mathcal{G}_t , can this predicate evaluate to true.
- (2) **The *jnb* predicate.** Given a transition graph \mathcal{G}_t , the *jnb* predicate is used to determine whether a set of trajectories is a joinable subset w.r.t. \mathcal{G}_t , i.e., $\{\mathcal{T}_x\} | jnb(\mathcal{T}_x) = \{\mathcal{T}_x\} \exists \mathcal{T}' (\mathcal{T}_x = \mathcal{T}')$, and \mathcal{T}' is a joinable subset. This can be performed by checking whether the location sequence for the chronologically merged records is a valid path in \mathcal{G}_t . As a special case, for a trajectory set with only one element, the *jnb* predicate evaluates to *true* if that element is a valid trajectory.

We first use the *cex* predicate to construct the trajectory graph \mathcal{G}_m . Specifically, each vertex v_i in \mathcal{G}_m corresponds to a $\mathbf{T}_i \in \mathcal{T}$, and each undirected edge (v_i, v_j) corresponds to a trajectory pair $(\mathbf{T}_i, \mathbf{T}_j)$ such that *cex*($\mathbf{T}_i, \mathbf{T}_j$) evaluates to true.

Example 3.1. Let us use $\mathbf{T}_1, \mathbf{T}_2$, and \mathbf{T}_3 to represent the three trajectories shown in Table 2. To construct \mathcal{G}_m , we first create

Figure 4: \mathcal{G}_m and \mathcal{G}_r for the Running Example

three vertices v_1, v_2 , and v_3 , corresponding to $\mathbf{T}_1, \mathbf{T}_2$, and \mathbf{T}_3 respectively. Since both *cex*($\mathbf{T}_1, \mathbf{T}_2$) and *cex*($\mathbf{T}_2, \mathbf{T}_3$) evaluate to true, two edges (v_1, v_2) and (v_2, v_3) are added to \mathcal{G}_m . Figure 4(a) shows the constructed trajectory graph for the dataset.

Such construction allows the problem of searching for joinable subsets to be transformed to operations on \mathcal{G}_m , as shown in the theorem below.

THEOREM 3.2. *A necessary but not sufficient condition for a trajectory set to be a joinable subset is that its corresponding vertex set in \mathcal{G}_m is a clique.*

To compute the joinable subsets, we first generate all cliques in \mathcal{G}_m and then use the *jnb* predicate to check whether their corresponding trajectory sets can really be joinable subsets. Actually, the clique generation process can be regarded as a preprocessing step which saves us from enumerating all the trajectory combinations. In general settings, listing all cliques in a graph is NP-hard [19]. Fortunately, since both the length of a VT and the number of trajectories contained in a candidate repair are bounded according to our aforementioned assumptions, the problem can be solved in polynomial time in our case. We present the detailed algorithm for generating the qualified-cliques in Section 4.1.2.

Example 3.3. For the trajectory graph shown in Figure 4(a), there are five cliques: $\{v_1\}, \{v_2\}, \{v_3\}, \{v_1, v_2\}$, and $\{v_2, v_3\}$. However, evaluating *jnb* on their corresponding trajectory sets reveals that there are only three joinable subsets: $\{\mathbf{T}_1\}, \{\mathbf{T}_1, \mathbf{T}_2\}$, and $\{\mathbf{T}_2, \mathbf{T}_3\}$.

3.2.2 Target ID Assignment. After generating all the joinable subsets, we assign target IDs to them. Given a joinable subset \mathcal{T}' , the target ID is decided by selecting a trajectory \mathbf{T}_c that maximizes the following equation.

$$\mathbf{T}_c = \underset{\mathbf{T}_i \in \mathcal{T}'}{\operatorname{argmax}} \left(\sum_{\mathbf{T}_j \in \mathcal{T}'} \frac{|\mathbf{T}_i|}{|\mathbf{T}_j|} \left(1 - \frac{\operatorname{dist}(\mathbf{T}_i.\operatorname{id}, \mathbf{T}_j.\operatorname{id})}{\max(|\mathbf{T}_i.\operatorname{id}|, |\mathbf{T}_j.\operatorname{id}|)} \right) \right) \quad (5)$$

In this equation, $|\mathbf{T}_i|$ ($|\mathbf{T}_j|$) is the length of trajectory \mathbf{T}_i (\mathbf{T}_j), $|\mathbf{T}_i.\operatorname{id}|$ ($|\mathbf{T}_j.\operatorname{id}|$) is the length of ID $\mathbf{T}_i.\operatorname{id}$ ($\mathbf{T}_j.\operatorname{id}$), and $\operatorname{dist}(\mathbf{T}_i.\operatorname{id}, \mathbf{T}_j.\operatorname{id})$ is the edit distance between them. The rationale behind the choice of this equation is that when all trajectories have the same length, our goal is to choose a target ID that can maximize the sum of similarities of all IDs with the target ID. We also give preference to longer trajectories, as the error rate for ID identification is usually low and it is unlikely for the same error to be made at consecutive locations in a trajectory. Note that we choose to use edit distance here to measure the (dis-)similarity between IDs, but other distance measures can also be used where appropriate.

Example 3.4. Based on Equation (5), we assign *GL21348*, *GL21348*, and *GL83248* as the target IDs for the three joinable subsets $\{\mathbf{T}_1\}, \{\mathbf{T}_1, \mathbf{T}_2\}$, and $\{\mathbf{T}_2, \mathbf{T}_3\}$ generated in Example 3.3 and combine them respectively to generate three candidate repairs: $R_1 = (\{\mathbf{T}_1\}, \text{GL21348})$, $R_2 = (\{\mathbf{T}_1, \mathbf{T}_2\}, \text{GL21348})$, and $R_3 = (\{\mathbf{T}_2, \mathbf{T}_3\}, \text{GL83248})$. Then we calculate their effectiveness values according to Equation (3), which are $\omega(R_1) = 0$, $\omega(R_2) = 0.428$, and $\omega(R_3) = 1.029$.

3.3 Compatible Repair Selection

In the previous phase, we have generated all candidate repairs \mathcal{R} . Next, we select compatible repairs from \mathcal{R} to maximize the objective function in Equation (4). The selection process can be mapped to operations on another undirected graph, namely the repair graph, \mathcal{G}_r , which can be constructed as follows: (1) for each candidate repair $R_i \in \mathcal{R}$, add a corresponding vertex v'_i to \mathcal{G}_r ; (2) if $R_i, R_j \in \mathcal{R}$ share an identical trajectory, add an undirected edge (v'_i, v'_j) to \mathcal{G}_r .

Example 3.5. To construct \mathcal{G}_r for the three candidate repairs generated in Example 3.4, we first add three corresponding vertices v'_1, v'_2 , and v'_3 . Since $jns(R_1) \cap jns(R_2) = \{T_1\}$ and $jns(R_2) \cap jns(R_3) = \{T_2\}$, two edges (v'_1, v'_2) and (v'_2, v'_3) are added. Finally, we get the repair graph shown in Figure 4(b).

Such construction allows us to view the problem of selecting compatible repairs as packing vertices from \mathcal{G}_r where no pairs are adjacent. This translates to the well known *weighted independent set problem*, which is NP-hard in common settings [23]. Considering the inherent relationships between repairs, we present a greedy algorithm to approximately solve this problem in Section 4.2.

4 ALGORITHMS

In this section, we present the core algorithms for the two-phase repair paradigm.

4.1 Algorithms for Repair Generation

4.1.1 Evaluating the cex and jnb predicates. Given a transition graph \mathcal{G}_t , the *cex* predicate determines whether two trajectories T_1 and T_2 can coexist in a joinable subset. The key idea in evaluating this predicate is to check whether the location sequence for the chronologically merged records is a subsequence of a path in \mathcal{G}_t . This can be considered a reachability problem, i.e., for the merged location sequence $loc_1 \rightarrow loc_2 \rightarrow \dots \rightarrow loc_q$ ($q = |T_1| + |T_2|$), if loc_i and loc_{i+1} belong to different trajectories, we check whether loc_{i+1} is reachable from loc_i .

A straightforward solution for this problem using breadth-first (or depth-first) search takes linear time, but we can do some pre-processing to have it done in constant time. Specifically, the Floyd Warshall algorithm [16] can be employed to calculate the shortest-path matrix M for \mathcal{G}_t , where $M[i][j]$ indicates the number of edges in the shortest path from loc_i to loc_j . After this preprocessing step, the reachability queries can be answered instantly by consulting the elements in M .

Moreover, recall that we have two user-defined bounds, the maximum length θ and the maximum time span η for each *VT*. Thus we should also check whether $|T_1| + |T_2| \leq \theta$ and whether the time span for the merged sequence exceeds η . Putting things together, we show the algorithm for evaluating the *cex* predicate in Algorithm 1.

Compared with the *cex* predicate, the *jnb* predicate is more strict in that it evaluates to *true* only if the given trajectories can perfectly make up a joinable subset. The algorithm for this predicate is similar to that for the *cex* predicate with the following two additional restrictions: (1) the location attributes in the earliest and the latest records of the input trajectories must be an entrance location and an exit location in \mathcal{G}_t , respectively, and (2) no matter whether two adjacent records (in the merged sequence) r_i and r_{i+1} belong to the same trajectory or not, there must be an

Algorithm 1 Algorithm for the *cex* predicate

Input: The reachability matrix M for \mathcal{G}_t ; the maximum length θ ; the maximum time span η ; two trajectories T_1 and T_2 .

Output: *true* if T_1 and T_2 can coexist in a joinable subset; *false* otherwise.

```

1: if  $|T_1| + |T_2| > \theta$  then
2:   return false
3: merge records in  $T_1$  and  $T_2$  by their timestamps to get a
   sequence  $r_1 \rightarrow r_2 \rightarrow \dots \rightarrow r_q$ ;
4: if  $r_q.ts - r_1.ts > \eta$  then
5:   return false
6: for all  $r_i$  and  $r_{i+1}$  in the merged sequence do
7:   if  $r_i.id \neq r_{i+1}.id$  then
8:     if  $M[i][i+1] \geq \theta$  then
9:       return false
10: return true

```

edge from $r_i.loc$ to $r_{i+1}.loc$. Due to space limitation, the detailed algorithm for evaluating the *jnb* predicate is omitted.

4.1.2 Generating Qualified Cliques. We now introduce the algorithm for generating the qualified cliques in \mathcal{G}_m . In general, enumerating all cliques in an undirected graph requires exponential time, and the running time is output-sensitive (i.e., the running time depends on the size of the output). However, when the trajectory length and clique size are bounded (by θ and ζ respectively), the problem can be much simplified. We show how to generate the qualified cliques in Algorithm 2, which runs in $O(|V_m|^\zeta)$ time.

Algorithm 2 Algorithm for generating qualified cliques

Input: The adjacency matrix representation of trajectory graph $\mathcal{G}_m = \{V_m, E_m\}$; a set C to store vertices in the current clique; an index list L for vertices; the maximum trajectory length θ ; the maximum clique size ζ .

Output: a set of generated cliques *results*.

```

1: fill  $L$  with  $1, 2, \dots, |V_m|$ 
2: function CLIQUE( $C, L$ )
3:   for  $i \leftarrow L.size(), 1$  do
4:      $v \leftarrow L.get(i)$ 
5:      $C \leftarrow C \cup \{T_v\}$ 
6:     create a new list  $L_{new}$ 
7:     for  $j \leftarrow 0, i$  do
8:        $w \leftarrow L.get(j)$ 
9:       if  $(v, w) \in E_m$  then
10:         $L_{new}.add(w)$ 
11:         $results \leftarrow results \cup \{C\}$ 
12:        if  $\neg L_{new}.empty()$  and  $C.RecordNumber < \theta$  and
            $|C| < \zeta$  then
13:          CLIQUE( $C, L_{new}$ )
14:           $C \leftarrow C \setminus \{T_v\}$ 
15:           $L.remove(i)$ 
16: return results

```

The main idea of the generation algorithm is backtracking. It iteratively adds to a temporary vertex set C a vertex that is adjacent to all existing ones in C from an input vertex list, outputs the result, starts a recursion with a new list of vertices that are adjacent to the newly added vertex, and finally removes the vertex added in this round. As shown in Line 12, unnecessary recursions are eliminated using the bounds θ and ζ .

Figure 5: An Example of Clique Generation

Example 4.1. Figure 5 shows an example of the clique generation process. Given a trajectory graph with 5 vertices, the 15 cliques are generated in turn with Algorithm 2. As shown in Figure 5(b), if $\zeta = 2$, the algorithm will automatically skip generating cliques beneath the dashed line.

4.2 Algorithms for Repair Selection

As discussed in Section 3.3, the repair selection problem corresponds to a weighted-independent set problem on \mathcal{G}_r , which is NP-hard. In search of efficient solutions, consider the effectiveness evaluation function in Equation (4). It is defined as an indicator of the potential quality improvement due to a repair, but by no means a definitive measure of the true improvement. That is, for two compatible repair sets \mathcal{R}'_1 and \mathcal{R}'_2 , if $\Omega(\mathcal{R}'_1) > \Omega(\mathcal{R}'_2)$, it just indicates that \mathcal{R}'_1 is likely better than \mathcal{R}'_2 , but not definitely, especially when the values of $\Omega(\mathcal{R}'_1)$ and $\Omega(\mathcal{R}'_2)$ are close. This is confirmed by a large number of experiments on different datasets, from which we find that the Ω values of the optimal compatible repair sets (which include all the correct repairs) are randomly distributed in the proximity of, but not exactly the same as, the optimal results from the weighted-independent set problem.

The observation inspires us to seek approximate solutions to the repair selection problem instead. Many heuristic algorithms have been proposed for the weighted-independent set problem (see [5] for a survey). Here we propose a greedy algorithm named *maximum-effectiveness first* (EMAX), which gives superior empirical results in our settings. As shown in Algorithm 3, the EMAX algorithm always selects from \mathcal{G}_r a vertex whose corresponding repair is evaluated to be the most effective according to Equation (3), and then discards its adjacent vertices until there is no vertex left.

Algorithm 3 The EMAX algorithm

Input: the repair graph $\mathcal{G}_r = (\mathbf{V}_r, \mathbf{E}_r)$.

Output: a set of selected vertices \mathcal{V} .

- 1: sort vertices in \mathbf{V}_r by the ω values of their corresponding repairs in a decreasing order
- 2: **for all** v in \mathbf{V}_r **do**
- 3: **if** $v.discard = false$ **then**
- 4: add v to \mathcal{V}
- 5: **for all** v_a adjacent to v **do**
- 6: $v_a.discard \leftarrow true$
- 7: **return** \mathcal{V}

Compared with the exact algorithm that requires exponential running time, the EMAX algorithm runs in only $O(|\mathbf{V}_r| \log |\mathbf{V}_r|)$ time. The rationale behind this heuristic is that, repairs evaluated to be more effective are more likely to be correct, and thus giving them priorities makes it more likely to select the best result.

Example 4.2. For the repair graph shown in Figure 4(b), the EMAX algorithm first selects the vertex v'_3 corresponding to candidate repair R_3 (since it is the most effective according to Equation (3)) and then discards v'_2 adjacent to v'_3 . Since the effectiveness of R_1 , the only vertex left, is zero, v'_1 will not be selected.

Figure 7: Overview of the Length-Indexed Grids

5 OPTIMIZATION

In this section, we provide some optimization methods to make the repair approach more efficient.

5.1 An Index for Constructing \mathcal{G}_m

The candidate repair generation phase requires evaluating the *ce χ* predicate on each pair of trajectories in \mathcal{T} for constructing the trajectory graph \mathcal{G}_m . Suppose that there are $|\mathbf{V}_m|$ trajectories. This procedure requires $O(|\mathbf{V}_m|^2)$ comparisons, which could be costly in practice. Recall that valid trajectories are upper-bounded in length and time span, and we thus make use of the bounds θ and η to filter out some unnecessary comparisons.

Definition 5.1. Start Time and End Time. The *start time* and the *end time* of a trajectory \mathbf{T} are defined as the timestamps of the earliest and latest records in \mathbf{T} , respectively.

Given a trajectory \mathbf{T}_k with start time ts_s and end time ts_e , another trajectory \mathbf{T}_u that may constitute a joinable subset with \mathbf{T}_k must first meet the length criterion, i.e., $|\mathbf{T}_u| \leq \theta - |\mathbf{T}_k|$. Also, for the bound on time span η , the max/min start time (denoted by max_s and min_s) and max/min end time (denoted by max_e and min_e) of \mathbf{T}_u should satisfy the following inequalities (which are demonstrated in Figure 6(a)): $ts_e - min_s \leq \eta$, $max_s - ts_s \leq \eta$, $ts_e - min_e \leq \eta$, and $max_e - ts_s \leq \eta$. According to these inequalities, both the start time and end time of \mathbf{T}_u should fall in $[ts_e - \eta, ts_s + \eta]$, and we can transform the criteria into a range query on a three-dimensional index structure on the trajectories called Length-Indexed Grids (LIG).

Overview. As shown in Figure 7(a), the three dimensions of LIG are the length, the start time and the end time of a trajectory. Specifically, we divide the time span of interest along both the start time and end time dimensions into time bins with fixed size t_b , resulting in a two-dimensional time grid shown in Figure 7(b). A separate time grid is created for each trajectory length appearing in the dataset.

The Data Structure. Figure 6(b) illustrates the data structure of LIG. An array is used to store the grids with different trajectory lengths. Each grid is actually a two-dimensional array. Trajectories are distributed to grids according to their start/end times and trajectories in the same grid are linked to be an element of

the two-dimensional array. We construct LIG by successively add trajectories. For each trajectory, we first decide the grid it belongs to according to the trajectory’s length. Then we assign a time grid for the trajectory and add it as a new element to the tail of the corresponding list.

Usage. We use the index to answer the range query by first deciding a set of feasible grids according to the trajectory’s length and the threshold θ . After that, in each grid, we select trajectory lists that meet the start/end time restrictions from the two-dimensional array. Without loss of generality, suppose that the timestamps of tracking records are represented as offsets to the earliest timestamp in the dataset. Then the target trajectories we are interested in should be contained in elements whose indices are bounded by $[\lfloor \frac{ts_s - \eta}{t_b} \rfloor \times t_b, \lceil \frac{ts_e + \eta}{t_b} \rceil \times t_b]$ in both dimensions.

With the index technique provided above, we can prune many useless trajectory comparisons. As the time grids are static, the index can be constructed efficiently in $\Theta(|V_m|)$ time. As such, the running time for generating \mathcal{G}_m can be significantly reduced.

5.2 A Pruning Method for Clique Generation

In Section 4.1.2, we show how to generate qualified cliques from the trajectory graph \mathcal{G}_m . All the trajectory sets corresponding to the cliques will be further checked by the *jnb* predicate to see if they are really joinable subsets. Considering that Algorithm 2 is output-sensitive, it will be more efficient if we can eliminate some worthless vertex combinations early on during the clique generation process. We propose an optimization method named *minimum cover prefix pruning* for this purpose.

Figure 8: The Minimum Cover Prefix

Definition 5.2. Minimum Cover Prefix. As shown in Figure 8, given a trajectory set $\mathcal{T} = \{T_1, T_2, \dots, T_p\}$, we can merge their tracking records chronologically to get a sequence $r_1 \rightarrow r_2 \rightarrow \dots \rightarrow r_q$. The *minimum cover prefix* (abbreviated as MCP) for \mathcal{T} is defined as the minimum prefix of this sequence that contains at least one tracking record from all trajectories in \mathcal{T} .

THEOREM 5.3. The MCP condition. Given a list of trajectories $[T_1, T_2, \dots, T_p]$ sorted by their start times in an increasing order (i.e., $T_i.startTime \leq T_{i+1}.startTime$), a necessary but not sufficient condition for these trajectories to compose a joinable subset is that the location sequence for the MCP of any $\{T_1, T_2, \dots, T_{p-k}\} (0 \leq k < p)$ must be a prefix of a valid path in \mathcal{G}_t .

According to Theorem 5.3, when generating cliques, if the vertices are added to C in an increasing order of the start times of their corresponding trajectories, we can prune some unnecessary vertex combinations according to the MCP condition. The checking is performed with a *pck* predicate.

The *pck* predicate. Similar to the *cex* and *jnb* predicates, given a trajectory graph \mathcal{G}_t , the *pck* predicate can be applied on one or more trajectories and evaluates to *true* iff the MCP condition holds, i.e., $\{\mathcal{T}_x | (pck(\mathcal{T}_x))\} = \{\mathcal{T}_x | \exists P(r_1.loc \rightarrow \dots \rightarrow r_k.loc = prefix(P)), [r_1, \dots, r_k]$ is the MCP of \mathcal{T}_x and $prefix(P)$ is the prefix of a valid path P in \mathcal{G}_t . In terms of “restrictiveness”, this predicate falls somewhere between the *cex* and *jnb* predicates. Compared with *cex*, it further requires that the location sequence must be a prefix of a valid path, not just a subsequence;

compared with *jnb*, it just ensures that the first location is an entrance location. Due to space limitation, the detailed algorithm for evaluating this predicate is omitted.

With the *pck* predicate defined, we try to modify the qualified-clique generation algorithm by pruning worthless results and recursions. First of all, we must ensure that the cliques are generated in the order of their trajectories’ start times. Fortunately, Algorithm 2 iterates through the vertices with an index list L . Thus, to keep the generation order, we just need to sort the vertices in \mathcal{G}_m . Then, each time before outputting a generated clique to the result set, we check its corresponding trajectory set with the *pck* predicate, and only if it evaluates to *true*, can we accept the clique and continue adding more vertices into the result set. The modified algorithm snippet is shown in Algorithm 4.

Algorithm 4 Clique generation with pruning

```

...
sort vertices in  $\mathcal{G}_m$  by their corresponding trajectories’ start
times in descending order
function CLIQUE( $C, L$ )
...
if pck( $C.trajectories$ ) = true then
    results  $\leftarrow$  results  $\cup$   $\{C\}$ 
    if  $\neg L_{new}.empty()$  and  $C.RecordNumber < \theta$  and
 $|C| < \zeta$  then
        CLIQUE( $C, L_{new}$ )
...

```

Example 5.4. Suppose that the vertices in Figure 5(a) are already sorted by the start times of their corresponding trajectories, i.e., $T_5.startTime \leq T_4.startTime \leq \dots \leq T_1.startTime$. If the MCP condition does not hold on $\{T_5\}$, any cliques containing v_5 (e.g., $\{v_5, v_4\}$ and $\{v_5, v_4, v_1\}$) will be pruned by the modified algorithm. For the same reason, if the MCP condition does not hold on $\{T_5, T_2\}$, the cliques $\{v_5, v_2\}$ and $\{v_5, v_2, v_1\}$ will be pruned. Obviously, the modified algorithm is more efficient thanks to the pruning of some cliques and unnecessary calculations.

6 EXPERIMENTS

We conduct extensive experiments on both real and synthetic datasets to thoroughly evaluate the properties of the proposed approach and compare it to baseline methods.

6.1 Experimental Settings

All algorithms are implemented in Java and run on a desktop PC with a 2.5GHz Intel i5 CPU and 8GB of memory. Each set of experiments are repeated at least 30 times and the average results are recorded.

A real dataset and a series of synthetic datasets with different characteristics are used in the experiments. According to Section 2.3, the repair approach we proposed in this paper is in the interest of local regions. For such small regions, the transition graphs may seem simple. However, note that even for such seemingly simple graphs, the repair problem is still quite challenging, as revealed in Section 3.

6.1.1 Datasets. Real Dataset. The real dataset is obtained from a real traffic surveillance system in a provincial capital in China. We choose a specific region of this city and extract 699 trajectories of vehicles which contain 2,045 tracking records between 8:00 a.m. and 9:00 a.m. on a particular day. Figure 9(a) illustrates the road network and the distribution of surveillance

(a) The Road Network (b) The Transition Graph

Figure 9: Road Network and Transition Graph

cameras in this region. The license plate numbers of the vehicles are captured by cameras located at A , B , C , and D whenever they pass by these sites. Figure 9(b) is the corresponding transition graph we derived. Due to OCR errors and other issues, some of the license plates in the dataset were misidentified. We manually label the plate numbers by examining the *original photos* taken by the cameras, which serves as the ground truth. In this way, we obtain a labeled dataset that contains both the raw and the true values. The default values of θ , η , ζ and λ for the real dataset are empirically set to 4, 600 seconds, 4, and 0.5, respectively, unless otherwise specified.

Synthetic Datasets. To generate a synthetic trajectory set for ID repair, we first choose a transition graph, based on either the real dataset or a sample of the California road network [21]. Then we repeatedly sample random valid paths and generate corresponding trajectories until we have obtained the desired number of trajectories. Without loss of generality, we assume that an ID consists of 7 to 9 lower-case letters only, which are independently and identically generated following a uniform distribution. The time span is sampled from the empirical distribution of travel time between the corresponding locations in the real dataset. After that, using the edit distance distribution for erroneous IDs in the real dataset as a ballpark, we randomly inject ID errors to the tracking records with a specified error rate, and eventually get a synthetic dataset. The default error rate is set to 20%, unless otherwise specified.

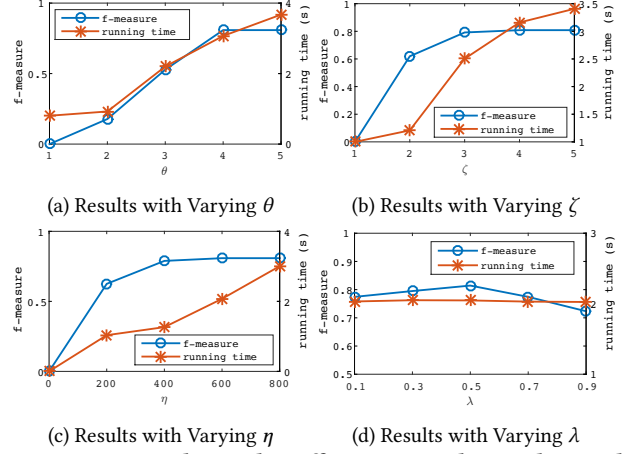

6.1.2 Metrics. We use elapsed time as the metric for efficiency, and adopt *precision*, *recall* and *f-measure* as the general metrics for effectiveness. Using \mathcal{T}_e to represent all the trajectories with ID errors, \mathcal{T}_r to represent those trajectories with ID rewritten by applying candidate repairs, and \mathcal{T}_c to represent all the trajectories whose IDs are correctly repaired, we define $\text{recall} = |\mathcal{T}_c|/|\mathcal{T}_e|$, $\text{precision} = |\mathcal{T}_c|/|\mathcal{T}_r|$, and $\text{f-measure} = \frac{2 \cdot (\text{precision} \cdot \text{recall})}{(\text{precision} + \text{recall})}$. There are also some specialized metrics used in certain groups of experiments, which will be introduced later.

6.2 Effects of Parameters

We first evaluate the effects of different parameters through a group of experiments on the real dataset.

The effects of θ , ζ , and η . Figures 10(a), 10(b) and 10(c) show the f-measure and running time with varying values of θ , ζ , and η , respectively, with all other parameter values fixed at their default values. We observe that for each of these parameters, the running time grows with increasing parameter values. For the f-measure, it initially increases as well, but eventually flattens out. This verifies our earlier observation that for a particular dataset, there exist bounds on these parameters, beyond which no further gains in repair effectiveness can be achieved. Thus, by carefully choosing the bounds, we can reduce the running time of the repair process significantly.

The effect of λ . Figure 10(d) shows the effect of λ in Equation (3). With λ varying from 0.1 to 0.9, the running time remains stable, and the f-measure first increases and then decreases after

(c) Results with Varying η (d) Results with Varying λ

Figure 10: Results with Different Bounds on the Real Dataset

$\lambda = 0.5$. The results imply that (1) there exists an optimal λ value with which the best results can be produced, and (2) the repair results are not sensitive to changes in λ .

6.3 Effects of Data Characteristics

We next conduct a set of experiments using synthetic datasets to investigate the impact of different data characteristics. All the datasets used in this set of experiments are produced based on 500 original trajectories (before injecting errors). The actual number of trajectories in a dataset is affected by different parameters (e.g., error rate and record missing rate), and will be shown for different groups of experiments. The default values of θ , η , ζ and λ for the synthetic datasets used here are set to 8, 600 seconds, 4, and 0.5, respectively.

6.3.1 Size and Density of the Transition Graph. The first data characteristics we explore are the size (number of vertices) and density (number of edges) of the transition graph. The experiments are conducted on synthetic trajectory sets generated from transition graphs with different sizes and different densities. We vary the density of a transition graph with 8 vertices $\mathcal{G}_t = (\mathbf{V}, \mathbf{E}, \mathbf{I}, \mathbf{O})$, where $\mathbf{V} = \{loc_1, loc_2, \dots, loc_8\}$, $\mathbf{E} = \{(loc_1, loc_2), (loc_2, loc_3), \dots, (loc_7, loc_8)\}$, $\mathbf{I} = \{loc_1\}$, and $\mathbf{O} = \{loc_8\}$, by randomly adding a specific number of edges (without duplicate) to it.

(a) Varying # of Vertices (b) Varying # of Edges Added

Figure 11: Effect of the Size and Density of Transition Graphs

The effect of graph size. Figure 11(a) shows the results on varying transition graph sizes. It is evident that both the f-measure and the running time decrease with the number of vertices increasing. That is because a transition graph with more vertices tends to have longer valid paths, and the longer the valid paths are, the harder it is to form candidate repairs that could "reassemble" the original trajectory;

The effect of graph density. The results for adding varying number of edges to a given transition graph are shown in 11(b).

The f-measure decreases while the running time increases with more edges added, due to the following reasons: (1) adding edges to the transition graph will increase the number of valid paths and thus there will be more candidate repairs; (2) with the number of candidate repairs growing, there may be more false positive repairs (vertices) being selected and that will cause the f-measure to deteriorate; and (3) having more candidate repairs also leads to longer candidate generation and selection time, resulting in an increase in the total running time.

The results above imply that our ID repair approach is more suitable for sparse transition graphs with limited number of vertices, which is actually the case in many, if not most, application scenarios. This is also consistent with our assumptions and analysis made in Section 2.3.

6.3.2 ID Error Rate. To evaluate the effect of the ID error rate, we create a cohort of synthetic datasets by randomly injecting ID errors, each time with a different error rate, into an identical original trajectory set.

(a) # of Trajectories/Repairs (b) F-Measure and Running Time
Figure 12: Effect of ID Error Rate

The experiment results are reported in Figures 12(a) and 12(b), from which we can observe that with the error rate increasing, (1) the number of trajectories for the input dataset increases linearly; (2) both the number of candidate repairs and the running time increase polynomially; and (3) the f-measure drops near linearly. The reason is as follows. Since ID errors can cause a trajectory to break into multiple pieces, the input number of trajectories grows linearly with respect to the error rate. Both the number of candidate repairs and the running time also increase accordingly. The f-measure drops mainly because intuitively it is more difficult to “reassemble” the original trajectory with more IDs misidentified. Also, recall that our repair approach assumes that all the correct IDs exist in the dataset, which may no longer hold if the error rate gets high. In summary, the lower the ID error rate is, the better our repair approach works.

6.3.3 Record Missing Rate. As mentioned in Section 1, in this work we only consider errors caused by ID misidentification, ignoring the effect of missing records. In practice, however, there may be a slight chance of record missing from the dataset. We thus conduct experiments to evaluate whether this has a significant impact on the effectiveness of the proposed approach. To this end, we first generate a synthetic dataset and then randomly remove records from it with varying record missing rates.

(a) # of Trajectories/Repairs (b) F-Measure and Running Time
Figure 13: Effect of Record Missing

As illustrated in Figures 13(a) and 13(b), with the missing rate increasing from 0% to 20%, all the metrics decrease. The reason is that (1) record missing will make some joinable subsets incomplete and thus cannot compose the corresponding candidate repairs (this is verified by the decrease of candidate repairs shown in Figure 13(a)); (2) trajectories belonging to different entities may be joined due to the absence of some trajectories; and (3) records containing the true ID for an entity may have all been removed, which makes some errors irreparable.

According to the experiment result, although having missing records has a notable impact on the effectiveness of the proposed ID repair approach, it is still applicable for datasets with relatively low record missing rates.

6.4 Effectiveness of the Optimization Methods

The main purpose of the next group of experiments is to explore the performance improvements brought by the Length-Indexed Grids (in Section 5.1), as well as the pruning method (in Section 5.2).

We conduct the experiments on synthetic datasets with the number of trajectories varying from 2,000 to 6,000 and the corresponding number of records varying from 5,189 to 15,795. All the datasets are generated using the same transition graph as that for the real dataset.

(a) Construction Time for G_m (b) Running Time with Different Data Sizes
Figure 14: Effectiveness of Optimization Methods

Figure 14(a) shows the running time of the trajectory graph construction process with different number of trajectories. From this figure we can observe that without indexing, the construction time of G_m grows superlinearly with the number of trajectories, whereas the trend becomes almost linear with the Length-Indexed Grids. This observation indicates that the Length-Indexed Grids can help eliminate a large number of unnecessary trajectory comparisons.

Figure 14(b) reports the running time of the whole repair process with the number of trajectories varying from 2,000 to 6,000. We can see that the time increases polynomially with the number of trajectories. Besides, compared with the basic clique generation algorithm, algorithm with the pruning method can reduce about 30% running time.

6.5 Comparison with Competing Approaches

To evaluate the effectiveness of our proposed method, we compare it with other approaches that use different repair selection algorithms or exploit different constraints.

6.5.1 Alternative Repair Selection Algorithms. In this set of experiments, we aim to investigate the performance of different algorithms for the repair selection phase. In addition to EMAX and the exact algorithms introduced in Section 4.2, we also implement three other algorithms for comparison. The first algorithm,

named *optimal selection*, is an oracle machine based algorithm that always selects and applies correct candidate repairs regardless of their ω values. Theoretically, this algorithm can achieve the highest quality improvement. The second and the third algorithms are minimum degree first (DMIN) and maximum degree first (DMAX). As their names suggest, they select the vertex with the minimum/maximum degree from \mathcal{G}_r in each step and discard adjacent vertices until there is no vertex left.

As the exact algorithm for weighted-independent set is time consuming, the experiments are conducted on 5 small synthetic datasets whose sizes do not exceed 100. Even so, the average running time for the exact algorithm is still thousands times longer than the other algorithms. Thus we only report on their effectiveness rather than the performance.

To measure the real quality of a dataset, we employ the metric *trajectory accuracy*, which is defined as the ratio of trajectories with correct IDs. Thereby, the real quality improvement after repairing can be measured by the increment in this metric. As trajectory merging can change the data size, we will only perform ID rewritings. Using ΔE (ΔA) and ΔE_{max} (ΔA_{opt}) to represent the selected Ω value (trajectory accuracy improvement) and the maximum selected Ω value (maximum trajectory accuracy improvement), the approximation ratio for maximum Ω value selection and data quality improvement can be calculated by $\Delta E/\Delta E_{max}$ and $\Delta A/\Delta A_{opt}$.

(a) Approximation Ratios for Repairs Selection

(b) Approximation Ratios for Quality Improvement

Figure 15: Approximation Ratios for Different Selection Algorithms on Synthetic Datasets

Figures 15(a) and 15(b) report the experiment results of maximum Ω value selection and data quality improvement, from which we can observe that (1) the selected Ω value can reflect the data quality improvement well, (2) the total selected Ω value for the optimal selection algorithm is randomly distributed around, rather than always coincides with, the maximum value, and (3) remarkably, the proposed EMAX algorithm can achieve an average approximation ratio of more than 0.95 and 0.85 for repair selection and real data quality improvement respectively, which significantly beats the other two heuristic algorithms. In summary, as the optimal selection algorithm is evasive in practice and the exact algorithm is time-consuming, the proposed EMAX algorithm seems highly promising.

6.5.2 Comparison with Other Repair Approaches. To evaluate our proposed ID repair approach, we implement a baseline approach based on ID similarity = 3, i.e., trajectories with ID

similarity ≤ 3 are considered to come from the same entity and thus will be merged. Also, we implement another greedy heuristic method based on neighborhood constraints proposed in [27]. We take the transition graph \mathcal{G}_t as the constraint graph and the trajectory graph \mathcal{G}_m as the instance graph. The cost function is set to be the edit distance of two ID strings. To make sure the algorithm terminates, we add a variation to the approach that edges are allowed to be removed from \mathcal{G}_m during relabeling.

The repair results of the three approaches are shown in Figure 16, from which we can observe that (1) while the precision of the other competing approaches is somewhat close to our proposed approach, their recall is significantly lower; and (2) the neighborhood constraint based method performs even worse than the baseline method for our problem. The recall of the ID similarity based approach is better than that of the neighborhood constraint based approach because it supports “partial recovery” of the original trajectories. Actually, both the ID similarity based approach and the neighborhood constraint based approach are binary constraints that only consider the relationship between trajectories pairs. In contrast, our transition graph based approach considers the relationships between multiple trajectories, which is why it can cover more correct repairs.

7 RELATED WORK

There has been a sizable body of work in the areas of data repair and data matching that can be considered related to our work, which we summarize below.

7.1 Data Repair

Most previous work on data repair has focused on relational data by exploiting the different types of dependencies [1], e.g., matching dependencies [12], differential dependencies [26], and order dependencies [28]. Fan et al. extend the functional and inclusion dependencies with conditions [6, 13] and also extend their data inconsistency detection method to distributed environments [14]. Although highly successful, most of the work has not considered spatial and temporal factors.

Moreover, sequential dependencies [18] are developed to constrain attributes’ transitions. Song et al. use neighborhood constraints to repair vertex labels in graphs [27]. Wang et al. employ the Petri Net to repair the names of event logs [29]. Similar to our study that focuses on repairing the IDs, Song et al. propose a method for cleaning timestamps facilitated by temporal constraints [25].

For unified approaches, Ilyas et al. propose a novel holistic repairing algorithm [8], as well as a general system [11] that puts multiple constraints into consideration and repairs them all at once. Similarly, Geerts et al. develop a uniform data-cleaning framework with a cell group and partial order based cleaning semantics [17]. However, those methods cannot be trivially adopted, since it is difficult to transform the constraints posed by transition graphs in our setting into the denial constraints or equality-generating dependencies required by those methods.

7.2 Data Matching

In the field of data matching, Yakout et al. try to identify the same entity in different transactions by detecting regularity patterns from merged behavior logs [32]. Similarly, Zhu et al. perform heterogeneous event matching by finding an optimal mapping that can maximize the frequency similarity of patterns [33].

When patterns are not explicitly given, Li et al. propose a temporal model, as well as an algorithm to perform temporal

Figure 16: Comparisons with Other Repair Approaches

records clustering [22]. They utilize both the usual similarity metrics and the temporal model with collected evidences to make the decision. Chiang et al. extend their work and develop a two-phase method called “static first, dynamic second” to reduce the complexity of the temporal model [7]. Also, they use signatures to improve the computing efficiency. Note that both their work and ours are to identify entities by exploring their transitions. The main difference is that while their work mainly focuses on when the state attributes of entities should change, we focus on how (through which paths) the entities pass through the area of interest.

8 CONCLUSIONS AND FUTURE WORK

We have studied a novel problem of repairing erroneous IDs in spatio-temporal trajectories with transition graphs. A two-phase repair paradigm, which includes candidate repair generation and compatible repair selection, is proposed to address this problem. Since both phases are intractable in general, we exploit the locality and sparsity properties of trajectories and present efficient solutions in restricted but practical scenarios. For the candidate repair generation phase, we propose a backtracking algorithm, as well as a pruning method to speed it up. For the candidate repair selection phase, we present a practical greedy algorithm. Extensive experiments are conducted on both real and synthetic data to study the effects of various parameters and data characteristics. In addition, we compare our proposed approach with some baseline methods and the results have confirmed its effectiveness.

One possible direction for future work would be to deploy our algorithms on some distributed repair systems with UDF support [20]. It would also be interesting to study solutions that could perform ID repair as the tracking records stream in.

ABSTRACT

In the last decade, many business applications have moved into the cloud. In particular, the “database-as-a-service” paradigm has become mainstream. While existing multi-tenant data management systems focus on single-tenant query processing, we believe that it is time to rethink how queries can be processed across multiple tenants in such a way that we do not only gain more valuable insights, but also at minimal cost. As we will argue in this paper, standard SQL semantics are insufficient to process cross-tenant queries in an unambiguous way, which is why existing systems use other, expensive means like ETL or data integration instead. We first propose MTSQL, an extension to standard SQL, which fixes the ambiguity problem. Next, we present MTBase, a query processing middleware that efficiently processes MTSQL on top of SQL. As we will see, there is a canonical, provably correct, rewrite algorithm from MTSQL to SQL, which may however result in poor query execution performance, even on high-performance database products. We further show that with carefully-designed optimizations, execution times can be reduced in such ways that the difference to single-tenant queries becomes marginal.

1 INTRODUCTION

Indisputably, cloud computing is one of the fastest growing businesses related to the field of computer science. Cloud providers promise good elasticity, high availability and a fair pay-as-you-go pricing model to their tenants. Moreover, corporations are no longer required to rely on on-premise infrastructure which is typically costly to acquire and maintain. While it is still an open research question whether and how these good promises can be kept with regard to databases [19, 32], all the big players, like Google [30], Amazon [8], Microsoft [34] and recently Oracle [38], have launched their own Database-as-a-Service (DaaS) cloud products.

All these products host massive amounts of data from multiple clients and are therefore *multi-tenant*. However, as pointed out by Chong et al. [17], the term *multi-tenant database* is ambiguous and can refer to a variety of DaaS schemes with different degrees of logical data sharing between tenants. On the other hand, as argued by Aulbach et al. [11], multi-tenant databases not only differ in the way how tenants logically share information, but also how information is physically separated. We conclude that the *multi-tenancy spectrum* consists of four different schemes: First, there are DaaS products that offer each tenant her proper database while relying on shared resources (*SR*), i.e. hardware (e.g.

CPU, network, storage) and/or software (e.g. buffer pools, system tables, system users, etc.). Examples include *SAP HANA* [42], *SqlVM* [36], *RelationalCloud* [35], *Snowflake* [18] and *Oracle’s multitenant container database (CDB)* [40]. Next, there are systems that share databases (*SD*), but each tenant gets her own set of tables within such a database, as for instance *Azure SQL DB* [20].

Finally, there are the two schemes where tenants not only share a database, but also the table layout (schema). Either, as for example in *Apache Phoenix* [9], tenants still have their private tables, but these tables share the same (logical) schema (*SS*), or the data of different tenants is consolidated into shared tables (*ST*) which is hence the layout with the highest degree of physical and logical sharing. Prominent examples for *ST* include Oracle’s Virtual Private Database [3] as well as different Microsoft Azure DaaS offerings [33, 34]. *SS* and *ST* layouts are not only used in DaaS, but also in Software-as-a-Service (SaaS) platforms, as for example in *Salesforce* [44]. The main reason why all these commercial systems prefer *ST* over *SS* is cost [11]. Moreover, if the number of tenants exceeds the number of tables a database can hold, which is typically a number in the range of ten thousands, *SS* becomes prohibitive. Conversely, *ST* databases can easily accommodate hundred thousands to even millions of tenants.

An important feature of *multi-tenant databases*, which, to the best of our knowledge, no DaaS or SaaS natively supports today, is *cross-tenant query processing*, i.e. combining data of different tenants and query this unified data set as if it was single-tenant, using SQL. In order to illustrate that *cross-tenant query processing* is indeed a highly relevant requirement, let us have a look at one of the many initiatives to democratize the use of personal data, the *Health Data Cooperative (HDC)* [27]. In HDC, all patient data is stored in a single, multi-tenant SaaS database, each patient being a tenant managing her own data. For clinical studies, however, it is essential to be able to run queries over a cohort of patients who give their consent, or, in other words enable *cross-tenant query processing*. Clearly, the health data use case has also another big challenge, which is data privacy. This aspect, despite being out of the scope of this paper, is considered essential future work.

There are several existing approaches to *cross-tenant query processing* which are summarized in Figure 1. The first approach is *data warehousing* [29] where data is *extracted* from several *data sources* (tenant databases/tables), *transformed* into one common format and finally *loaded* into a new database where it can be queried by the client. This approach has high integration transparency in the sense that once the data is loaded, it is in the expected format as required by the client and she can ask any query she wants, using plain SQL. Moreover, as all data is in a single place, queries can be optimized. On the down-side of this approach – well-known and argued by many [10, 14, 37] – are costs in terms of both, developing and maintaining such *ETL*

*most of the work performed while at ETH

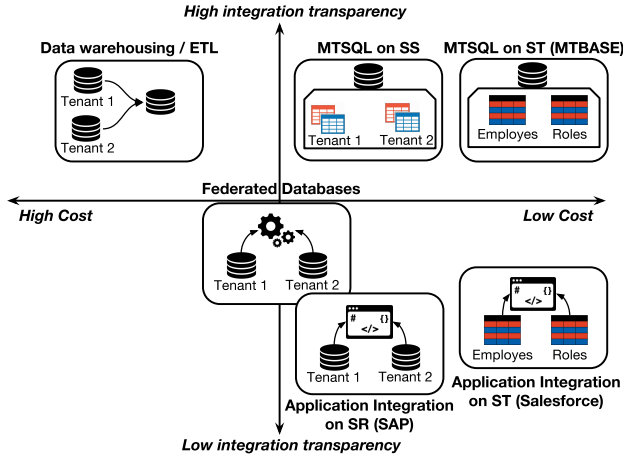

Figure 1: Cross-tenant query processing systems

pipelines, as well as maintaining a separate copy of the data. Another disadvantage is *data staleness* in the presence of frequent updates.

Federated Databases [26, 31] reduce some of these costs by integrating data *on demand*, i.e. there is no data copying. However, maintenance costs are still significant as for every new data source, a new integrator/wrapper has to be developed. As data resides in different places (and different formats), queries can only be optimized to a very small extent (if at all), which is why the degree of integration transparency is considered sub-optimal. Finally, systems like *SAP HANA* [42] and *Salesforce* [44], which are mainly tailored towards single-tenant queries, offer some degree of *cross-tenant query processing*, but only through their application logic, not natively. This means that the set of queries that can be asked is limited, accounting for low integration transparency.

We believe that the reason why none of these previous works uses a native approach, i.e. SQL plus transparent rewriting, for *cross-tenant query processing* is that there is an *ambiguity problem*.¹ Consider, for instance, the *ST* database in Figure 2, which we are going to use as a running example throughout the paper. Further assume that we would like to query the joint dataset of tenants 0 and 1: As shown on the left, we might want to join *Employees* with *Roles*. Joining on *role_id* alone is not enough as this would also join *Alice* with *executive*, which does not correspond to the expected output because *Alice* is a professor, and only a professor. In this case, a rewrite algorithm would have to add the tenant-ID *ttid* to the join predicate. On the other hand, joining the *Employees* table with itself on *E1.age = E2.age*, as illustrated on the right, does not require *ttid* to be present in the join predicate because it actually makes sense to include results like (*Alice*, *Ed*) because they are indeed the same age.

An additional challenging fact is that different tenants might store their data in different units. In our example, tenant 0 might store her employees’ salaries in a different currency than tenant 1. If this is the case, computing the average salary across all tenants clearly involves some value conversions that should, ideally, happen without the client noticing or even worrying about.

This paper presents *MTSQL* as a solution to these ambiguity problems, following a native approach. *MTSQL* extends the SQL API and provides additional data definition syntax and corresponding semantics specifically-suited for *cross-tenant query*

¹Note, however, that SQL plus transparent rewriting works for *single-tenant query processing* in a multi-tenant system. Apache Phoenix [9] and Oracle’s Virtual Private Database [3] do exactly that.

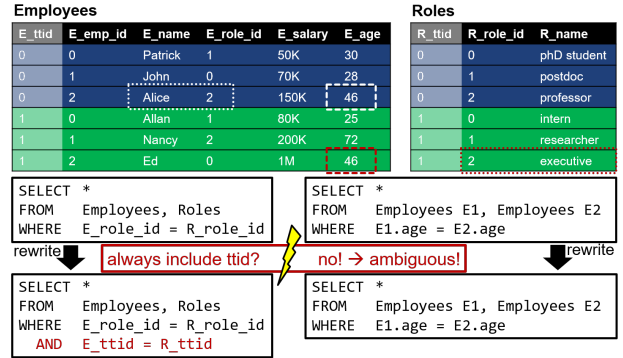

Figure 2: Multi-tenant database in *basic layout (ST)*, illustrating the ambiguity problem in *cross-tenant queries*

processing. It enables high integration transparency because once the schema is defined and the database connection established, any client, with any desired data format, can ask any query at any time and do so by using nothing else but plain SQL. Moreover, as data resides in a single database (*SS* or *ST*), queries can be aggressively optimized with respect to both, standard SQL semantics and additional *MTSQL* semantics. As *MTSQL* adopts the single-database layout, it is also very cost-effective, especially if used on top of *ST*. Also, data conversion only happens as needed, which perfectly fits the cloud’s *pay-as-you-go* cost model and thus makes *MTSQL* an attractive option to complement existing *DaaS* offerings. Specifically, the paper makes the following contributions:

- It defines the syntax and semantics of *MTSQL*, a database language that extends SQL and solves the ambiguity problem for *cross-tenant query processing*.
- It presents the design and implementation of *MTBase*, a database middleware that executes *MTSQL* on top of any *shared-table* multi-tenant database.
- It studies *MTSQL*-specific optimizations for query execution in *MTBase*.
- It extends the well-known TPC-H benchmark in order to run and evaluate *MTSQL* workloads, resulting in new benchmark called *MT-H*.
- It evaluates the performance and the implementation correctness of *MTBase* with *MT-H*, concluding with satisfactory results.

The rest of this paper is organized as follows: Section 2 defines *MTSQL*, while Section 3 gives an overview on *MTBase*. Section 4 discusses the *MTSQL*-specific optimizations which are validated in Section 5. Section 6 shortly summarizes lines of related work, specifically focusing on the relation of *MTSQL* to data integration as well as data privacy, whereas the paper is concluded in Section 7.

2 MTSQL

In order to model the specific aspects of *cross-tenant query processing* in *multi-tenant databases*, we developed *MTSQL*, which will be described in this section. *MTSQL* extends SQL in two ways: First, it extends the SQL interface with two additional parameters, *C* and *D*. *C* is the tenant ID (or *ttid* for short) of the client who submits a statement and hence determines the format in which the result must be presented. The data set, *D*, is a set of *ttids* that refer to the tenants whose data the client wants to query. Secondly, *MTSQL* extends the syntax and semantics of SQL, as well as its Data Definition Language (DDL), Data Manipulation

Language (DML) and Data Control Language (DCL, consists of GRANT and REVOKE statements).

As mentioned in the introduction, there are several ways how a multi-tenant database can be laid out: Figure 2 shows an example of the *ST* scheme, also referred to as *basic layout* in related work [11] where tenants’s data is consolidated using the same tables. Meanwhile, there also exists the *SS* scheme, also referred to as *private table layout*, where every tenant has her own set of tables. In that scheme, *data ownership* is defines as part of the table name (e.g. *Roles_1*, *Roles_2*, ...) while in *ST*, records are explicitly annotated with the *ttid* of their *data owner*, using an extra meta column in the table which is invisible to the client.

As these two approaches are semantically equivalent, the MTSQL semantics that we are about to define, apply to both. In the case of the *SS*, applying a statement *s* with respect to *D* simply means to apply *s* to the logical union of all private tables owned by a tenant in *D*. In *SS*, *s* is applied to tables filtered according to *D*. In order to keep the presentation simple, the rest of this paper assumes an *ST* scheme, but sometimes defines semantics with respect to *SS* if that makes the presentation easier to understand.

2.1 MTSQL API

MTSQL needs a way to incorporate the additional parameters *C* and *D*. As *C* is the *ttid* of the tenant that issues a statement, we assume it is implicitly given by the SQL connection string. *ttids* are not only used for identification and access control, but also for data ownership. While this paper uses integers for simplicity reasons, *ttids* can have any data type, in particular they can also be database user names.

```
SET SCOPE = "IN (1,3,42)";
```

Listing 1: Simple SCOPE expression using IN

```
SET SCOPE = "FROM Employees WHERE E_salary > 180K";
```

Listing 2: Complex SCOPE expression with sub-query

D is defined using the MTSQL-specific SCOPE runtime parameter on the SQL connection. This parameter can be set in two different ways: Either, as shown in Listing 1, as *simple scope* with an IN list stating the set of *ttids* that should be queried, or as in Listing 2, as a sub-query with a FROM and a WHERE clause (*complex scope*). The semantics of the latter is that every tenant that owns at least one record in one of the tables mentioned in the FROM clause that satisfies the WHERE clause is part of *D*. The SCOPE variable defaults to {*C*}, which means that by default a client processes only her own data. Defining a simple scope with an empty IN list, on the other hand, makes *D* include all the tenants present in the database.

Making *C* and *D* part of the connection allowed for a clear separation between the end users of MTSQL (for which *ttids* do not make much sense and hence remain invisible) and administrators/programmers that manage connections (and are aware of *ttids*).

2.2 Data Definition Language

DDL statements are issued by a special role called the *data modeller*. In a multi-tenant application, this would be the SaaS provider (e.g. a Salesforce administrator) or the provider of a specific application. However, the data modeller can delegate this privilege to any tenant she trusts using a GRANT statement, as will be described in Section 2.3.

There are two types of tables in MTSQL: tables that contain common knowledge shared by everybody (like the *Regions* table in *TPC-H* [43]) and those that contain data of a specific tenant (i.e. *Employees* and *Roles* in Figure 2). More formally, we define the *table generality* of *Regions* as *global* and the one of *Employees* as *tenant-specific*. In order to process queries across tenants, MTSQL needs a way to distinguish whether an attribute is *comparable* (can be directly compared against attribute values of other tenants), *convertible* (can be compared against attribute values of other tenants after applying a well-defined *conversion function*) or *tenant-specific* (it does semantically not make sense to compare against attribute values of other tenants). An overview of these types of *attribute comparability*, together with examples from Figure 2, is shown in Table 1.

type	description	examples
comparable	can be directly compared to and aggregated with other values	E_age, R_name
convertible	other values need to be converted to the format of the current tenant before comparison or aggregation	E_salary
tenant-specific	values of different tenants cannot be compared with each other	E_role_id, R.role_id

Table 1: Overview on attribute comparability in MTSQL

2.2.1 CREATE TABLE Statement. The MTSQL-specific keywords for creating (or altering) tables are GLOBAL, SPECIFIC, COMPARABLE and CONVERTIBLE. An example of how they can be used is shown in Listing 3. Note that SPECIFIC can be used for tables and attributes. Moreover, using these keywords is optional as we define that tables are global by default, attributes of tenant-specific tables default to *tenant-specific* and those of global tables to *comparable*.²

```
1 CREATE TABLE Employees SPECIFIC (
2   E_emp_id INTEGER NOT NULL SPECIFIC,
3   E_name VARCHAR(25) NOT NULL COMPARABLE,
4   E_role_id INTEGER NOT NULL SPECIFIC,
5   E_salary VARCHAR(17) NOT NULL CONVERTIBLE
6   @currencyToUniversal @currencyFromUniversal,
7   E_age INTEGER NOT NULL COMPARABLE,
8   CONSTRAINT pk_emp PRIMARY KEY (E_emp_id),
9   CONSTRAINT fk_emp FOREIGN KEY (E_role_id) REFERENCES Roles (
10  R_role_id)
11 );
```

Listing 3: Exemplary MTSQL CREATE TABLE statement, MT-specific keywords marked in bold

2.2.2 Conversion Functions. Cross-tenant query processing requires the ability to execute comparison predicates on *comparable* and *convertible attribute*. While comparable attributes can be directly compared to each other, convertible attributes, as their name indicates, have to be converted first, using conversion functions. Each tenant has a pair of conversion functions for each attribute to translate from and to a well-defined universal format. More formally, a *conversion function pair* is defined as follows:

Definition 2.1. (*toUniversal* : $X \times T \rightarrow X$, *fromUniversal* : $X \times T \rightarrow X$) is a valid MTSQL conversion function pair for attribute *A*, where *T* is the set of tenants in the database and *X* is the domain of *A*, if and only if:

- (i) There exists a *universal format* for attribute *A*:³

$$image(toUniversal(\cdot, t_1)) = image(toUniversal(\cdot, t_2)) = \dots = image(toUniversal(\cdot, t_{|T|}))$$
- (ii) For every tenant $t \in T$, the partial functions $toUniversal(\cdot, t)$ and $fromUniversal(\cdot, t)$ are bijective functions.

²Global tables (shared among all tenants!) can only have comparable attributes anyway.

³ $image(f)$ denotes the mathematical image, i.e. the range of function *f*.

(iii) *fromUniversal* is the inverse of *toUniversal*: $\forall t \in T, x \in X : \text{fromUniversal}(\text{toUniversal}(x, t), t) = x$

These three properties imply the following two corollaries that we are going to need later in this paper:

COROLLARY 1. *toUniversal* and *fromUniversal* are equality preserving: $\forall t \in T : \text{toUniversal}(x, t) = \text{toUniversal}(y, t) \Leftrightarrow x = y \Leftrightarrow \text{fromUniversal}(x, t) = \text{fromUniversal}(y, t)$

COROLLARY 2. Values from any tenant t_i can be converted into the representation of any other tenant t_j by first applying *toUniversal*(\cdot, t_i), followed by *fromUniversal*(\cdot, t_j) while equality is preserved:

$$\forall t_i, t_j \in T : x = y \Leftrightarrow \text{fromUniversal}(\text{toUniversal}(x, t_i), t_j) = \text{fromUniversal}(\text{toUniversal}(y, t_i), t_j)$$

The reason why we opted for a two-step conversion through universal format is that it allows each tenant t_i to define her share of the conversion function pair, i.e. *toUniversal*(\cdot, t_i) and *fromUniversal*(\cdot, t_i), individually without the need of a central authority. Moreover, this design greatly reduces the overall number of partial conversion functions as we need at most $2 \cdot |T|$ partial function definitions, compared to $|T|^2$ functions in the case where we would define a direct conversion for every pair of tenants.

```
1 CREATE FUNCTION phoneToUniversal (VARCHAR(17), INTEGER) RETURNS
  VARCHAR(17)
2 AS 'SELECT SUBSTRING($1, CHAR_LENGTH(PT_prefix)+1) FROM
  Tenant, PhoneTransform WHERE T_tenant_key = $2 AND
  T_phone_prefix_key = PT_phone_prefix_key;'
3 LANGUAGE SQL IMMUTABLE;
```

Listing 4: Converting a phone number to universal form (without prefix), PostgreSQL syntax

```
1 CREATE FUNCTION phoneFromUniversal (VARCHAR(17), INTEGER)
  RETURNS VARCHAR(17)
2 AS 'SELECT CONCAT(PT_prefix, $1) FROM Tenant, PhoneTransform
  WHERE T_tenant_key = $2 AND T_phone_prefix_key =
  PT_phone_prefix_key;'
3 LANGUAGE SQL IMMUTABLE;
```

Listing 5: Converting to a specific phone number format, PostgreSQL syntax

Listings 4 and 5 show an example of such a conversion function pair. These functions are used to convert phone numbers with different prefixes, like “+”, “00” or any other specific county exit code⁴, and the universal format is a phone number without prefix. In this example, converting phone numbers simply means to lookup the tenant’s prefix and then either prepend or remove it, depending whether we convert from or to the universal format. Note that the exemplary code also contains the keyword `IMMUTABLE` to state that for a specific input the function always returns the same output, which is an important hint for the query optimizer. While this keyword is PostgreSQL-specific, some other vendors, but by far not all, offer a similar syntax.

It is important to mention that the *equality-preserving* property as mentioned in Corollary 1 is a minimal requirement for conversion functions to make sense in terms of producing coherent query results among different clients. There are, however conversion functions that exhibit additional properties, for example:

- order-preserving with respect to tenant t :
 $x < y \Leftrightarrow \text{toUniversal}(x, t) < \text{toUniversal}(y, t)$

⁴The country exit code is a sequence of digits that you have to dial in order to inform the telco system that you want to call a number abroad. A full list of country exit codes can be found on <http://www.howtocallabroad.com/codes.html>.

- homomorphic with respect to tenant t and function h :
 $\text{toUniversal}(h(x_1, x_2, \dots), t) = h(\text{toUniversal}(x_1, t), \text{toUniversal}(x_2, t), \dots)$

We will call a conversion function pair *fully-order-preserving* if *toUniversal* and *fromUniversal* are order-preserving with respect to all tenants. Consequently, a conversion function pair can also be *fully-h-preserving*.

Listings 6 and 7 show an exemplary conversion function pair used to convert currencies (with USD as universal format). These functions are not only equality-preserving, but also fully-SUM-preserving: as the currency conversion is nothing but a multiplication with a constant factor⁵ from `CurrencyTransform`, it does not matter in which format we sum up individual values (as long as they all have that same format). As we will see, such special properties of conversion functions are another crucial ingredient for query optimization.

```
1 CREATE FUNCTION currencyToUniversal (DECIMAL(15,2), INTEGER)
  RETURNS DECIMAL(15,2)
2 AS 'SELECT CT_to_universal*$1 FROM Tenant, CurrencyTransform
  WHERE T_tenant_key = $2 AND T_currency_key =
  CT_currency_key;'
3 LANGUAGE SQL IMMUTABLE;
```

Listing 6: Converting a currency to universal form (USD), PostgreSQL syntax

```
1 CREATE FUNCTION currencyFromUniversal (DECIMAL(15,2), INTEGER)
  RETURNS DECIMAL(15,2)
2 AS 'SELECT CT_from_universal*$1 FROM Tenant,
  CurrencyTransform WHERE T_tenant_key = $2 AND
  T_currency_key = CT_currency_key;'
3 LANGUAGE SQL IMMUTABLE;
```

Listing 7: Converting from USD to a specific currency, PostgreSQL syntax

The conversion function examples shown in Listings 4 to 7 assume the existence of tables holding additional conversion information (`CurrencyTransform` and `PhoneTransform`) as well as a table with references into these tables (named `Tenants` table). The way how a tenant can define her portion of the conversion functions is then simply to choose a specific currency and phone format as part of an initial setup procedure. However, this is only one possible implementation. MTSQL does not make any assumptions or restrictions on the implementation of conversion function pairs themselves, as long as they satisfy the properties given in Definition 2.1.

MTSQL is not the first work that talks about conversion functions. In fact, there is an entire line of work that deals with data integration and in particular with schema mapping techniques [11, 23, 25]. These works mention and take into account conversion functions, like for example a multiplication or a division by a constant. More complex conversion functions, including regular-expression-based substitutions and other arithmetic operations, can be found in *Potter’s Wheel* [41] where *conversion* is referred to as *value translation*. All these different conversion functions can potentially also be used in MTSQL which is, to the best of our knowledge, the first work that formally defines and categorizes conversion functions according to their properties.

2.2.3 Integrity Constraints. MTSQL allows for *global* integrity constraints that every tenant has to adhere to (with respect to the entirety of her data) as well as *tenant-specific* integrity constraints (that tenants can additionally impose on their own

⁵We are aware of the fact that currency conversion is not at all constant, but depends on rapidly changing exchange rates. However, we want to keep the examples as simple as possible in order to illustrate the underlying concepts. However, the general ideas of this paper also apply to temporal databases.

data). An example of a *global* referential integrity constraint is shown in the end of Listing 3. This constraint means that for every tenant, for each entry of `E_role_id`, a corresponding entry `R_role_id` has to exist in `Roles` and must be owned by that same tenant. Consider for example employee *John* with `R_role_id 0`. The constraint implies that their must be a *role 0* owned by tenant 0, which in that case is *PhD student*. If the constraint were only *tenant-specific* for tenant 1, John would not link to roles and `E_role_id 0` would just be an arbitrary numerical value. In order to differentiate *global* from *tenant-specific* constraints, the scope is used.⁶

2.2.4 Other DDL Statements. `CREATE VIEW` statements look the same as in plain SQL. As for the other DDL statements, anyone with the necessary privilege can define global views on *global* and *tenant-specific* tables. Tenants are allowed to create their own, tenant-specific views (using the default scope). The selected data has to be presented in universal format if it is a *global* view and in the *tenant-specific* format otherwise. `DROP VIEW`, `DROP TABLE` and `ALTER TABLE` work the same way as in plain SQL.

2.3 Data Control Language

Let us have a look at the MTSQL `GRANT` statement:

```
GRANT <privileges> ON <database|table> TO <ttid>;
```

Listing 8: MTSQL GRANT syntax

As in plain SQL, this grants some set of access privileges (`READ`, `INSERT`, `UPDATE` and/or `DELETE`) to the tenant identified by *ttid*. In the context of MTSQL, however, this means that the privileges are granted with respect to *C*. Consider the following statement:

```
GRANT READ ON Employees TO 42;
```

Listing 9: Example of an MTSQL GRANT statement

In the *private* table layout, if *C* is 0, then this would grant tenant 42 read access to `Employees_0`, but if *C* is 1, tenant 42 would get read access to `Employees_1` instead. If a grant statement grants to *ALL*, then the grant semantics also depend on *D*, more concretely if $D = \{7, 11, 15\}$ the privileges would be granted to tenants 7, 11 and 15.

By default, a new tenant that joins an MTSQL system is granted the following privileges: `READ` access to global tables, `READ`, `INSERT`, `UPDATE`, `DELETE`, `GRANT` and `REVOKE` on his own instances of tenant-specific tables. In our example, this means that a new tenant 111 can read and modify data in `Employees_111` and `Roles_111`. Next, a tenant can start asking around to get privileges on other tenants' tables or also on global tables. The `REVOKE` statement, as in plain SQL, simply revokes privileges that were granted with `GRANT`.

2.4 Query Language

Just as in FlexScheme [11, 12], queries themselves are written in plain SQL and have to be filtered according to *D*. Whereas in FlexScheme *D* always equals $\{C\}$ (a tenant can only query her own data), MTSQL allows cross-tenant query processing, which means that the data set can include other tenants than *C* and can in particular contain more than one element. As mentioned in the

⁶Remembering that an empty IN list refers all tenants, this is exactly what is used to indicate a global constraint. Additionally, all constraints created as part of a `CREATE TABLE` statement are global as well.

introduction, this creates some new challenges that have to be handled with special care.

2.4.1 Client Presentation. As soon as tenants can query other tenants' data, the MTSQL engine has to be make sure to deliver results in the proper format. For instance, looking again at Figure 2, if tenant 0 queries the average salary of all employees of tenant 1, then this should be presented in USD because tenant 0 stores her own data in USD and expects other data to be in USD as well. Consequently, if tenant 1 would ask that same query, the result would be returned as is, namely in EUR.

2.4.2 Comparisons. Consider a join of `Roles` and `Employees` on `role_id`. As long as the dataset size is only one, such a join query has the same semantics as in plain SQL (or FlexScheme). However, as soon as tenant 1, for instance, asks this query with $D = \{0, 1\}$, the join has to take the *ttids* into account. The reason for this is that `role_id` is a *tenant-specific* attribute and should hence only be joined within the same tenant in order to prevent semantically wrong results like John being an intern (although tenant 0 does not have such a role) or Nancy being a professor (despite the fact that tenant 1 only has roles *intern*, *researcher* and *executive*).

Comparison or join predicates containing *comparable* and *convertible* attributes, on the other hand, just have to make sure that all data is brought into universal format before being compared. For instance, if tenant 0 wants to get the list of all employees (of both tenants) that earn more than 100K USD, all employee salaries have to be converted to USD before executing the comparison.

Finally, MTSQL does not allow to compare *tenant-specific* with other attributes. For instance, we see no way how it could make sense to compare `E_role_id` to something like `E_age` or `E_salary`.

2.5 Data Manipulation Language

MTSQL DML works the same way as in FlexScheme [11, 12] if $D = \{C\}$. Otherwise, if $D \neq \{C\}$, the semantics of a DML statement are defined such that it is applied to each tenant in *D* separately. Constants, `WHERE` clauses and sub-queries are interpreted with respect to *C*, exactly the same way as for queries (c.f. Section 2.4). This implies that executing `UPDATE` or `INSERT` statements might involve value conversion to the proper tenant format(s).

3 MTBASE

Based on the concepts described in the previous section, we implemented MTBase, an open-source MTSQL engine [1]. As shown in Figure 3, the basic building block of MTBase is an MTSQL-to-SQL translation middleware sitting between a traditional DBMS and the client. In fact, as it communicates to the DBMS (and to the client) by the means of pure SQL, MTBase works in conjunction with any off-the-shelve DBMS. For performance reasons, the proxy maintains a cache of MT-specific meta data, which is persisted in the DBMS along with the actual user data. Conversion functions are implemented as UDFs that might involve additional meta tables, both of which are also persisted in the DBMS. MTBase implements the *basic data layout*, which means that *data ownership* is implemented as an additional (meta) *ttid* column in each *tenant-specific* table as illustrated in Figure 2). There are some dedicated meta tables: `Tenant` stores each tenant's privileges and conversion information and `Schema` stores information about table and attribute comparability. Additional

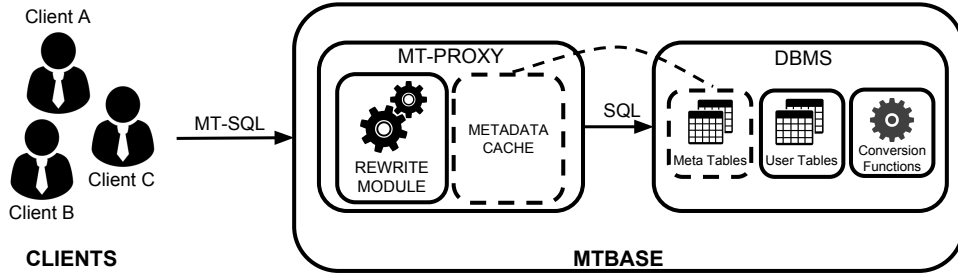

Figure 3: MTBase architecture

meta tables can (but do not have to) be used to implement conversion function pairs, as for example `CurrencyTransform` and `PhoneTransform` shown in Listings 4 to 7.

While the rewrite module was implemented in Haskell and compiled with GHC [6], the connection handling and the meta data cache maintenance was written in Python (and run with the Python2 interpreter) [4]. Haskell is handy because we can make full use of pattern matching and additive data types to implement the rewrite algorithm in a quick and easy-to-verify way, but any other functional language, like e.g. Scala [5], would also do the job. Likewise, there is nothing fundamental in using Python, any other framework that has a good-enough abstraction of SQL connections, e.g. JDBC [7], could be used.

Upon opening a connection at the middleware, the client’s *ttid*, *C*, is derived from the connection string and used throughout the entire lifetime of that connection. Whenever a client sends a MTSQL statement *s*, first if the current scope is complex, a SQL query *q_s* is derived from this scope and evaluated at the DBMS in order to determine the relevant dataset *D*. After that, *D* is compared against privileges of *C* in the `Tenant` table and *ttids* in *D* without the corresponding privilege are pruned, resulting in *D'*. Next, *C*, *D'* and *s* are input into the rewrite algorithm which produces a rewritten SQL statement *s'* which is then sent to the DBMS before relaying the result back to the client. Note that in order to guarantee correctness in the presence of updates, *q_s* and *s'* have to be executed within the same transaction and with a consistency level at least *repeatable-read* [13] (even if the client does not impose any transactional guarantees). If *s* is a DDL statement, the middleware also updates the MT-Specific meta information in the DBMS and the cache.

The rest of this section explains the MTSQL-to-SQL rewrite algorithm in its canonical form and proves its correctness with respect to Section 2.4, while Section 4 shows how to optimize the rewritten queries such that they can be run on the DBMS with reasonable performance.

3.1 Canonical Query Rewrite Algorithm

Our proposed canonical MTSQL-to-SQL rewrite algorithm works top-down, starting with the outer-most SQL query and recursively rewriting sub-queries as they come along. For each sub-query, the SQL clauses are rewritten one-by-one. The algorithm makes sure that for each sub-query the following invariant holds: the result of the sub-query is filtered according to *D'* and presented in the format required by *C*. Note that this invariant also helps to formally prove the correctness of the rewrite algorithm as we will show in Section 3.2.

The pseudo code of the general rewrite algorithm for rewriting a (sub-) query is shown in Algorithm 1. Note that `FROM`, `GROUP BY`, `ORDER BY` and `HAVING` clause can be rewritten without any

additional context while `SELECT` and `WHERE` need the whole query as an input because they might need to check the `FROM` for additional information, for instance they must know to which original tables certain attributes belong.

```

1: Input: C: ttid, D: set of ttids, Q: MTSQL query
2: Output: SQL query
3: function REWRITEQUERY(C, D, Q)
4:   new-select ← rewriteSelect(C, D, Q)
5:   new-from ← rewriteFrom(C, D, Q.from())
6:   new-where ← rewriteWhere(C, D, Q)
7:   new-group-by ← rewriteGroupBy(C, D, Q.groupBy())
8:   new-order-by ← rewriteOrderBy(C, D, Q.orderBy())
9:   new-having ← rewriteHaving(C, D, Q.having())
10:  return new Query (new-select, new-from, new-where,
    new-group-by, new-order-by, new-having)

```

Algorithm 1: Canonical Query Rewrite Algorithm

In the following, we will look at the rewrite functions for the different SQL clauses. Because of space constraints, we only provide the high-level ideas and illustrate them with suitable minimal examples. However, we strongly encourage the interested reader to check-out the Haskell code [2] which in fact almost reads like a mathematical definition of the rewrite algorithm.

SELECT The rewritten `SELECT` clause has to present every attribute *a* in *C*’s format, which, if *a* is convertible, is achieved by two calls to the conversion function pair of *a* as can be seen in the examples of Listing 10 where `-->` simply denotes rewriting. If *a* is part of compound expression (as in line 6), it has to be converted before the functions (in that case `AVG`) are applied. Note that in order to make a potential super-query work correctly, we also rename the result of the conversion, either by the new name that it got anyway (as in line 6) or by the name that it had before (as in line 3). Rewriting a star expression (line 9) in the uppermost query also needs special attention, in order not to provide the client with confusing information, like *ttids* which should stay invisible.

```

1 -- Rewriting a simple select expression:
2 SELECT E_salary FROM Employees; -->
3 SELECT currencyFromUniversal(currencyToUniversal(E_salary, ttid)
  , C) as salary FROM Employees;
4 -- Rewriting an aggregated select expression
5 SELECT AVG(E_salary) as avg_sal FROM Employees; -->
6 SELECT AVG(currencyFromUniversal(currencyToUniversal(E_salary,
  ttid), C)) as avg_sal FROM Employees;
7 -- Rewriting star expression, hiding irrelevant info
8 SELECT * FROM Employees; -->
9 SELECT E_name, E_salary, E_age FROM Employees;

```

Listing 10: Examples for Rewriting `SELECT` clause

WHERE There are essentially three steps that the algorithm has to perform in order to create a correctly rewritten `WHERE` clause (as shown in Listing 11). First, conversion functions have to be

added to each convertible attribute in each predicate in order make sure that comparisons are executed in the correct (client) format (lines 2 to 6). This happens the same way as for a SELECT clause. Notably, all constants are always in C 's format because it is C who asks the query. Second, for every predicate involving two or more tenant-specific attributes, additional predicates on $ttid$ have to be added (line 9), unless if the attributes are part of the same table, which means they are owned by the same tenant anyway. Predicates that contain `tenant-specific` together with other attributes cause the entire query to be rejected as was required in Section 2.4.2. Last, but not least, for every base table in the FROM clause, a so-called D-filter has to be added to the WHERE clause (line 12). This filter makes sure that only the relevant data (data that is owned by a tenant in D') gets processed.

```

1 -- Comparison with a constant:
2 .. FROM Employees WHERE E_salary > 50K -->
3 .. WHERE currencyFromUniversal(currencyToUniversal(E_salary,ttid
   ),C) > 50K) ..
4 -- General comparison:
5 .. FROM Employees E1, Employees E2 WHERE E1.E_salary > E2.
   E_salary -->
6 .. WHERE currencyFromUniversal(currencyToUniversal(E1.E_salary,
   E1.ttid),C) > currencyFromUniversal(currencyToUniversal(E1.
   E_salary,E1.ttid),C) ..
7 -- Extend with predicate on ttid
8 .. FROM Employees, Roles WHERE E_role_id = R_role_id -->
9 .. FROM Employees, Roles WHERE E_role_id = R_role_id AND
   Employees.ttid = Roles.ttid ..
10 -- Adding D-filters for D' = {3,7}
11 .. FROM Employees E, Roles R .. -->
12 .. WHERE E.ttid IN (3,7) AND R.ttid IN (3,7) ..

```

Listing 11: Examples for Rewriting WHERE clause

FROM All tables referred by the FROM clause are either base tables or temporary tables derived from a sub-query. Rewriting the FROM clause simply means to call the rewrite algorithm on each referenced sub-query as shown in Algorithm 2. A FROM table might also contain a JOIN of two tables (sub-queries). In that case, the two sub-queries are rewritten and then the join predicate is rewritten in the exact same way like any WHERE.

Notably, this algorithm preserves the desired invariant for (sub-) queries: the result of each sub-query is in client format and filtered according to D' , and, due to the rewrite of the SELECT and the WHERE clause of the current query, base tables, as well as joins, are also presented in client format and filtered by D . We conclude that the result of the current query therefore also preserves the invariant.

```

1: Input:  $C$ :  $ttid$ ,  $D$ : set of  $ttids$ ,
2:  $FromClause$ : MTSQL FROM clause
3: Output: SQL FROM clause
4: function REWRITEFROM( $C, D, FromClause$ )
5:    $res \leftarrow \text{extractBaseTables}(FromClause)$ 
6:   for all  $q \in \text{extractSubQueries}(FromClause)$  do
7:      $res \leftarrow res \cup \{ \text{rewriteQuery}(C, D, q) \}$ 
8:   for all  $(q_1, q_2, cond) \in \text{extractJoins}(FromClause)$  do
9:      $q'_1 \leftarrow \text{rewriteQuery}(C, D, q_1)$ 
10:     $q'_2 \leftarrow \text{rewriteQuery}(C, D, q_2)$ 
11:     $cond' \leftarrow \text{rewriteWhere}(C, D, cond)$ 
12:     $res \leftarrow res \cup \{ \text{createJoin}(q'_1, q'_2, cond') \}$ 
return  $res$ 

```

Algorithm 2: Rewrite Algorithm for FROM clause

GROUP-BY, ORDER-BY and HAVING HAVING and GROUP-BY clauses are basically rewritten the same way like the expressions in the SELECT clause. Some DBMSs might throw a

warning stating that grouping by a comparable attribute a is ambiguous because the way we rewrite a in the WHERE clause and rename it back to a , we could actually group by the original or by the converted attribute a . However, the SQL standard clearly says that in such a case, the result should be grouped by the outer-more expression, which is exactly what we need. ORDER-BY clauses need not be rewritten at all.

SET SCOPE Simple scopes do not have to be rewritten at all. The FROM and WHERE clause of a complex scope are rewritten the same way as in a sub-query. In order to make it a valid SQL query, the rewrite algorithm adds a SELECT clause that projects on the respective $ttids$ as shown in Listing 12.

```

1 SET SCOPE = "FROM Employees WHERE E_salary > 180K"; -->
2 SELECT ttid FROM Employees WHERE currencyFromUniversal(
   currencyToUniversal(E_salary,ttid),C) > 180K;

```

Listing 12: Rewriting a complex SCOPE expression

3.2 Algorithm Correctness

PROOF. We prove the correctness of the canonical rewrite algorithm with respect to Section 2.4 by induction over the composable structure of SQL queries and by showing that the desired invariant (the result of each sub-query is filtered according to D' and presented in the format required by C) holds: First, as a base, we state that adding the D-filters in the WHERE clause and transforming the SELECT clause to client format for every base table in each lowest-level sub-query ensures that the invariant holds. Next, as an induction step, we state that the way how we rewrite the FROM clause, as it was described earlier, preserves that property. The top-most SQL query is nothing but a composition of sub-queries (and base tables) for which the invariant holds. This means that the invariant holds for the entire query, which is hence guaranteed to deliver the correct result. \square

3.3 Rewriting DDL and DML Statements

Rewriting DDL and DML statements is very similar to rewriting queries, in fact, predicates are rewritten in exactly the same way. The remaining questions are how to rewrite *tenant-specific* referential integrity constraints (using check constraints) and how to apply DML statements to a dataset $D \neq \{C\}$ (by executing the proper value transformations separately for each client). While the semantics and the intuition how to implement them should be clear, we refer again to the extended version of this paper [15] for further examples and explanations.

4 OPTIMIZATIONS

As we have seen, there is a canonical rewrite algorithm that correctly rewrites MTSQL to SQL. However, we will show in Section 5 that the rewritten queries often execute very slowly on the underlying DBMS. The main reason for this is that the pure rewritten queries call two conversion functions on every transformable attribute of every record that is processed, which is extremely expensive. Luckily, the execution costs can be reduced dramatically when applying the optimization passes that we describe in this section. As we assume the underlying DBMS to optimize query execution anyway, we focus on optimizations that a DBMS query optimizer cannot do (because it needs MT-specific context) or does not do (because an optimization is not frequent enough outside the context of MTBase). We differentiate between *semantic optimizations*, which are always applied because they never

make a query slower and *cost-based* optimizations which are only applied if the predicted costs are smaller than in the original query.

```

1 -- dropping D-filter if D is the empty scope:
2 SELECT E_age FROM Employees WHERE E_ttid IN (1,2); -->
3 SELECT E_age FROM Employees;
4 -- dropping ttid from join predicate if |D| = 1:
5 SELECT E_age, R_name FROM Employees, Roles WHERE E_role_id =
   R_role_id AND E_ttid = R_ttid AND E_ttid IN (2) AND R_ttid
   IN (2); -->
6 SELECT E_age, R_name FROM Employees, Roles WHERE E_role_id =
   R_role_id AND E_ttid IN (2) AND R_ttid IN (2);
7 -- dropping conversion functions if D = {C}:
8 SELECT currencyFromUniversal(currencyToUniversal(E_salary,
   E_ttid),0) AS E_salary FROM Employees; -->
9 SELECT E_salary FROM Employees;

```

Listing 13: Examples for trivial semantic optimizations

4.1 Trivial Semantic Optimizations

There are a couple of special cases for C and D that allow to save conversion function calls, join predicates and/or D -filters. First, if D includes all tenants, that means that we want to query all data and hence D -filters are no longer required as shown in line 3 of Listing 13. Second, as shown in line 6, if $|D| = 1$, we know that all data is from the same tenant, which means that including $ttid$ in the join predicate is no longer necessary. Last, if we know that a client queries her own data, i.e. $D = \{C\}$ corresponds to the default scope, we know that even convertible attributes are already in the correct format and can hence remove the conversion function calls (line 9).

4.2 Other Semantic Optimizations

There are a couple of other semantic optimizations that can be applied to rewritten queries. While *client presentation push-up* and conversion push-up minimize the number of conversions by delaying conversion to the latest possible moment, *aggregation distribution* takes into account specific properties of conversion functions (as mentioned in Section 2.2.2). If conversion functions are UDFs written in SQL it is also possible to inline them. This typically gives queries an additional speed up.

```

1 -- before optimization
2 SELECT Dom.name1, Dom.sal1 as sal, COUNT(*) as cnt FROM (
3   SELECT E1.name as name1, currencyFromUniversal(
4     currencyToUniversal(E1.E_salary, E1.E_ttid), C) as sal1
5   FROM Employees E1, Employees E2
6   WHERE currencyFromUniversal(currencyToUniversal(E1.E_salary,
7     E1.E_ttid), C) >
8     currencyFromUniversal(currencyToUniversal(E2.E_salary, E2.
9     E_ttid), C)
10 ) as Dom GROUP BY Dom.name1, sal, cnt ORDER BY cnt;
11 -- after optimization
12 SELECT Dom.name1, currencyFromUniversal(Dom.sal1, C) as sal,
13   COUNT(*) as cnt FROM (
14   SELECT E1.name as name1, currencyToUniversal(E1.E_salary, E1.
15     E_ttid) as sal1
16   FROM Employees E1, Employees E2
17   WHERE currencyToUniversal(E1.E_salary, E1.E_ttid) >
18     currencyToUniversal(E2.E_salary, E2.E_ttid)
19 ) as Dom GROUP BY Dom.name1, sal, cnt ORDER BY cnt;

```

Listing 14: Example for client presentation push-up

4.2.1 Client Presentation and Conversion Push-Up. As conversion function pairs are equality-preserving, it is possible in some cases to defer conversions to later, for example to the outermost query in the case of nested queries. While *client presentation push-up* converts everything to universal format and defers conversion to client format to the outermost SELECT clause, *conversion push-up* pushes this idea even more by also delaying the conversion to universal format as much as possible. Both optimizations are beneficial if the delaying of conversions allows the query execution engine to evaluate other (less expensive) predicates first. This means that, once the data has to be converted, it is already

more filtered and therefore the overall number of (expensive) conversion function calls becomes smaller (or, in the worst case, stays the same). Naturally, if we delay conversion, this also means that we have to propagate the necessary *ttids* to the outer-more queries and keep track of the current data format.

Listing 14 shows a query that ranks employees according to the fact how many salaries of other employees their own salary dominates. With *client presentation push-up*, salaries are compared in universal instead of client format, which is correct because of the equality-preserving property (c.f. Corollary 1) and saves half of the function calls in the sub-query.

Conversion push-up, as shown in Listing 15, reduces the number of function calls dramatically: First, as it only converts salaries in the end, salaries of employees aged less than 45 do not have to be considered at all. Second, the WHERE clause converts the constant (100K) instead of the attribute (E_salary). As the outcome of conversion functions is immutable (c.f. Section 2.2.2) and C is also constant, the conversion functions have to be called only once per tenant and are then cached by the DBMS for the rest of the query execution, which becomes much faster as we will see in Section 5.

```

1 -- before optimization
2 SELECT AVG(X.sal) FROM (
3   SELECT currencyFromUniversal(currencyToUniversal(E_salary,
4     E_ttid), C) as sal
5   FROM Employees WHERE E_age >= 45 AND
6     currencyFromUniversal(currencyToUniversal(E_salary, E_ttid), C)
7     > 100K) as X;
8 -- after optimization
9 SELECT AVG(currencyFromUniversal(currencyToUniversal(X.sal, X.
10   sal_ttid),C)) FROM (
11   SELECT E_salary as sal, E_ttid as sal_ttid
12   FROM Employees WHERE E_age >= 45 AND
13     E_salary > currencyFromUniversal(currencyToUniversal(100K,
14     E_ttid), C) as X);

```

Listing 15: Example for conversion push-up

4.2.2 Aggregation Distribution. Many analytical queries contain aggregation functions, some of which aggregate on *convertible* attributes. The idea of aggregation distribution is to aggregate in two steps: First, aggregate per tenant in that specific tenant format (requires no conversion) and second, convert intermediary results to universal (one conversion per tenant), aggregate those and convert the final result to client format (one additional conversion). This simple idea reduces the number of conversion function calls for N records and T different data owners of these records from $(2N)$ to $(T + 1)$. This is significant because T is typically much smaller than N (and cannot be greater).

Compared to pure *conversion push-up*, which works for any conversion function pair, the applicability of *aggregation distribution* depends on further algebraic properties of these functions. Gray et al. [24] categorize numerical aggregation functions into three categories with regard to their ability to distribute: *distributive* functions, like COUNT, SUM, MIN and MAX distribute with functions F (for partial) and G (for total aggregation). For COUNT for instance, F is COUNT and G is SUM as the total count is the sum of all partial counts. There are also *algebraic* aggregation functions, e.g. AVG, where the partial results are not scalar values, but tuples. In the case of AVG, this would be the pairs of a partial sums and partial counts because the total average can be computed from the sum of all sums, divided by the sum of all counts. Finally, *holistic* aggregation functions cannot be distributed at all.

We would like to extend the notion of Gray et al. [24] and define the *distributability of an aggregation function a with respect to a conversion function pair $(from, to)$* . Table 2 shows some examples for different aggregation and conversion functions. First

	$to(x) = c \cdot x$	$to(x) = a \cdot x + b$	$to = \text{order-preserving}$	$to = \text{equality-preserving}$
COUNT	✓	✓	✓	✓
MIN	✓	✓	✓	✗
MAX	✓	✓	✓	✗
SUM	✓	✓	✗	✗
AVG	✓	✓	✗	✗
<i>Holistic</i>	✗	✗	✗	✗

Table 2: Distributability of different aggregation functions over different categories of conversion functions

of all, we want to state that, as all conversion functions have scalar values as input and output, they are always fully-COUNT-preserving, which means that COUNT can be distributed over all sorts of conversion functions. Next, we observe that all *order-preserving functions* preserve the minimum and the maximum of a given set of numbers, which is why MIN and MAX distribute over the first three categories of conversion functions displayed in Table 2. We further notice that if *to* (and consequently also *from*) is a multiplication with a constant (first column of Table 2), *to* is fully-MIN-, fully-MAX- and fully-SUM-preserving, which is why these aggregation functions distribute. As SUM and COUNT distribute, AVG, an algebraic function, distributes as well.

Finally looking at the second column of Table 2, we see that even linear functions are SUM- and AVG-preserving. To see why, we can think about computing the average over all tenants as a weighted average of partial (per-tenant) averages for AVG and multiply these partial averages with the partial counts to reconstruct the total sum [15, Appendix B].

```

1 -- before optimization
2 SELECT SUM(currencyFromUniversal(currencyToUniversal(E_salary,
   E_ttid), C)) as sum_sal FROM Employees
3 -- after optimization
4 SELECT currencyFromUniversal(SUM(t.E_partial_salary), C) as
   sum_sal FROM (SELECT currencyToUniversal(SUM(E_salary),
   E_ttid) as E_partial_salary FROM Employees GROUP BY E_ttid)
   as t;

```

Listing 16: Example for conversion function distribution

We conclude this subsection by observing that the conversion function pair for *phone format* (c.f. Listings 4 and 5) is not even *order-preserving* and does therefore not distribute while the pair for *currency format* (c.f. Listings 6 and 7) distributes over all standard SQL aggregation functions. An example of how this can be used is shown in Listing 16.

```

1 -- before optimization
2 SELECT currencyFromUniversal(currencyToUniversal(E_salary,
   E_ttid), C) as E_salary FROM Employees
3 -- after optimization
4 SELECT (C1.CT_from_universal * C2.CT_to_universal * E_salary) as
   E_salary
5 FROM Employees, Tenant T1, Tenant T2, CurrencyTransform1,
   CurrencyTransform2
6 WHERE T1.T_tenant_key = C AND T1.T_currency_key =
   CurrencyTransform1.CT_currency_key AND
7 T2.T_tenant_key = E_ttid AND T2.T_currency_key =
   CurrencyTransform2.CT_currency_key

```

Listing 17: Example for function inlining

4.2.3 Function Inlining. As explained in Section 2.2.2, there are several ways how to define conversion functions. However, if they are defined as a SQL statement (potentially including lookups into meta tables), they can be directly inlined into the rewritten query in order to save calls to UDFs. Function inlining typically also enables the query optimizer of the underlying DBMS to optimize much more aggressively. In WHERE clauses, conversion functions could simply be inlined as sub-queries, which, however often results in sub-optimal performance as calling a sub-query on each conversion is not much cheaper than calling the corresponding UDF. For SELECT clauses, the SQL standard does anyway not allow to inline as a sub-query as this can result in attributes

not being contained neither in an aggregate function nor in the GROUP BY clause, which is why most commercial DBMS reject such queries (while PostgreSQL, for instance executes them anyway). This is why the proper way to inline functions is by using a join as shown in Listing 17. Our results in Section 5 suggest that function inlining, though producing complex-looking SQL queries, results in very good query execution performance.

It is important to mention that function inlining should only happen after the other semantic optimization passes because these other passes are able to *reduce the number* of required UDF calls, while function inlining can only make a UDF call *faster*. Furthermore, it is important to understand that, while some clever query optimizers do indeed inline UDF calls already, none of the query optimizers that we looked at seems to perform *client presentation* and *conversion push-up*, let alone *aggregation distribution*, despite the fact that the foundation for these transformations [24, 28] have been established already more than 20 years ago.

5 EXPERIMENTS AND RESULTS

This section presents the evaluation of MTBase using an extension from the well-known TPC-H benchmark [43], called *MT-H* [15]. We first evaluated the benefits of different optimization steps from Section 4 and found that the combination of all of these steps brings the biggest benefit. Second, we analyzed how MTBase scales with an increasing number of tenants. With all optimizations applied and for a dataset of 100 GB on a single machine, MTBase scales up to thousands of tenants with very little overhead. We also validated result correctness as explained in Section 5.1 and can report only positive results.

5.1 MT-H Benchmark

MT-H uses the same database schema as TPC-H, but considers the Customer, Order, and Lineitem tables *tenant-specific* and the remaining tables *global*. Attributes C_acctbal, O_totalprice, and L_extendedprice are considered *convertible* with respect to the conversion functions of Listings 6 and 7 and C_phone with respect to Listings 4 and 5. While C_custkey, O_orderkey, O_custkey, L_orderkey are *tenant-specific*, all remaining attributes are *comparable*. A detailed description on this benchmark, including the validation of query results, can be found in our technical report [15].

5.2 Setup

In our experiments, we used the following two setups: The first setup is a PostgreSQL 9.6 Beta installation, running on Debian Linux 4.1.12 on a 4x16 Core AMD Opteron 6174 processor with 256 GB of main memory. The second installation runs a commercial database (which we will call *System C*) on a commercial operating system and on the same processor with 512 GB of main memory. Although both machines have enough secondary storage capacity available, we decided to configure both database management systems to use in-memory backed files in order to achieve the best performance possible. Moreover, we configured the systems to use all available threads, which enabled *intra-query parallelism*.

5.3 Workload and Methodology

As the MT-H benchmark has a lot of parameters and in order to make things more concrete, we worked with the following two scenarios: *Scenario 1* handles the data of a business alliance of a couple of small to mid-sized enterprises, which means there are 10 tenants with $sf = 1$ and each of them owns more or less

Table 5: Response times [sec] of 22 TPC-H queries for MTBase-on-PostgreSQL with $sf = 1$, $T = 10$, $\rho = \text{uniform}$, $C = 1$, $D = \{1, 2, \dots, 10\}$, for different levels of optimizations, versus TPC-H with $sf = 1$

the same amount of data ($\rho = \text{uniform}$). *Scenario 2* simulates the HDC use case [27] and hence needs to be is a huge database ($sf = 100$) of medical records coming from thousands of tenants, like hospitals and private practices. Some of these institutions have vast amounts of data while others only handle a couple of patients ($\rho = \text{zipf}$). A research institution wants to query the entire database ($D = \{1, 2, \dots, T\}$) in order to gather new insights for the development of a new treatment. We looked at this scenario for different numbers of T .

In order to evaluate the overhead of *cross-tenant query processing* in MTBase compared to single-tenant query processing, we also measured the standard TPC-H queries with different scaling factors. When D was set to all tenants, we compared to TPC-H with the same scaling factor as MT-H. For the cases where D had only one tenant (out of ten), we compared with TPC-H with a scaling factor ten times smaller.

Every query run was repeated three times in order to ensure stable results. We noticed that three runs are needed for the response times to converge (within 2%). Thus we always report the last measured response time for each query with two significant digits.

All experiments were executed with both setups (PostgreSQL and *System C*). Whereas the major findings were the same on both systems, PostgreSQL optimizes conversion functions (UDFs) much better by caching their results. *System C*, on the other hand does not allow UDFs to be defined as deterministic and hence cannot cache conversion results. This eliminates the effect of *conversion push-up* when applied to comparison predicates where we convert the constant instead of the attribute (c.f. Listing 15). This being said, the rest of this section only reports results on PostgreSQL while we encourage the interested reader to also consult our additional results [15] to confirm that the main conclusions drawn from the PostgreSQL experiments generalize.

opt level	optimization passes
canonical	none
o1	trivial optimizations
o2	o1 + client presentation push-up + conversion push-up
o3	o2 + conversion function distribution
o4	o3 + conversion function inlining
inl-only	o1 + conversion function inlining

Table 6: Different optimization levels for evaluation

5.4 Benefit of Optimizations

In order to test the benefit of the different combinations of optimizations applied, we tested *Scenario 1* with different optimization levels as shown in Table 6. From *o1* to *o4* we added optimizations incrementally, while the last optimization level (*inl-only*) only applied trivial optimizations and function inlining in order to test whether the other optimizations are useful at all.

Table 3 shows the MT-H queries for different optimization levels and *Scenario 1* ($sf = 1$, $T = 10$) where client 1 queries her own data. As we can see, in that case, applying trivial optimizations in *o1* is enough because these already eliminate all conversion functions and joins and only the D-filters remain. Executing these filters seems to be very inexpensive because most response times of the optimized queries are close to the baseline, TPC-H with $sf = 0.1$. Queries 2, 11 and 16 however, take roughly ten times longer than the baseline. This is not surprising when taken into account that these queries only operate on *shared tables* which have ten times more data than in TPC-H. The same effect can be observed in Q09 where a significant part of the joined tables are shared.

Table 4 shows similar results, but for $D = 2$, which means that now conversion functions can no longer be optimized away.

Figure 4: Response times (relative to TPC-H) of *o4* and *inlining-only* optimization levels for selected MT-H queries, $sf = 100$, T scaling from 1 to 100,000 on a log-scale, MTBase-on-PostgreSQL

While most of the queries show a similar behaviour than in the previous experiment, for the ones that involve a lot of conversion functions (i.e. queries 1, 6 and 22), we see how the performance becomes better with each optimization pass added. We also notice that while function inlining is very beneficial in general, it is even more so when combined with the other optimizations.

Finally, Table 5 shows the results where we query all data, i.e. $D = \{1, 2, \dots, 10\}$. This experiment involves even more conversion functions from all the different tenant formats into universal. In particular, when looking again at queries 1, 6 and 22, we observe the great benefit of *conversion function distribution* (added with optimization level *o3*), which, in turn, only works as great in conjunction with *client and conversion function push-up* because aggregation typically happens in the outermost query while conversion happens in the sub-queries. Overall, *o4*, which contains all optimization passes that MTBase offers, is the clear winner.

5.5 Cross-Tenant Query Processing at Large

In our final experiment, we evaluated the cost of *cross-tenant query processing* up to thousands of tenants. More concretely, we measured the response time of conversion-intensive MT-H queries (queries 1, 6 and 22) for a varying number of tenants between 1 and 100,000, for a large dataset where $sf = 100$ and for the best optimization level (*o4*) as well as for *inlining-only*. The obtained results were then compared to plain TPC-H with $sf = 100$, as shown in Figure 4. First of all, we notice that the cost overhead compared to *single-tenant query-processing* (TPC-H) stays below a factor of 2 and in general increases very moderately with the number of tenants. An interesting artifact can be observed for query 22 where MT-H for one tenant executes faster than plain TPC-H. The reason for this is a sub-optimal optimization decision in PostgreSQL: one of the most expensive parts of query 22, namely to find customers with a specific country code, is executed with a parallel scan in MT-H while no parallelism is used in the case of TPC-H.

6 RELATED WORK

MTBase builds heavily on and extends a lot of related work. This section gives a brief summary of the most prominent lines of work that influenced our design.

Data Integration Data integration (DI) is generally about finding schema and data mappings between the original schemas of different data sources and a target schema specified by the client application [23, 25, 41]. As such, DI techniques are applicable to the entire spectrum of multi-tenant databases because even if tenants use different schemas or databases, these techniques can identify correlations and hence extract useful information. Our work embraces and builds on top of the latest DI work, solving

the DI problem very efficiently for a specific case (*SS* and *ST*). More concretely, we automatically determine join predicates from schema meta data and optimize conversion functions similar to those used in DI by thoroughly analyzing and exploiting their algebraic properties. In addition, instead of translating data into a specific client format (and update periodically), we convert it to any required client format efficiently and *just-in-time*.

Database Federation: DI is often combined with database federation [26, 31], which means that there exist small program modules (called *integrators*, *mediators* or simply *wrappers*) to map data from different sources (possibly not all of them SQL databases) into one common format. While data federation generalizes well across the entire spectrum of multi-tenant databases, maintaining such wrapper architectures is expensive, both in terms of code maintenance and update processing. Conversely, MTSQL enables cross-tenant query processing in a more efficient and flexible way in the context of *SS* and *ST* databases.

Data Warehousing: Another approach how data integration can happen is during extract-transform-load (ETL) operations from different (OLTP) databases into a data warehouse [29]. Data warehouses have the well-known drawbacks that there are costly to maintain and that the data is possibly outdated [10, 14, 37]. Meanwhile, MTBase was specifically designed to work well in the context of integrated OLTP/OLAP systems, also known as *hybrid transaction-analytical processing (HTAP)* systems, and could therefore be advocated as *in-situ* or *just-in-time* data integration. Another interesting approach to *just-in-time*, respectively *on-demand* data integration, are *lenses* [45] which allow to speed up ETL processes by lowering the result accuracy to the specific level required by the application.

Shared-resources (SR) systems: In related work, this approach is also often called *database virtualization* or *database as a service (DaaS)* when it is used in the cloud context. Important lines of work in this domain include (but are not limited to) *SqlVM/Azure SQL DB* [20, 36], *RelationalCloud* [35], *SAP-HANA* [42], *Snowflake* [18] and *Oracle’s multitenant container database (CDB)* [40], most of which is well summarized in [22]. *MTBase* complements these systems by providing a platform that can accommodate more, but typically smaller tenants.

Shared-databases (SD) systems: This approach, while appearing in the *spectrum of multi-tenant databases* by Chong et al. [17], is rare in practice. *Sql Azure DB* [20] seems to be the only product that has an implementation of this approach. However, even Microsoft strongly advises against using SD and instead recommends to either use SR or ST [34].

Shared-tables (ST) systems: Work in that area includes Salesforce [44], Apache Phoenix [9], FlexScheme [11, 12] and Azure SQL Database [34]. Their common idea, as in *MTSQL*, is to use an invisible *tenant identifier* to identify which records belong to which tenant and rewrite SQL queries in order to include filters on this `ttid`. *MTSQL* extends these systems by providing the necessary features for cross-tenant query processing.

Privacy/Confidentiality: Clearly, *cross-tenant query processing* almost immediately raises the question of data confidentiality. In the case of the HDC, for instance, patients might consent to their data being used in aggregated analytics, but they most certainly would not want sensitive, personal information, like their social security number, to appear in any report. While it is out of the scope of this paper to thoroughly discuss data confidentiality in a multi-tenant system, this work establishes proper syntax and semantics for *cross-tenant query processing*, which lays the ground for building appropriate encryption mechanisms [16, 21] atop as is sketched in our technical report [15].

UDFs and Complex Expressions: *Oracle MLE* [39] is a system that allows for highly-optimized execution of user-defined functions, which makes it a promising candidate to further investigate optimization of *conversion functions*. For instance, we would like to look at optimizing complex expressions, containing several nested user-defined function calls, as a whole.

7 CONCLUSION

This paper presented *MTSQL*, a new language to address *cross-tenant query processing* in multi-tenant databases. *MTSQL* extends SQL with multi-tenancy-aware syntax and semantics, which allows to efficiently optimize and execute cross-tenant queries in *MTBase*. *MTBase* is an open-source system that implements *MTSQL*. At its core, it is an *MTSQL*-to-SQL rewrite middleware sitting between a client and any multi-tenant DBMS of choice. The performance evaluation with a benchmark adapted from TPC-H showed that *MTBase* (on top of PostgreSQL) can scale to thousands of tenants at very low overhead and that our proposed optimizations to *cross-tenant queries* are highly effective.

In the future, we plan to further analyze the interplay between the *MTBase* query optimizer and its counter-part in the DBMS execution engine in order to assess the potential of cost-based optimizations. We also want to study conversion functions that vary over time and investigate how *MTSQL* can be extended to temporal databases. Moreover, we would like to look more into the privacy issues of multi-tenant databases, in particular how to enable *cross-tenant query processing* if data is encrypted.

ABSTRACT

The plethora of graphs and relational data give rise to many interesting graph-relational queries in various domains, e.g., finding related proteins retrieved by a relational subquery in a biological network. The maturity of RDBMSs motivated academia and industry to invest efforts in leveraging RDBMSs for graph processing, where efficiency is proven for vital graph queries. However, none of these efforts process graphs natively inside the RDBMS, which is particularly challenging due to the impedance mismatch between the relational and the graph models. In this paper, we propose to manage graphs as first-class citizens inside the relational engine. We realize our approach inside *VoltDB* [6], an open-source in-memory relational database, and name this realization GRFusion. The SQL and query engine of GRFusion are empowered to declaratively define graphs and execute cross-data-model query plans acting on graphs and relations, resulting in up to four orders-of-magnitude in query-time speedup w.r.t. state-of-the-art approaches.

1 INTRODUCTION

Graphs are ubiquitous in various application domains, e.g., social networks, road networks, biological networks, and communication networks [3, 8, 9, 12]. The data of these applications can be viewed as graphs, where the vertexes and the edges have relational attributes [46], or as traditional relational data with latent graph structures [51]. Applications would issue queries that consult the topology of the graphs along with the data associated with the vertexes and the edges or other data sources (e.g., relational tables in an RDBMS). For instance, a user may be interested to find the shortest path over a road network while restricting the search to certain types of roads, e.g., avoiding toll roads.

In an RDBMS, the filtering predicates can be expressed as relational predicates, and they may reference relational tables that have indirect relation with the queried graphs. We refer to these queries as graph-relational queries (or *G+R* queries, for short). *G+R* queries have two main ingredients: 1) graph operations, e.g., shortest-path computation, and 2) relational predicates or relational sub-queries. For example, selecting specific users from relational tables to find the nearest hospitals using shortest-path evaluation on top of a road-network.

As RDBMSs are pervasive and mature, various approaches for using an RDBMS to manage graph data have been proposed, e.g.,

Grail [25] and Aster [45]. The literature has two main approaches that share the idea of building an application on top of an RDBMS to support graphs without modifying the internals of the RDBMS. We refer to these approaches as *Native Relational-Core* and *Native Graph-Core*. In this paper, we propose and investigate a hybrid approach that we term *Native G+R Core* that exploits the strengths of the former two approaches, and we realize our approach inside VoltDB [7, 10].

The *Native Relational-Core* approach (e.g., as in SQLGraph [46] and Grail [25]) embeds a graph inside of relational tables of specific schema. Then, an application on top of the RDBMS is built to translate specific types of graph queries into SQL statements for the RDBMS to execute. For example, Grail can translate shortest-path queries to procedural SQL [25], while SQLGraph translates Gremlin queries with some restrictions [5] into SQL queries [46]. Figure 1(a) illustrates the general architecture of the *Native Relational-Core* approach. Although many graph queries and algorithms are hard to translate into SQL statements, tools can be developed to automate the translation. However, the main issue of the *Native Relational-Core* approach is that the graph operations are evaluated by a sequence of relational operations (e.g., self-joins) that may be more expensive than traversing a native graph representation. Moreover, the *Native Relational-Core* approach does not guarantee an easy-to-comprehend relational schema of the embedded graphs in an RDBMS, e.g., the storage-optimized relational schema generated automatically by SQLGraph is hard for users to understand and write ad-hoc graph-relational queries [46].

The second approach, namely *Native Graph-Core* (e.g., as in Ringo [38], GraphGen [51, 52]), assumes that graphs are already stored in an RDBMS, where an application on top of the RDBMS is built to extract these graphs to analyze them outside the realm of the RDBMS. This approach follows the same philosophy as that of specialized graph databases, where an RDBMS has nothing to do with query execution. Figure 1(b) illustrates the general architecture of the *Native Graph-Core* approach. Notice that a graph in the *Native Graph-Core* requires re-extraction if the relational tables storing the graph in the RDBMS are updated. Moreover, users cannot issue declarative graph-relational queries that reference both the extracted graphs and any other relational data in the RDBMS. One solution to allow graph-relational queries in the *Native Graph-Core* approach is to build another layer that queries both the RDBMS and the extracted graph. This solution is similar to that of Teradata Aster [45], where a data movement fabric and two different query executors (i.e., a relational executor and a graph executor) are used in processing graph-relational queries. However, integrating the results from the graph and the relational executors imposes additional overhead. In summary, the

Native Relational-Core and the *Native Graph-Core* approaches use a vanilla RDBMS, where graphs are not natively recognized by the RDBMS. However, if the necessary layers of the RDBMS are modified to manage graphs as first-class citizens, processing and managing graphs will be more efficient.

In this paper, we investigate a third approach, namely *Native G+R Core*, where graphs are recognized as first-class citizens inside an RDBMS. We address the impedance mismatch between the graph and the relational model, and we realize the *Native G+R Core* approach in a centralized version of VoltDB [7, 10], the open-source implementation of the H-Store in-memory relational DBMS [32]. In-memory data management witnessed early academic and industrial contributions, where the current affordability of large main-memory hardware motivated several and diverse research efforts [14, 15, 23, 30, 33, 35, 36, 38, 39, 44, 49–51, 53].

We refer to our realization of this approach as GRFusion. The main idea of GRFusion is to natively process graphs inside an RDBMS by combining the *Native Relational-Core* and the *Native Graph-Core* approaches under the same umbrella. GRFusion realizes this idea by separating the graph topology from the relational data associated with the vertexes and the edges, and by proposing graph operators to process the graph topology inside the RDBMS, where the graph operators seamlessly co-exist with other relational operators in the same query execution pipeline (or QEP, for short). A graph topology in GRFusion is realized as a native graph structure, where each vertex or edge has pointers to the relational tuples describing their attributes. Hence, a graph topology in GRFusion can be viewed as a traversal index of the relational tuples of the vertexes and the edges. In short, GRFusion presents cross-data-model QEPs, where the inputs to the QEPs can be either relational data or native graph structures.

Figure 1(c) illustrates the general idea of the *Native G+R Core* approach. First, the end-user provides a declarative statement to create graph views that are initialized from relational data, where a graph view is materialized as a new database object. Second, the user is allowed to query the graph views as well as other relational tables or views in the same query. Table 1 contrasts the *Native Relational-Core*, *Native Graph-Core*, and *Native G+R*

Core approaches. The objective of this paper is not to replace the specialized graph systems. However, the main objective is to empower the pervasive relational databases to support graph traversal queries natively and efficiently. Consequently, the relational-data owners can process important class of graph queries through their RDBMS systems without the cost and the overhead of migrating their data and manage it in a separate graph system. The contributions of this paper are as follows:

- Introducing graphs as native objects inside a relational database system, namely VoltDB (Section 3), where online graph updates are supported (Section 3.3).
- Allowing users to seamlessly query and operate on graphs and relations simultaneously and declaratively without leaving the realm of the relational database system (Section 4).
- Introducing graph operators for graph traversals (Section 5.1), and showing their ability to seamlessly co-exist with the relational operators to construct cross-data-model query execution pipelines (Section 5.2).
- Addressing the impedance mismatch between the graph model and the relational model (Section 5.3).
- Conducting an extensive performance study of GRFusion w.r.t. state-of-the-art systems, and reasoning about the benefits of processing graphs in a graph-native representation inside an RDBMS. We compare to SQLGraph, Grail, Neo4j, and Titan, where GRFusion achieves up to four orders-of-magnitude query-time speedup (Section 7).

2 OVERVIEW OF GRFUSION

In GRFusion, graphs are assumed to be initially stored in relations. In the simplest case, a relational table may have a row for each vertex, and another table may have a row for each edge. Also, the vertexes or the edges data can be obtained through a relational materialized view that joins or filters multiple relational tables. To allow flexibility, GRFusion provides the user with a declarative language to define and query graphs (see Figure 2). A graph is defined in GRFusion by what we term *graph views*. A *graph view* identifies the relational tables or the relational views that store

the attributes of the vertexes and edges, namely, the *vertexes relational-source*, and the *edges relational-source*, respectively. *Graph views* define a view of the relational data in the graph model and materializes the graph topology in main-memory in native graph data structures. The materialized graph topology has a *native graph representation* that holds pointers (e.g., tuple identifiers) to the relational data that describe the vertexes and the edges. The main idea behind materializing the graph topology is to empower the relational database engine with the ability to realize complex graph algorithms. Thus, GRFusion helps fill the gap between the relational model and the massive body of research that assumes a graph model. Listing 1 shows how a graph view is created in GRFusion from the relational sources of Figure 3, which is detailed in Section 3.1.

Once a graph view is defined, GRFusion allows the user to write pure graph queries, pure relational queries, or queries that mix both graph and relational operations. GRFusion’s query engine views the relational data in either the relational or the graph model according to the incoming query. In particular, the graph clauses in a query are mapped to graph operators in the QEP, where a graph operator accepts only graph representations as input. GRFusion allows the graph operators and the relational operators to co-exist in the same QEP, where the operator type determines the data model of viewing the data (i.e., graph views for the graph model, and relations for the relational model).

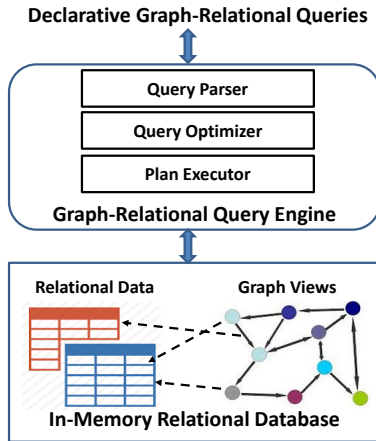

Figure 2: GRFusion’s architecture allows the query engine to process data in both the relational and the graph models.

3 GRAPHS AS DATABASE OBJECTS

As users can create tables in relational databases, they can also create materialized graph views in GRFusion as database objects. A graph view is created once as a singleton object, and can be referenced by multiple users and queries. In Section 3.1, we highlight how graph views are defined declaratively in GRFusion. Section 3.2 illustrates how the topology of a graph in GRFusion is decoupled from the graph data, and how they can be inter-linked. Because dynamic graphs are essential in many applications, the support for graph updates is addressed in Section 3.3.

3.1 Creating Graph Views

GRFusion has a declarative *Create Graph View* statement to create graph views initialized from relational data. The statement has four main objectives: (1) Identifying the name of the graph view to create, (2) Identifying and extracting the graph’s set of vertexes

Users			
uid	fName	lName	dob

Figure 3: A sample social-network in the relational model.

from the underlying relational sources, (3) Identifying and extracting the graph’s set of edges from the underlying relational sources, and (4) Materializing a native graph data structure in memory that reflects the graph topology based on adjacency-list structures. Notice that graph traversal operations can be performed efficiently over this native graph representation and is linked back to the corresponding relational data tuples that describe it. Notice further that the relational source can either be a table or a materialized relational-view because the graph data attributes for the edges and/or the vertexes can be constructed from multiple data sources.

Figure 3 illustrates how a graph view is created in GRFusion. Assume that the data of a social network is stored in the relational tables as in the figure. Tables *Users* and *Relationships* represent the vertexes and the edges of the social network, respectively. Each vertex or edge has an identifier in the relational tables. To illustrate, consider Listing 1 that shows an example of creating a graph view, namely the *SocialNetwork* graph view, in GRFusion from the relational sources in Figure 3. A vertex in the *SocialNetwork* graph has its Id from *Users.uid* and has the two attributes *lName* and *birthdate* that get their values from *Users.lName* and *Users.dob*, respectively. Similarly, Table *Relationships* defines the edges of the *SocialNetwork* graph, where the edge Id comes from *Relationships.relId*, the endpoints come from *Relationships.uid1* and *Relationships.uid2*, and the two edge attributes *sDate*, *relative* refer to Attributes *startDate*, *isRelative* of Table *Relationships*, respectively. For the graph view defined by the *Create Graph View* statement, if the set of vertexes is *V*, and the set of edges is *E*, then, the endpoints of an edge in *E* are constrained to be included in *V*.

Listing 1: A Social Network Graph View Example

```
CREATE UNDIRECTED GRAPH VIEW SocialNetwork
VERTEXES (ID = uid, lstName = lName,
  ↪ birthdate = dob) FROM Users
EDGES (ID = relId, FROM = uid1, TO = uid2,
  ↪ sDate = startDate, relative =
  ↪ isRelative) FROM Relationships
```

3.2 Decoupling the Graph Topology and the Graph Data

The *Create Graph View* statement updates the system catalog of GRFusion to store the definition of the graph view. Creating a graph view results in the materialization of the graph topology as a native graph structure in the main-memory managed by GRFusion (as a singleton object that multiple users and queries can reference). However, the attributes of the vertexes and the edges stored in the relational sources are not replicated in the native graph structure, and main-memory tuple pointers are used to link

Figure 4: A graph view materializes the topology and holds pointers to the relational data of the vertexes and the edges.

the graph topology to the relational sources. To illustrate, Figure 4 demonstrates how the graph topology is separated from the graph data (i.e., the relational attributes of the vertexes and the edges). As in Figure 4, each vertex or edge has a main-memory tuple pointer that points to the corresponding relational tuple storing the attributes of this vertex or edge. Notice that the design of GRFusion allows a vertex or edge in a graph topology to store multiple tuple-pointers if the relational sources are vertically partitioned (e.g., to support semistructured RDF data, where not all the vertexes or edges share the same set of attributes). Without loss of generality, we assume a single tuple pointer per vertex or edge as the focus is to explore the benefits of empowering an RDBMS with native graph-processing.

The graph topology follows the graph model, where the topology is represented physically as a graph data-structure based on adjacency-lists. The key idea behind this native graph representation is to allow for the efficient execution of graph traversals, where relational joins can be mitigated when traversing a graph. The reason is that materializing the topology of a graph view can be thought of as a traversal index, where each vertex, say V , is associated with the identifiers of both the outgoing edges and the incoming edges of V . Given a graph view, say GV , its topology can be constructed using a single pass over the relational sources defining the vertexes and the edges of GV .

Notice that there is a bi-directional linkage between the graph topology and the graph's corresponding relational data. To illustrate, let T be a relational tuple containing the attribute values of Vertex V . Using the `VertexId` attribute of T , GRFusion can locate Vertex V in the graph representation in $O(1)$ time using the hash map of the native graph structure. Also, using the tuple pointer associated with Vertex V in the graph data-structure, Tuple T can be located in $O(1)$ time. The benefit of separating the graph topology from the graph data is two-fold. First, the size of the graph view is not affected by the size of the graph data that can be very large in some cases. Second, the attributes of the vertexes and the edges in the relational sources can be easily updated without affecting the native graph representation.

3.3 Graph Updates

GRFusion supports *serializable* graph updates that affect the topology or the attributes stored in the relational sources. The topology is affected only when vertexes/edges are added or deleted. GRFusion relies on the design and the implementation of VoltDB to maintain pointers to the relational tuples on memory reallocations.

3.3.1 Graph-Data Updates. Updating the attribute data of an edge or vertex is straightforward as the attributes are stored in relations outside the native graph representation. Hence, these relational attributes can be updated directly. However, updating the `VertexId` and the `EdgId` attributes need special handling because these attributes are used for navigating from the relational store to the native graph structure (e.g., to probe path-traversal operators in a QEP as in Section 5). Although updating the identifiers are not common, GRFusion maintains the consistency of the identifiers in the graph representation when updating their corresponding attributes in the relational sources. Also, GRFusion maintains the referential integrity of the *edges relational-source* when updating a vertex identifier in the *vertexes relational-source*.

3.3.2 Graph-Topology Updates. GRFusion allows topological updates when the relational sources are either relational tables or a relational views selecting from a single table. GRFusion associates each relational source, say R , with the identifiers of the graph views that reference R . When inserting a new tuple into R , the transaction of the insertion statement updates the graph-view topology as part of the transaction (i.e., adding a new vertex or adding a new edge in the graph representation). Similarly, when deleting a vertex or edge, the deletion statement detects the graph views associated with R and updates the affected graph views accordingly as part of the deletion transaction. For example, if R is an *edges relational-source* for a graph view, say GV , the edge in GV corresponding to a deleted tuple is removed from GV .

4 THE PATHS QUERY CONSTRUCT

As graph traversal queries form a massive body of graph queries (e.g., reachability and shortest path queries [19, 24, 26, 42, 43, 47]), GRFusion extends the SQL language to declaratively find paths in graph views. GRFusion introduces the *PATHS* construct to query its graph views. For a graph view, say GV , GRFusion recognizes $GV.PATHS$ in the From clause of a select statement (as it is treated conceptually as a set of paths). Conceptually, this allows GRFusion to traverse and retrieve simple paths from GV that satisfy a path criteria (e.g., predicates on the attributes of the edges forming the path). In addition to $GV.PATHS$, GRFusion recognizes $GV.VERTEXES$, and $GV.EDGES$, to reference the vertexes, and the edges of GV , respectively. We focus on the $GV.PATHS$ construct as the other constructs are straightforward.

GRFusion models a path as an ordered list of edges, where each edge has a start and end vertexes. The edges and the vertexes of a path, say PS , can be indexed and referenced by relational predicates as follows:

- **PS.Edges[StartIndex..EndIndex].EdgeAttribute:** References an attribute of the edges starting from $StartIndex$ until $EndIndex$. A value of '*' for the $EndVertex$ placeholder indicates that all the edges starting from $StartIndex$ should satisfy the relational predicate.
- **PS.Vertexes[StartIndex..EndIndex].VertexAttribute:** References an attribute of the vertexes starting from $StartIndex$ until $EndIndex$. A value of '*' for the $EndVertex$ placeholder indicates that all the vertexes starting from $StartIndex$ should satisfy the relational predicate.

Observe that the aforementioned *EdgeAttribute*, and the *VertexAttribute* placeholders can refer to any attribute of the edges or the vertexes that have been defined at the time of creating Graph-view GV . In addition, each vertex in Path PS has two additional integral attributes, namely *FanIn* and *FanOut*. Also, Path PS allows

accessing to some path-specific properties, e.g., $PS.StartVertexId$ and $PS.Length$ refer to the identifier of the start vertex and the length of Path PS , respectively.

To illustrate how paths can be queried in GRFusion, consider Query Q_p in Listing 2. The From clause of Q_p specifies that the paths are being traversed from the SocialNetwork graph view, where the *vertexes relational-source* of the SocialNetwork graph is Relation *Users*. The query displays the last names of the friends of friends of all the users with Job = ‘Lawyer’. Conceptually, Q_p is evaluated by selecting the sub-graph, say G_{sub} , containing edges with start dates after ‘1/1/2000’. Using Sub-graph G_{sub} , GRFusion explores paths consisting of two edges that originate from the vertexes corresponding to lawyers in the social network. Notice that Listing 2 could use *SocialNetwork.VERTEXES* instead of *Users*. However, Listing 2 uses the *Users* relation to show how relational tables can be joined with the paths of a graph view. Notice that the details of the extended query language of GRFusion are not the main focus of this paper. However, we provide sample code snippets that are relevant to illustrating the evaluation of the graph-relational queries supported by GRFusion.

Listing 2: Friends-of-Friends Path Query Q_p

```
SELECT PS.EndVertex.lstName
FROM Users U, SocialNetwork.Paths PS
WHERE U.Job = 'Lawyer' AND PS.StartVertex.
  ↳ Id = U.uId AND PS.Length = 2 AND PS.
  ↳ Edges[0..*].StartDate > '1/1/2000'
```

Listing 3 presents a reachability query Q_r that queries a protein-interaction network represented by the BioNetwork graph view, and checks if *Protein X* interacts directly (i.e., by an edge) or indirectly (i.e., by a path) with *Protein Y* through either a covalent or stable interaction types. $PS.PathString$ corresponds to the string representation of Path PS . Notice that many paths can exist between the vertexes corresponding to the specified proteins. So, Query Q_r uses the *LIMIT 1* clause because retrieving one path is sufficient to decide on reachability.

Listing 3: Reachability Query Q_r

```
SELECT PS.PathString
FROM Proteins Pr1, Proteins Pr2, BioNetwork
  ↳ .Paths PS
WHERE Pr1.Name = 'Protein X' AND Pr2.Name =
  ↳ 'Protein Y' AND PS.StartVertex.Id =
  ↳ Pr1.Id AND PS.EndVertex.Id = Pr2.Id
  ↳ AND PS.Edges[0..*].Type IN ('
  ↳ covalent', 'stable') LIMIT 1
```

In addition to the ability of referencing the attributes of the edges or vertexes forming a path, say PS , GRFusion allows aggregation functions on the attributes of the vertexes or the edges of PS . The aggregate functions on the attributes of paths have the same usage and constraints as those on relational attributes. For example, if the edges of PS have an attribute, say *Weight*, a query can compute the sum of the weight values across all the edges of PS , i.e., $sum(PS.Edges.Weight)$ can appear in the select-clause of a query to compute the sum of the weights associated with the edges of Path PS .

The PATHS construct can also retrieve sub-graphs based on specific patterns (e.g., the topology of the sub-graph, attributes of the vertexes/edges of the subgraph). For instance, finding triangular structures with specific edge properties, and counting these triangles are important primitives for Machine-Learning,

Figure 5: QEP for Query Q_v .

e.g., [48], where a triangle structure can be viewed as a loop of three edges. Listing 4 presents Query Q_t that counts the number of triangles, where the edges have specific values for their *Label* attribute. Notice the use of the *Path.Length* property, where it is necessary to retrieve only triangles (as the sub-graph of interest has only three edges).

Listing 4: Subgraph Pattern Query to Find Triangles Q_t

```
SELECT Count (P)
FROM MLGraph.Paths P Where P.Length = 3 AND
  ↳ P.Edges[0].Label = 'A' AND P.Edges
  ↳ [1].Label = 'B' AND P.Edges[2].Label
  ↳ = 'C' AND P.Edges[2].EndVertex = P.
  ↳ Edges[0].StartVertex
```

More interestingly, paths can be joined to query more complex sub-graph patterns. Similar to relational engines that can perform self-joins for a relational table, GRFusion allows self-joins of the paths of a given graph view. This is possible as the vertexes and the edges of the paths to join can be referenced by relational join predicates.

5 GRAPH-RELATIONAL QUERY PROCESSING

In this section, we explain how GRFusion evaluates graph-relational queries. Section 5.1 introduces the primitive graph operators of GRFusion, while Section 5.2 illustrates how the graph operators integrate with typical relational operators in a cross-data-model QEP, where the graph operators appear in the leaf level of the QEP. Then, Section 5.3 discusses the conceptual query evaluation of graph-relational queries in GRFusion.

5.1 Graph Operators

GRFusion defines three primitive operators to evaluate the graph constructs of graph-relational queries. In particular, GRFusion defines the *VertexScan*, *EdgeScan*, and *PathScan* operators that iterate over a graph view’s vertexes, edges, and paths, respectively. The PathScan operator is a lazy operator following the iterator model [28] to avoid eager generation of paths that might not be required by parent operators. The reason of this design decision is that many queries (e.g. reachability) limit the number of paths to be retrieved, and consequently generating all/multiple paths may be expensive and unnecessary.

5.1.1 Vertex Scan and Edge Scan Operators. Operators *VertexScan* and *EdgeScan* allow GRFusion to iterate over the vertexes and edges of a given graph view, respectively. For example, the *VertexScan* operator provides an alternative access method for accessing the vertexes of a graph view, where the fan-in and fan-out properties of any vertex can be efficiently retrieved in constant time. To illustrate, consider Query Q_v in Listing 5. Q_v selects from the set of vertexes of the SocialNetwork graph view, and then applies some relational operators afterwards. To evaluate Q_v , GRFusion constructs the query execution pipeline, say QEP_v ,

as in Figure 5. Operator *VertexScan* scans the vertexes of the graph defined by the *SocialNetwork* graph view from the in-memory graph structure (represented as *MemGraph* in Figure 5, that references the singleton graph structure of the graph view). Vertexes with last name ‘Smith’ are selected and a relational projection operation selects only the birth date and the fan-out properties.

Listing 5: Vertexes Selection Query

```

SELECT VS.birthdate, VS.fanOut
FROM SocialNetwork.Vertexes VS
WHERE VS.lstName = 'Smith'

```

5.1.2 The PathScan Operator. In GRFusion, the *PathScan* operator is responsible for traversing a graph view to construct simple paths identified by a graph query. *PathScan* is a logical operator that has three physical operators with three corresponding graph-traversal algorithms. All the physical operators explore a traversed vertex only once to avoid loops, i.e., the paths in GRFusion are simple paths. In particular, the query optimizer maps a logical *PathScan* operator into *DFScan*, *BFScan*, or *SPScan*, corresponding to depth-first search, breadth-first search, or shortest-path search physical operators, respectively. In this section, we focus on the logical semantics of the path scan operator. We defer the discussion of the physical operators to Section 6.

As a logical operation, the paths-discovery process in GRFusion starts from a set of start vertexes to avoid materializing all possible paths. These start vertexes are either stated explicitly in the query (e.g., $PS.StartVertex.Id = Value$) or are generated by other operators during query evaluation (e.g., $PS.StartVertex.Id = VS.Id$ as in Listing 2). In the latter scenario, the start vertexes selected by some operators (e.g., *TableScan*, relational sub-query), are used to probe the *PathScan* traversal operator. If the start vertexes of a path selection are not defined, all the vertexes of the corresponding graph view will be used as starting vertexes. Notice that the paths in GRFusion are not eagerly materialized by a *PathScan* operator, rather they are lazily generated.

To illustrate how paths are explored in GRFusion, consider Query Q_p in Listing 2. Q_p explicitly states that the path discovery process starts from the vertexes corresponding to lawyers in the social network. Figure 6 demonstrates the query evaluation pipeline QEP_p that evaluates Query Q_p , where *MemGraph* refers to the singleton materialized graph structure of the graph view. In particular, Q_p starts the traversal process from each qualified vertex. Notice that the qualified vertexes are retrieved using a relational operator (e.g., by a *TableScan* or *IndexScan* operators) in Figure 6. The reason is that using a relational access method with filtering predicates on the *vertexes relational-source* is more efficient than using the tuple pointers in the graph view to filter all the vertexes on the fly. Because of the seamless integration of the relational and graph models in GRFusion, this optimization alternative is feasible. While traversing the graph view, only the edges with start dates after ‘1/1/2000’ are considered. Also, QEP_p explores paths of length two only (i.e., consisting of two edges) that originate from a given start vertex. As an effective optimization, GRFusion pushes predicates, e.g., path-length predicates, to be considered during the traversal process. This optimization allows GRFusion to apply early pruning of paths, and to reduce the size of the intermediate results flowing through the query pipeline. Consequently, the performance of the query evaluation process is boosted w.r.t. the processing time as well as the temporary memory used for the intermediate results.

Figure 6: GRFusion joins a relational table with a graph-view traversal-operator for Query Q_p .

5.2 Cross-Model Query-Execution-Pipelines

A query in GRFusion can reference relations or relational views with graph views simultaneously. A pure relational engine has a main structure (i.e., tuple) that is passed among the relational operators in a query evaluation pipeline (QEP). GRFusion allows its query engine to view data by two different data models, namely, the relational model and the graph model. GRFusion allows a single QEP to have two main categories of operators that interact seamlessly in a QEP. The first category contains the relational operators (e.g., select, project, relational join) that can interact directly with relational tables. The second category contains graph operators that can operate on graph views. GRFusion integrates both categories of operators by allowing a relational operator to operate on the result of a graph operator. In particular, GRFusion unifies the interface of the output of both the relational and the graph operators. Specifically, the query engine of GRFusion abstracts graph processing by using three data types that extend the *Tuple* data type, namely the *Vertex*, *Edge*, and *Path* data types, where each has a schema that depends on the queried graph-view, as explained below.

In GRFusion, a vertex, say V , is represented in a QEP by a tuple, say T , where each attribute of V becomes an attribute in T . For example, a graph vertex in Listing 1 is represented by a tuple with attributes: $(uid, lstName, birthdate)$. In addition, Vertex V has the following properties:

- **FanOut:** Contains the number of V ’s outgoing edges.
- **FanIn:** Contains the number of V ’s incident edges.

An edge E is represented by a tuple with attributes corresponding to E ’s attributes in addition to the following attributes:

- **From:** Contains the start vertex of Edge E .
- **To:** Contains the end vertex of Edge E .

GRFusion defines the *Path* data type, where a path, say P , is a sequence of identifiers of the edges that form P . In particular, P is an extended tuple with the following attributes defining its schema:

- **Length:** Is the number of edges in P .
- **StartVertex:** Is the start vertex of P .
- **EndVertex:** Is the end vertex of P .
- **Vertexes:** Is the list of vertexes forming P .
- **Edges:** Is the list of edges forming P .

5.3 Conceptual Evaluation of Graph-Relational Queries in GRFusion

GRFusion addresses the impedance mismatch between the graph model and the relational model by unifying the type of the elements that move among the relational and the graph operators within a QEP. To illustrate, we list below the high-level steps

that describe GRFusion’s conceptual evaluation of declarative graph-relational queries, i.e., ones that reference relation(s) and graph-view(s):

- The relational tables and views are joined together using all the relational predicates in the WHERE clause of the query. This step yields a single resultant relation, say R .
- Each graph operator operates on a graph view, say GV , using its in-memory singleton graph-structure, say Mem_{GV} . In case of using different aliases on the same graph view, each alias is assigned an independent pointer to Mem_{GV} .
- When querying a combination of relations, relational views, vertexes, edges, or paths, all the graph operators operate only on graph views. Observe that the output of each graph operator is an extended type of the relational *Tuple* type. Hence, the output of the graph operators can be ingested by the relational operators (e.g., the joins) in the same QEP seamlessly, where a relational join outer tuple can be used to probe a graph operator in the inner (e.g., see Figure 6).
- The predicates in the WHERE clause of the query that have not been consumed in producing R are used to join R with all the vertexes, edges, and paths referenced by the query.
- The SELECT list is used to perform projection.

6 QUERY OPTIMIZATION

GRFusion optimizes graph-traversal queries with two objectives in mind: (1) pruning undesired paths as early as possible to optimize the runtime, and (2) favoring traversal algorithms with less-memory requirements. The second goal is vital as memory should be consumed discreetly in an in-memory system. Optimization techniques for early pruning are discussed in Sections 6.1 and 6.2. In Section 6.3, we address the traversal-algorithm selection.

6.1 Path Length Inference

The query optimizer of GRFusion infers the allowed length of the paths described by the queries. The main objective is to make sure that a path returned from the PathScan operator is unlikely to be rejected by a parent operator (e.g., a join operator) due to a predicate referencing the path length. For instance, if a query has the filter " $PS.Edges[5..*].Att1 = Value$ ", then PathScan infers that the minimum path length to return is 6 (indexing is zero-based). Hence, PathScan will not return a path of length 5 or less. Many real-world queries specify the length of the desired paths, e.g., triangle-counting queries [48] specify a path length of three, the popular friends-of-friends queries restrict a path length to two, and many reachability queries put a cap on the maximum length of the path connecting the queried endpoints.

For each collection of paths, say PS , that is referenced in the *From*-clause, the query optimizer analyzes the predicates referencing the length of PS explicitly (e.g., $PS.Length = value$), or implicitly (e.g., by analyzing the logical operators as in $PS.Edges[5..*].Att1 = X$ AND $PS.Edges[7..9].Att2 = Y$), to predict the range of allowed lengths of the paths to return. Then, the inferred path length is considered by PathScan while traversing the graph (e.g., an inferred maximum path length of 8 will prune any path of length ≥ 9).

6.2 Pushing Filters Ahead of Path Scans

To prune paths early, all the filters related to discovering the paths of a graph view are pushed ahead of the *PathScan* operator. For instance, for a graph view’s paths, say PS , Predicate " $PS.Edges[0..*].Cost < 10$ " is pushed so that *PathScan*

can prune any potential path explored with an edge of cost ≥ 10 . Similarly, predicates that refer to aggregates on a path’s attributes will be computed and checked during the *PathScan* evaluation. For example, consider a query, say Q , with the predicate " $Sum(PS.Edges.Cost) < 100$ ". When *PathScan* explores Path P while evaluating Q , *PathScan* will accumulate the cost-attribute of the edges of P during the traversal. If the accumulated cost exceeds 100, P will be dropped and will not flow to the operators next in the QEP.

6.3 Logical to Physical Operator Mapping

Recall from Section 5.1.2 that the *PathScan* operator is a logical operator that is mapped into one of three physical traversal operators for execution, namely, depth-first search, breadth-first search, and shortest-path search based on Dijkstra’s algorithm [24].

The shortest-path physical operator, namely *SPScan*, is very useful in top-k shortest path queries. Listing 6 illustrates how the user can instruct the optimizer to use *SPScan*. Given a non-negative numerical edge attribute, *SPScan* traverses the graph using Dijkstra’s algorithm [24], and returns the next shortest-path as requested (i.e., pulled) by the parent operator in the QEP. *SPScan* is useful in many applications, e.g., recommendation systems and route discovery, to avoid the costly straightforward plan, i.e., avoid enumerating all paths, then filtering, sorting, and then returning the top ones.

For general graph-traversals where shortest paths are not defined, GRFusion can use either a depth-first search (i.e., a *DFScan* operator), or a breadth-first search (i.e., a *BFScan* operator). The user can give a query hint to decide on depth-first or breadth-first evaluations. To illustrate how GRFusion decides on the physical operator to perform a general graph traversal in the absence of an explicit query-hint, assume that a query, say Q , searches for Path P of Length L . Assume further that Query Q targets a graph view where the average fan-out is F . Following an analysis similar to that in [41], a depth-first search can contain on average $F * L$ vertexes in its stack data structure. In contrast, a breadth-first search can contain F^L vertexes in its queue data structure. Hence, GRFusion uses BFS if $F < \sqrt[L]{L}$ to optimize for memory. This optimization is applicable if the path length can be inferred and by maintaining the average fan-out statistic for each graph view in the system catalog. Otherwise, GRFusion uses the default scan operator that the user can set based on the expected workload (e.g., BFS can still be better if the underlying graph has a large diameter and frequent queries find the desired paths after one or two hops). GRFusion has a configuration to store the average fan-out of graph views as a statistics object. If this configuration is enabled, GRFusion runs a thread in the backend to compute the average fan-out using the compact graph-view structures.

Listing 6: Declarative Shortest-Path Query

```
SELECT TOP 2 PS
FROM RoadNetwork.Paths PS HINT(SHORTESTPATH
  ↳ (Distance)), RoadNetwork.Vertexes
  ↳ Src, RoadNetwork.Vertexes Dest
WHERE PS.StartVertex.Id = Src.Id AND PS.
  ↳ EndVertex.Id = Dest.Id AND Src.
  ↳ Address = "Address 1" AND Dest.
  ↳ Address = "Address 2"
```

7 EXPERIMENTAL EVALUATION

We experimentally evaluate the performance of GRFusion, a realization of the proposed *Native G+R Core* approach inside a centralized version of VoltDB. We compare GRFusion to the state of the art of the *Native Relational-Core* approach, namely SQLGraph [46], and we compare to Grail [25]. Although Grail uses a different computational model than GRFusion, they both have the common ground of executing queries through an RDBMS. We also compare GRFusion to two popular specialized graph systems, Neo4j [4] and Titan [11]. The reason for comparing with specialized graph systems, which follow the *Native Graph-Core* approach, is to show that graph-traversal queries can be efficiently handled by GRFusion.

Mitigating the disk IO cost from the baselines: As GRFusion is an in-memory system, the experiments are designed to mitigate the disk cost of all the baselines we compare to. We implemented SQLGraph and Grail as described in [46], and [25], respectively, on top of the in-memory VoltDB system. We configured Titan to use the in-memory storage configuration, and we set Neo4j to run and execute over a RAM disk on Linux.

We consider two important categories of graph queries, namely, traversal-based queries and pattern-matching queries, where the queries can take additional filtering predicates. For traversal-based queries, we evaluate reachability queries (e.g., Listing 3). We also evaluate shortest-path queries to compare with Grail [25]. For pattern-matching queries, we evaluate the triangle-counting query using filtering predicates on the edges while varying selectivity. The triangle-counting query is a primitive operator in many machine-learning and knowledge-discovery techniques, e.g., [48]. Experiments are conducted on a machine running Linux kernel 3.17.7 on 32 cores of Intel Xeon 2.90 GHz with 384 GB of main-memory.

7.1 Datasets

We use real graph datasets that represent four different application domains, namely, road networks, biological networks, authorship networks, and social networks. For the road networks, we use the continental-sized Tiger dataset [9] that covers the entire U.S., where the edges represent road segments, and the vertexes represent road intersections. For the biological networks, we use the String protein-interaction dataset [8], where the vertexes represent proteins, and the edges represent interactions among the proteins. We use the DBLP [1] dataset for the authorship networks, where the vertexes represent authors, and the edges represent co-authorship relations. We use the Twitter dataset [3] for the social-network application, where the dataset represents the follower graph of Twitter. The vertexes in Twitter represent users, where an edge from User A to User B denotes that User A follows User B. Table 2 summarizes the properties of these datasets.

Controlling sub-graph selectivity: We study the effect of selecting a subgraph from an underlying graph before performing a graph operation (e.g., selecting a sub-graph containing 10% of the edges of the entire graph before executing a shortest-path query or a topological pattern-matching query on the selected sub-graph). For each dataset, we vary the selectivity of the queries from 5% to 50%.

Evaluating the effect of graph-views in the *Native G+R Core* approach: To accurately study the performance gains due to the graph-views of the *Native G+R Core* w.r.t. the *Native Relational-Core* approach, we use breadth-first search instead of depth-first search, and we do not push the predicates ahead of the path scan operator in GRFusion for all the reachability-queries experiments.

7.2 Unconstrained Reachability Queries

We contrast the performance of GRFusion with that of SQLGraph, Neo4j, and Titan, when processing reachability queries without filtering predicates on the graph edges. Given two nodes, say A and B , a reachability query returns true if a path exists from Node A to Node B . The query-processing time of a reachability query is affected by the path length of the query result. The reason is that the increase in the number of edges traversed directly corresponds to the number of relational joins in the *Native Relational-Core* approach (e.g., SQLGraph).

For each dataset in Table 2, we generate random reachability queries with different path lengths that make the query endpoints connected. We vary the path length from 2 to 20. For each path length, say l , we generate 10,000 random queries, say Q_l . We run Q_l and measure the average query-processing time using GRFusion, SQLGraph, Neo4j, and Titan.

Figure 7 shows the average query-processing time of running the queries using all four systems, where the x-axis and the y-axis give the path-length of the query answers and the query-processing time in milliseconds, respectively. GRFusion achieves up to four orders-of-magnitude speedup in query-processing time compared to SQLGraph, where the speedup increases as the graph size increases. For instance, the speedup reaches 599x for the DBLP graph, and 2483x for the larger String graph. The reason is that GRFusion uses the compact graph view that captures the graph topology, where the graph views act as navigational indexes. Hence, GRFusion does not perform any relational join on the relational sources to traverse the graphs. In contrast, SQLGraph performs a relational join for each edge traversal during the path discovery process. Consequently, the query-processing time in SQLGraph increases as the path length of the query result increases. Moreover, the SQLGraph approach may not scale in main-memory RDBMSs when the graph size is very big due to the size of the intermediate results of the relational joins. To illustrate, in Figure 7(d), in the Twitter dataset, the *Native Relational-Core* represented by SQLGraph does not execute if the query evaluation requires more than four relational joins. The reason is that the intermediate temporary-memory of the join operators exceeds 6 GB, which is 60 times the 100-MB recommended limit in VoltDB. To allow room for query-evaluation pipelining to reduce the intermediate results, and to mitigate the limits of the main-memory, we execute the Twitter queries on a popular disk-based commercial RDBMS. The queries on the Twitter graph time-out after 5 hours of execution when the traversal depth of the queries exceeds four. In contrast, the systems following the *Native Graph-Core* represented by Neo4j and Titan scale for deep graph-traversal queries on large graphs as the overhead of the relational joins does not exist, where a deep graph-traversal query is a query that explores paths of long lengths, i.e., many edges, which corresponds to many joins in the *Native Relational-Core*. However, GRFusion that realizes the proposed *Native G+R Core* approach is able to scale for deep graph-traversal queries with better performance than those of the native graph systems.

Comparing GRFusion to the specialized graph databases Neo4j and Titan, GRFusion has a query-time speedup that exceeds three orders-of-magnitude for the String graph (see Figure 7(c)). We attribute these performance gains of GRFusion over the specialized graph databases to implementation factors and not to a fundamental change in the computational model. The reason is that GRFusion is based on VoltDB that has a low-overhead concurrency model (e.g., no lock overhead as in the specialized graph

Dataset	Number of Vertexes	Number of Edges	Construction Time	Memory Size (GB)
Tiger Road Network	24,412,259	58,698,439	2.08 Min	0.88
DBLP Co-Author Network	1,007,047	6,592,656	1.59 Sec	0.09
String Protein Network	1,520,673	348,473,440	3.81 Min	4.17
Twitter Follower Network	41,652,230	1,468,365,182	10.87 Min	17.81

Table 2: The graph views in GRFusion are fast to construct with low memory overhead for the datasets of the evaluation.

databases). Moreover, VoltDB has an optimized memory manager written in C++ that is significantly more efficient than the JAVA memory managers of both Neo4j and Titan. Theoretically, if we remove all the implementation-specific factors, the performance of GRFusion should be comparable to that of the specialized graph systems as both are processing native graph representations. In Section 7.3, we present the performance of GRFusion when evaluating queries that do not only consult the graph topology, but also the edges’ attributes stored in the relational sources.

7.3 Reachability Queries with Filtering Predicates

We evaluate the performance of reachability queries in GRFusion and compare it to the baselines when the queries are associated with a filtering predicate. To study the effect of sub-graph selectivity (i.e., selecting the sub-graph to perform the query on), we generate reachability queries similar to the ones described in Section 7.2 with varying selectivities. We vary the selectivity parameter from 5% to 50% using synthesized edge attributes to control the selectivity. We limit the path length of the results of the generated queries to 20 to emphasize the effect of the selectivity of the sub-graph to operate on.

Figure 8 shows the average query-processing time for executing the reachability queries with filtering predicates using all 4 systems and datasets, where the x-axis and the y-axis are the edge-selectivity of the queries, and the query-processing time in milliseconds, respectively. Observe that, for the relatively-small DBLP graph in Figure 8(a), SQLGraph outperforms Neo4j and Titan as the relational engine can execute joins and apply filtering predicates efficiently on relations of small cardinalities. GRFusion outperforms both SQLGraph and the specialized graph engines. There are two main reasons behind GRFusion’s performance gains. First, GRFusion uses a compact graph data structure to perform the traversal and avoids relational joins completely to explore the underlying graph. Second, GRFusion relies on the relational engine to evaluate the filtering predicates on the edges. Recall that GRFusion has a direct pointer to an edge’s tuple that is accessed in $O(1)$ time to evaluate the query filtering-predicate using the efficient logic of the relational engine. Hence, GRFusion combines the strengths of both the graph systems and the relational systems to achieve the best-of-both-worlds in terms of performance. However, the efficient evaluation of the filtering predicates and the cost of the relational joins in SQLGraph do not pay off when the size of the relations increase. To illustrate, refer to Figure 8(b), where the performance of SQLGraph degrades as more edges are selected. For the String dataset in Figure 8(c), SQLGraph exceeds the temporary memory limits of VoltDB after selecting a subgraph of size larger than 25% of the queried graph for the reasons illustrated in Section 7.2. For the largest Twitter dataset, SQLGraph is not able to perform even on a subgraph of a 5% selectivity. The reason is that the cost of 20 relational joins on the large Twitter table exceeds the temporary-memory limits of VoltDB, and time-out

the queries on a commercial disk-based RDBMS after 5 hours of execution. Also, as the number of self-joins increases in the *Native Relational-Core* approach, the relational optimizer may not be able to select the best join algorithm due to inaccurate cardinality estimations of the intermediate results (see [27] for details).

The relational engine is efficient in performing filtering predicates. This set of experiments demonstrates the power of extending the relational engine with a native graph-core processor that is optimized for graph traversals and that uses efficient memory representation. Figure 8 demonstrates the scalability and the efficiency of GRFusion in contrast to the baselines in handling graph queries with filtering predicates. Notice that increasing the edge-selectivity factor of the queries has less impact on Neo4j, Titan, and GRFusion than on SQLGraph w.r.t. query-processing time. The reason is that these queries are evaluated on a graph structure by performing the filtering predicates on the fly as the graph is being traversed. The selectivity affects the query performance of all the approaches. However, it is more impactful in the case of pure-relational evaluation. For example, in Figure 8(b), the processing time of SQLGraph increases by 138x when changing the selectivity from 5% to 50%, in contrast to an increase of 1.72x in GRFusion on the same setup.

7.4 Sub-Graph Pattern Matching

We evaluate the performance of the triangle-counting query. Given a graph, say G , a triangle-counting query, say Q_{TC} , counts all the sub-graphs of a triangle pattern (e.g, see Listing 4). Notice that the *Native Relational-Core* approach, e.g., SQLGraph, can scale for this specific pattern query as only two relational joins are needed for query evaluation. This is the reason for choosing this pattern query besides its importance as a primitive in many applications [48]. Figure 9 gives the performance of evaluating triangles queries on the DBLP, Tiger, and String graph datasets, where the x-axis and the y-axis are the edge-selectivity of the queries and the query-processing time in milliseconds, respectively.

Notice that in Figure 9, the SQLGraph approach outperforms both Neo4j and Titan when the selected sub-graph size is small, e.g., up to a selectivity of 10% for the DBLP dataset as in Figure 9(a). Also, notice that SQLGraph is more sensitive to the selectivity parameter than all the other approaches including GRFusion. Although only two joins are required by SQLGraph in this type of queries, increasing the number of tuples to join increases the query processing time, which results in better performance by Neo4j and Titan when increasing the selectivity parameter. For instance, Neo4j and Titan are more efficient than SQLGraph for the String dataset in Figure 9(c) for a selectivity parameter greater than 20%.

Figure 9 illustrates that GRFusion outperforms SQLGraph, Neo4j, and Titan by up to one order of magnitude in query performance. We attribute this performance advantage by GRFusion to the same reasons reported in Section 7.2.

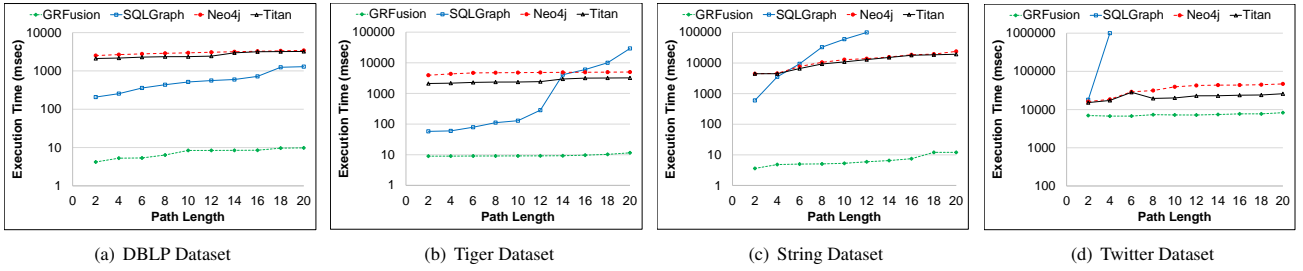

Figure 7: GRFusion achieves up to 4 orders-of-magnitude query-time speedup for *unconstrained reachability queries*.

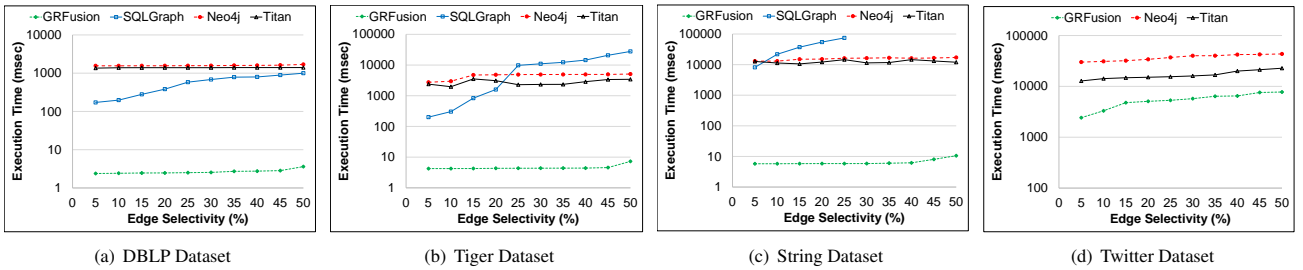

Figure 8: GRFusion achieves up to 4 orders-of-magnitude query-time speedup for *reachability queries with filtering predicates*.

Figure 9: GRFusion finds all the triangles with filtering predicates with a query-time speedup of one order-of-magnitude.

7.5 Shortest-Path Queries with Filtering Predicates

We conduct an experiment using the Tiger road network to assess the performance of GRFusion in evaluating the single-source shortest-path query (or SSSP, for short) in contrast to Grail [25]. The purpose of this experiment is to show that a simple algorithm, e.g., Dijkstra’s algorithm [24], executing inside a relational database system can achieve significant performance gains over a pure-relational approach, e.g., as in Grail [25], when evaluating SSSP queries, or more generally, intensive traversal queries. Notice that the computational model of Grail is based on the vertex-centric computational approach that is different from the graph-traversal model of GRFusion. However, both approaches have a common ground due to using an RDBMS in the evaluation. We implement the SSSP query of Grail as reported in Listing 3 in Grail’s paper [25]. Our Grail implementation is an in-memory implementation on top of VoltDB to mitigate the disk IO cost, and we allow Grail to filter the edges while processing to report the effect of sub-graph selections on the query-execution performance.

We generate 1000 random sources from which we execute an SSSP query to all the other vertexes, and we report the average query execution time for various sub-graph selectivity factors.

Figure 10: GRFusion executes SSSP queries natively inside an RDBMS few-thousand times faster than Grail.

Figure 10 gives the performance of evaluating SSSP queries on the Tiger road network, where the x-axis and the y-axis are the edge-selectivity of the queries and the query-processing time in milliseconds, respectively. GRFusion achieves more than three orders-of-magnitude query-time speedup w.r.t. Grail. Notice that we do not use an advanced SSSP evaluation method. Instead, we use a straightforward Dijkstra’s algorithm that utilizes efficient filtering-predicates of the relational database engine. This emphasizes the point that having a native and an efficient graph representation inside an RDBMS can fill the gap between the RDBMSs and

the graph algorithms that are designed for native graph structures, where these graph algorithms can achieve significant performance gains when compared to equivalent pure-relational query evaluation approaches.

7.6 The Overhead of Graph Views

As graph views are materialized in GRFusion, we report the construction time as well as the consumed memory space for each dataset. Table 2 illustrates that the construction time ranges from two seconds to 10 minutes according to the size of the graph. The reason is that the construction process passes only once by the vertexes relational-source as well as the edges relational-source. Similarly, Table 2 shows the memory size due to the materialization of the topology of every graph. The consumed memory is of acceptable overhead because only the graph topology is materialized, where each vertex and edge holds pointers to the relational data instead of replicating the relational data inside the graph views. For example, only 0.88 GB is needed to construct a graph view for the continental-sized US road network. Moreover, the overhead of updating the graph views is low. On average, it takes 0.04 milliseconds to add a new edge into an existing graph view, i.e., the total time to insert a tuple in the relational source as well as updating the topology of the corresponding graph view. For both the deletions and insertions of vertexes and edges, GRFusion incurs 5%-11% additional overhead to the time of manipulating the relational sources. The reason for this low overhead is that the logic of manipulating the graph views is linear in time w.r.t. the number of affected vertexes or edges as illustrated in Section 3.3.

8 RELATED WORK

Graphs Integration with Relational Databases: There is a plethora of database systems that adopt the graph data model (e.g., Neo4j [4] and Titan [11]). These systems have powerful graph querying features. However, it has been shown that for many graph queries, the performance of these systems can be achieved or exceeded by a vanilla relational database [25, 46]. For graph-relational queries, a graph database is useful if it is feasible to: a) import all the relational data into the graph database, or b) develop a custom layer where results from the graph database and the relational database are integrated to form the final results. In contrast, GRFusion allows efficient execution of graph-relational queries with neither the overhead of importing data nor the overhead of integrating query results from different systems. Commercial systems, e.g., Oracle Graph and Aster [45], follow the architecture of processing graph-relational queries using different run-time systems, where the results are combined at the end. For example, Aster allows defining graph functions that can be referenced in the FROM-Clause of a SQL statement. During query execution, the graph function is extracted and evaluated using a graph runtime system. Eventually, the result from the **external** graph-runtime is transformed into a relational table that can be integrated with the parent SQL query. Similarly, G-SPARQL [40] is a SPARQL-like language for querying attributed graphs, where a graph is represented and processed using a hybrid Memory/Disk model, and the query-execution is split between the RDBMS and a memory-based layer outside the RDBMS. In contrast, GRFusion executes the graph operations as well as the relational operations of a query through a cross-data-model QEP without leaving the realm of the RDBMS.

Several graph libraries and systems target graph analytics, e.g., CRAY Graph Engine [13], Pregel [34] and its open source version

Giraph [2], GraphLab, GraphFrames [22]. For graph analytics, it may be acceptable to import data from relational databases for analytical purposes. In contrast, GRFusion also serves OLTP scenarios. This is possible as the relational data in GRFusion is not deeply copied into the graph views. Moreover, the updates to the relational data that affect the topology of the defined graph views incur little overhead to update the in-memory graph structures in GRFusion.

Relational Databases with Modified Layers for Graph Processing: In this category, the internals of an RDBMS are modified to some extent, but not to a level that executes a graph-relational query through the same QEP as in GRFusion. For example, SAP HANA Graph and GRAPHITE [37] allow graph operations to directly execute on the relational data in a column-store without replication. However, two different runtime components execute the graph-relational queries. In contrast, GRFusion uses a single runtime leading to better performance. In [18], an access method is proposed to process graphs stored on disk under certain locality assumptions. In contrast, GRFusion is a main-memory system that traverses a graph by realizing a light-weight structure describing the graph topology.

Extracting Graphs from Relational Databases: In this category, graphs stored in relational tables are extracted from the database system to be under the control of an independent application. This independent application allows for querying the extracted graphs using graph APIs. Ringo [38] and GraphGen[51, 52] are representatives of this approach. In contrast, GRFusion processes graphs inside the relational database and does not extract the graphs outside the realm of the database engine. Additionally, GRFusion supports dynamic graphs, where online updates are possible. Notice that to support graph-relational queries, e.g., in Ringo or GraphGen, the relational part of the query should be processed by the relational database, and the graph operations should be processed by Ringo or GraphGen, where another external layer will be responsible for integrating the graph results and the relational results into the final query result.

Encoding Graphs in Relational Databases: In this line of work (e.g., SQLGraph [46], Grail [25]), graphs are stored in relational tables with schema optimized for specific graph queries. After encoding graphs in a vanilla relational database, a translation layer is designed to translate the supported graph queries into complex SQL statements for the relational database to execute. Although the query performance of this approach is comparable to specialized graph databases for specific queries, these systems make it difficult for users to write declarative graph-relational queries. In particular, the schema of the relations storing the graph data may not be suitable for users to query directly and join with other relational data. The reason is that the schema is usually auto-generated based on the input graph for optimization purposes.

Tailored Operators for Specific Graph Operations: In this category, several research efforts (e.g., [17, 20, 21]) have been conducted since the 1980s and until recently (e.g., [16, 26]). However, most of these efforts target specific query types (e.g., transitive closure, shortest paths). Unlike GRFusion, these approaches also do not support a unified/cross-model declarative language to query both graph and relational objects simultaneously. In [17, 20], Relational Algebra is extended with operators to allow for recursive queries. Although the proposed recursive algebra helps execute some graph traversal queries, query execution is not efficient because the graph operators execute over relational tables and not over native graph representations. For instance, several iterations with insertions into temporary tables are needed to keep track

of the traversal state. Similarly, Vertica [31] presents optimizations for graph-relational queries. However, the graph operations execute over pure relational structures and not on graph representations. Thus, costly relational joins are mandatory in many cases to traverse graphs. In contrast, GRFusion’s graph operators process native graph structures in main-memory without performing costly joins and without manipulating temporary tables to traverse a graph topology. Dar et al. [21] use relational operators repetitively to compute the transitive closure of a graph represented in a predefined relational schema. Gao et al. [26] present specific optimizations to process shortest-path queries over graphs stored in a relational database. GRFusion is more general and can join graph views with relational tables in the same query. Moreover, GRFusion addresses the impedance mismatch between the graph model and the relational model. In EmptyHeaded [16], graphs in a relational storage are queried using a datalog-like language [29]. The core idea of EmptyHeaded is to leverage join algorithms with strong theoretical guarantees in addition to using advanced query-compilation techniques. In contrast, GRFusion avoids relational joins completely when traversing the topology of a graph view.

9 CONCLUSION

We introduce the notions of in-memory materialized graph views, graph operators that seamlessly integrate with relational operators in query evaluation pipelines, memory management, and query optimization techniques for optimizing graph-relational queries. GRFusion is a realization of the proposed *Native G+R Core* approach inside VoltDB. The key idea behind GRFusion is to show the effect of extending an RDBMS to handle natively and seamlessly graph and relational data through cross-data-model QEPs. We introduce the PATH construct, and the extended SQL language of GRFusion to declaratively express graph-relational queries. GRFusion constructs in-memory graph structures to capture the graph topology and exploits the relational engine’s power in evaluating the relational constructs of the queries. Consequently, GRFusion efficiently handles deep graph-traversal queries without any relational joins to explore the connectives of the vertexes of a graph. We evaluate GRFusion using various graph queries w.r.t specialized graph engines and systems following the *Native Relational-Core* approach, where GRFusion achieves up to four orders-of-magnitude query-time speedup.

ABSTRACT

The trip planning query searches for preferred routes starting from a given point through multiple Point-of-Interests (PoI) that match user requirements. Although previous studies have investigated trip planning queries, they lack flexibility for finding routes because all of them output routes that strictly match user requirements. We study trip planning queries that output multiple routes in a flexible manner. We propose a new type of query called *skyline sequenced route (SkySR)* query, which searches for all preferred sequenced routes to users by extending the shortest route search with the semantic similarity of PoIs in the route. Flexibility is achieved by the *semantic hierarchy* of the PoI category. We propose an efficient algorithm for the SkySR query, *bulk SkySR algorithm* that simultaneously searches for sequenced routes and prunes unnecessary routes effectively. Experimental evaluations show that the proposed approach significantly outperforms the existing approaches in terms of response time (up to four orders of magnitude). Moreover, we develop a prototype service that uses the SkySR query, and conduct a user test to evaluate its usefulness.

1 INTRODUCTION

Recently, technological advances in various devices, such as smart phones and automobile navigation systems, have allowed users to obtain real-time location information easily. This has triggered the development of location-based services such as Foursquare, which exploit rich location information to improve service quality. The users of the location-based services often want to find short routes that pass through multiple Points-of-Interest (PoIs); consequently, developing trip planning queries that can find the shortest routes that passes through user-specified categories has attracted considerable attention [4, 10]. If multiple PoI categories, e.g., restaurant and shopping mall, are in an ordered list (i.e., a *category sequence*), the trip planning query searches for a *sequenced route* that passes PoIs that match the user-specified categories in order.

Example 1.1. Figure 1 shows a road network with the following PoIs: “Asian restaurant”, “Italian restaurant”, “Gift shop”, “Hobby shop”, and “Arts&Entertainment (A&E)”. Assume that a user wants to go to an Asian restaurant, an A&E place, and a gift shop in this order from start point v_q . The sequenced route query outputs route R1 because it is the shortest route from v_q that satisfied the user requirements (Asian restaurant, A&E, gift shop).

Existing approaches find the shortest route based on the user query. However, such approaches may find an unexpectedly long

Figure 1: An example of a road network with PoIs

Figure 2: Examples of category trees in Foursquare

route because the found PoIs may be distant from the start point. A major problem with the existing approaches is that they only output routes that *perfectly* match the given categories [5, 14, 16]. To overcome this problem, we introduce flexible similarity matching based on PoI category classification to find shorter routes in a flexible manner. In the real-world, category classification often forms a *semantic hierarchy*, which we refer to as a *category tree*. For example, in Foursquare¹, the “Food” category tree includes “Asian restaurant,” “Italian restaurant,” and “Bakery” as subcategories, and the “Shop &Service” category includes “Gift shop,” “Hobby shop,” and “Clothing store” as subcategories (Figure 2). We employ this semantic hierarchy to evaluate routes in terms of two aspects, i.e., route length and the semantic similarity between the categories of the PoIs in the route and those specified in the user query. As a result, we can find effective sequenced routes that *semantically* match the user requirement based on the semantic hierarchy. For example, in Figure 1, route R2 satisfies the user requirement because it semantically matches the category sequence because Italian and Asian restaurants are in the same category tree. However, this approach may find a significantly large number of sequenced routes because the number of PoIs that flexibly match the given categories increases significantly. To reduce the number of routes to be output, we employ the skyline concept [2], i.e., we restrict ourselves to searching for the routes that are not worse than any other routes in terms of their scores (i.e., numerical values to evaluate the routes). Based on this concept, we propose the *skyline sequenced route (SkySR) query*, which applies the skyline concept to the route length and semantic similarity (i.e., we consider route length and semantic similarity as route scores). Given a start point and a sequence

¹<https://developer.foursquare.com/categorytree>

Table 1: Example routes in New York city

Approach	Distance	Sequenced route
Existing (e.g., [16])	3239 meters	Cupcake Shop → Art Museum → Jazz Club
Proposed	3239 meters	Cupcake Shop → Art Museum → Jazz Club
	1858 meters	Dessert Shop → Art Museum → Jazz Club
	1392 meters	Dessert Shop → Museum → Jazz Club
	823 meters	Dessert Shop → Museum → Music Venue

of PoI categories, a SkySR query searches for sequenced routes that are no worse than any other routes in terms of length and semantic similarity.

Example 1.2. Table 1 shows real-world examples of sequenced routes in New York city where a user plans to go to a cupcake shop, an art museum, and then a jazz club in this order. The existing approaches output a single route that matches the user’s requirement perfectly. The proposed approach can output three additional routes that are shorter than the route found by the existing approach. Note that the additional routes also satisfy the user query semantically. The user can select a preferred route among all the four routes depending on how far he/she does not want to walk or their available time.

The SkySR query can provide effective trip plans; however, it incurs significant computational cost because a large number of routes can match the user requirement. Therefore, the SkySR query requires an efficient algorithm. The challenge is to search for SkySRs efficiently by reducing the search space without sacrificing the exactness of the result. We propose *bulk SkySR* algorithm (BSSR for short) that finds exact SkySRs efficiently. Recall that a feature of SkySRs is that their scores are no worse than those of other sequenced routes. BSSR exploits the branch-and-bound algorithm [9], which effectively prunes unnecessary routes based on the upper and lower bounds of route scores. In addition, to improve efficiency more, we employ four techniques to optimize BSSR. (1) First, we initially find sequenced routes to calculate the upper bound. (2) We tighten the upper bound by arranging the priority queue and (3) tighten the lower bound by introducing minimum distances. (4) we keep intermediate results for later processing, which refer to as *on-the-fly caching*. Our approach significantly outperforms existing approaches in terms of response time (up to four orders of magnitude) without increasing memory usage or sacrificing the exactness of the result.

The main contributions of this paper are as follows.

- We introduce a semantic hierarchy to the route search query, which allows us to search for routes flexibly.
- We propose the *skyline sequenced route (SkySR) query*, which finds all preferred routes related to a specified category sequence with a semantic hierarchy (Section 4).
- We propose an exact and efficient algorithm and its optimization techniques to process SkySR queries (Section 5).
- We discuss variations and extensions of the SkySR query. The SkySR query can be applied to various user requirements and environments (Section 6).
- We demonstrate that the proposed approach works well in terms of response time and memory usage by performing extensive experiments. (Section 7).
- We develop a prototype service that employs the SkySR query and conduct a user test to evaluate usefulness of the SkySR query. (Section 8).

The remainder of this paper is organized as follows. Section 2 introduces related work. Section 3 describes the problem formulation, and Section 4 defines the SkySR query. Section 5 presents the proposed algorithm. In Section 6, we discuss variations and extensions of the SkySR query. Sections 7 and 8 present experiment and user test results, respectively, and Section 9 concludes the paper.

2 RELATED WORK

First, we review trip planning query studies related to the SkySR query. Then, we review some studies related to the skyline operator. To the best of our knowledge, no study has considered a skyline sequenced route; thus, our problem cannot be solved efficiently using existing approaches.

Trip planning: We categorize trip planning queries in Table 2. Note that all existing trip planning queries only output routes that perfectly match the user-specified category sequences. Moreover, since most trip planning queries assume Euclidean distance, they cannot find SkySRs, in which road network distance is assumed. Dai et al. [4] proposed a personalized sequenced route and assumed that PoIs have ratings as well as categories and that users assign weighting factors as preferences. Although this personalized sequenced route considers route lengths and ratings, it only outputs the route that perfectly matches the given categories and has the best score based on lengths, ratings, and preferences. Only the optimal sequenced route (OSR) is applicable to find SkySRs without modification because the OSR and SkySR are based on the same settings (except for scoring). Sharifzadeh et al. [16] proposed two algorithms to find OSRs in road networks: the *Dijkstra-based solution* and the *Progressive Neighbor Exploration (PNE) approach*. The main difference between these algorithms is that the Dijkstra-based solution employs the Dijkstra algorithm to search for PoIs and the PNE approach employs the nearest neighbor search. It has been reported that these algorithms are comparable in terms of performance [16]. Thus, we consider both algorithms to verify the performance of the proposed approach.

Skyline: The skyline operator was proposed previously [2]. Few studies have considered the skyline concept for route searches. Recently, the skyline route (or skyline path) has received considerable attention [1, 6, 8, 13, 17, 18, 20]. A skyline route assumes that edges on road networks are associated with multiple costs, such as distance, travel time, and tolls. Here, the objective is to find skyline routes from a start point to a destination considering these multiple costs. However, since we specify a category sequence rather than a destination, we cannot apply conventional algorithms to find SkySRs. The continuous skyline query in road networks (e.g., [7]) searches for the skyline PoIs for a moving object considering both the PoI category and the distances to the moving object. Because continuous skyline queries search for a single PoI category, these solutions are not applicable to SkySR queries, which obtain routes that pass through multiple PoIs.

3 PRELIMINARIES

Table 3 summarizes the notations used in this paper. We assume a connected graph $G = (\mathbb{V} \cup \mathbb{P}, \mathbb{E})$, where \mathbb{V} , \mathbb{P} , and $\mathbb{E} \subseteq (\mathbb{V} \cup \mathbb{P}) \times (\mathbb{V} \cup \mathbb{P})$ represent the sets of vertices, PoI vertices, and edges, respectively. This graph corresponds to a road network that contains PoIs. The numbers of vertices, PoI vertices, and edges are denoted $|\mathbb{V}|$, $|\mathbb{P}|$, and $|\mathbb{E}|$, respectively. PoI vertex $p \in \mathbb{P}$ is associated with category $c \in \mathbb{C}$, where \mathbb{C} is the set of categories. We denote the category of PoI vertex p as c_p , and assume that

Table 2: Types of trip planning queries.

Type	Distance metrics	Order	Destination	Result	Scores
SkySR (proposed)	Network	Total	Yes or No	Exact	Length and semantic
Optimal sequenced route (OSR) [16]	Euclidean or Network	Total	Yes or No	Exact	Length
Sequenced route [5, 14]	Network	Total	Yes	Exact	Length
Personalized sequenced route [4]	Euclidean	Total	No	Approximate	Length and rating
Trip planning [10]	Euclidean or Network	Non	Yes	Approximate	Length
Multi rule partial sequenced route [3]	Euclidean	Partial	No	Approximate	Length
Multi rule partial sequenced route [11]	Euclidean	Partial	No	Exact	Length
Multi-type nearest neighbor [12]	Euclidean	Non	No	Exact	Length

Table 3: Notations

Symbol	Meaning
\mathbb{V}	Set of vertices
\mathbb{P}	Set of PoI vertices
\mathbb{E}	Set of edges
p	PoI vertex
\mathbb{C}	Set of categories
c	Category
t	Category tree
c_p	Category of PoI vertex p
t_c	Category tree of c
\mathbb{P}_c	Set of PoI vertices associated with c
\mathbb{P}_t	Set of PoI vertices associated with t
\mathbb{S}	Category sequence (sequence of categories)
\mathbf{R}	Route (sequence of PoI vertices)
\mathbb{S}_R	Sequential PoI categories in \mathbf{R}
$l(\mathbf{R})$	Length score of \mathbf{R}
$s(\mathbf{R})$	Semantic score of \mathbf{R}
\mathcal{R}	Set of routes
$\mathcal{E}(\mathbf{R})$	Set of super-routes of \mathbf{R}
\mathcal{S}	Minimal set of sequenced routes
S_q	Category sequence specified by user
v_q	Start point specified by user

each PoI is associated with a single category. Each category is associated with category tree t , and we denote the category tree of category c as t_c . We denote the set of PoI vertices associated with c and the set of PoI vertices associated with the category tree t as \mathbb{P}_c and \mathbb{P}_t , respectively. If a PoI vertex is associated with category c , it is also associated with all ancestor categories of c in t_c . Each edge $e(u_i, u_j)$ in \mathbb{E} is associated with a weight $w(u_i, u_j)$ (≥ 0). The weight can represent either travel duration or distance. Next, we define several terms required to introduce the skyline sequenced route (SkySR).

Definition 3.1. (Category sequence) A category sequence $\mathbf{S} = \langle c_S[1], c_S[2], \dots, c_S[|\mathbf{S}|] \rangle$ is a sequence of categories, where $|\mathbf{S}|$ is the size of \mathbf{S} . $c_S[i] \in \mathbb{C}$ denotes the i -th category in \mathbf{S} . A *super-category sequence* of \mathbf{S} is a category sequence where each i -th category is either $c_S[i]$ or an ancestor of $c_S[i]$ ($1 \leq i \leq |\mathbf{S}|$) in the category tree.

Definition 3.2. (Route) A route $\mathbf{R} = \langle p_R[1], \dots, p_R[|\mathbf{R}|] \rangle$ is a sequence of PoI vertices in a road network, where $p_R[i] \in \mathbb{P}$ and $|\mathbf{R}|$ denote the i -th PoI vertex in \mathbf{R} and the size of \mathbf{R} , respectively. \mathbb{S}_R denotes the category sequence of \mathbf{R} (i.e., $\langle c_{p_R[1]}, \dots, c_{p_R[|\mathbf{R}|]} \rangle$). In addition, we define a *super-route* of \mathbf{R} as an extended route of \mathbf{R} , such as $\langle \mathbf{R}, p_i, p_j, \dots \rangle$. In other words, a super-route of \mathbf{R} is obtained by adding a sequence of PoI vertices to the end of \mathbf{R} . \mathcal{R} and $\mathcal{E}(\mathbf{R})$ denote a set of routes and a set of super-routes of \mathbf{R} , respectively. Moreover, given a route $\mathbf{R} = \langle p_R[1], \dots, p_R[|\mathbf{R}|] \rangle$ and a PoI vertex p , we define $\mathbf{R} \oplus p = \langle p_R[1], \dots, p_R[|\mathbf{R}|], p \rangle$.

Definition 3.3. (Category similarity) Given two categories c and c' , the similarity $sim(c, c') \in [0, 1]$ is calculated by an arbitrary function such as the *Wu and Palmer similarity* or path

length [15, 19]. We assume the following relations in the similarity.

- c is irrelevant to c' if both exist in different category trees; thus, we obtain $sim(c, c') = 0$.
- c *semantically matches* c' if c and c' are in the same category tree; thus, we obtain $0 < sim(c, c') \leq 1$.
- c *perfectly matches* c' if c and c' are the same; thus, we obtain $sim(c, c') = 1$.

Note that a semantic match subsumes a perfect match.

We define a *sequenced route* using the above definitions. The difference between our definition of *sequenced route* and the previous definition [16] is that we consider category similarity.

Definition 3.4. (Sequenced route) Given category sequence $\mathbf{S} = \langle c_S[1], \dots, c_S[|\mathbf{S}|] \rangle$, $\mathbf{R} = \langle p_R[1], \dots, p_R[|\mathbf{R}|] \rangle$ is a *sequenced route* of category sequence \mathbf{S} if and only if it satisfies (i) $|\mathbf{R}| = |\mathbf{S}|$, (ii) $c_S[i]$ semantically matches $c_{p_R[i]}$ for all i such that $1 \leq i \leq |\mathbf{S}|$, and (iii) all PoI vertices in \mathbf{R} differ each other.

Definition 3.5. (Route scores) Given category sequence \mathbf{S} and vertex v as a start point, we define two scores for route \mathbf{R} : *length score* $l(\mathbf{R}) \in [0, \text{inf}]$ and *semantic score* $s(\mathbf{R}) \in [0, 1]$. We define the length score $l(\mathbf{R})$ as follows:

$$l(\mathbf{R}) = D(v, p_R[1]) + \sum_{i=1}^{|\mathbf{R}|-1} D(p_R[i], p_R[i+1]), \quad (1)$$

where $D(u_i, u_j)$ denotes the smallest weight sum of the edges on the routes between vertices (or PoIs) u_i and u_j . The semantic score $s(\mathbf{R})$ is calculated by an aggregation function f as follows:

$$s(\mathbf{R}) = f(h_1, h_2, \dots, h_{|\mathbf{R}|}), \quad (2)$$

where h_i denotes $sim(c_S[i], c_{p_R[i]})$. We assume that, if all $h_i = 1$, $s(\mathbf{R}) = 0$, i.e., if all PoI vertices in a route perfectly match the categories, the semantic score of the given route is 0. We also assume that $\underline{s}(\mathbf{R})$ is the possible minimum semantic score of \mathbf{R} when it is a sequenced route. Without loss of generality, preferred routes have small length and semantic score.

4 THE SKYLINE SEQUENCED ROUTE QUERY

Here, we define the SkySR query. Intuitively, a SkySR is a potential route that may be the best route related to the user's requirement. A potential route is a route that is not *dominated* by any other routes; the notion of *dominance* is used in the *skyline operator* [2]. We define dominance for sequenced routes and SkySR query in the following.

Definition 4.1. (Dominance) Let \mathcal{R} be the set of all sequenced routes starting from point v for category sequence \mathbf{S} . For two sequenced routes $\mathbf{R}, \mathbf{R}' \in \mathcal{R}$, we say that \mathbf{R} dominates \mathbf{R}' if we have (i) $l(\mathbf{R}) < l(\mathbf{R}')$ and $s(\mathbf{R}) \leq s(\mathbf{R}')$ or (ii) $s(\mathbf{R}) < s(\mathbf{R}')$ and $l(\mathbf{R}) \leq l(\mathbf{R}')$. If two sequenced routes have the same length and

semantic scores, the routes are *equivalent* in the dominance, and a set of sequenced routes is *minimal* if it has no equivalent routes.

Definition 4.2. (SkySR query) Given vertex v_q as a start point and category sequence S_q , a skyline sequenced route is a sequenced route not dominated by other routes. Let \mathcal{R} be the set of all sequenced routes from start point v_q for category sequence S_q , and let \mathcal{S} be a *minimal* set of the sequenced routes. The SkySR query returns \mathcal{S} that includes sequenced routes such that all $\mathbf{R} \in \mathcal{S}$ are SkySRs and all $\mathbf{R}' \in \mathcal{R} \setminus \mathcal{S}$ are dominated by or equivalent to some of $\mathbf{R} \in \mathcal{S}$.

An naive solution to find SkySRs is to first enumerate SkySR candidates by iteratively executing OSR queries for any super-category sequences of S_q and then check the dominance among the routes. The number of super-category sequences of S_q increases exponentially as the depth of the category in the category tree and the size of S_q increase. Thus, although OSR algorithms can find a sequenced route efficiently, we must repeat many searches. As a result, the naive solution needs significantly high computational cost to find SkySRs.

5 PROPOSED ALGORITHM

In this section, we present the proposed approach, which we refer to as the *bulk SkySR algorithm* (BSSR), that finds SkySRs efficiently. Section 5.1 presents the BSSR design policy, and Section 5.2 explains the BSSR procedure. In Section 5.3, we propose optimization techniques for BSSR. We also theoretically analyze its performance in Section 5.4. Finally, we show a running example of BSSR in Section 5.5. In Section 5, we assume undirected graphs in which each PoI vertex is associated with only one category and that users give sequences of single PoI categories. However, in a real application, the graphs would be directed graphs, each PoI vertex would be associated with multiple categories, and users may specify complex categories. Section 6 describes how we handle the above conditions.

5.1 Design Policy

Our idea to improve efficiency is to find sequenced routes simultaneously (i.e., by searching sequenced routes in bulk) in order to reduce the search space. We have two choice as the basis for our approach; Dijkstra-based or nearest neighbor-based approaches [16]. We use the Dijkstra-based approach as the basis of our algorithm. Recall that a SkySR query has two scores for a route, i.e., length and semantic scores. To find all SkySRs, we must find routes that have small category scores even if the routes have large length scores. However, PoIs that are included in the routes with small category scores could be distant from the start point. Although the nearest neighbor-based approach finds the closest PoIs, it cannot efficiently find such PoIs. On the other hand, the Dijkstra-based approach searches for all PoI vertices that match a PoI category. Therefore, the Dijkstra-based approach is more suitable for the SkySR query than the nearest neighbor-based approach.

Although our approach finds sequenced routes simultaneously, it entails a large number of executions of the Dijkstra algorithm. This is because, since the number of PoI candidates increases, a large number of possible routes increases. The search space does not become small effectively. To effectively reduce the search space, we exploit the branch-and-bound algorithm, which uses the upper and lower bounds of a branch of the search space to solve an optimization problem effectively. With BSSR, each branch corresponds to each route. For the upper and lower

bounds, we compute the bounds during finding the set of SkySRs. Specifically, we compute the upper bound of a route from the already found sequenced routes, and we compute the lower bound from the current searched route (i.e., not a sequenced route yet). With the upper and lower bounds, we can safely prune unnecessary routes to improve efficiency.

To further increase efficiency, we propose optimization techniques for BSSR. In order to exploit the branch-and-bound algorithm, it is necessary to initialize the upper bound. Thus, we first search for a sequenced route to initialize the upper bound. However, it may take high computational cost to find a sequenced route. Therefore, we propose a *nearest neighbor-based initial search method* (NNinit) that finds sequenced routes efficiently by greedily finding PoI vertices. In addition, to effectively update the upper bound, we assign a priority to each route and use the priority queue to efficiently find routes that are likely to give an effective upper bound. To compute the lower bound, we compute the possible minimum distance and add it to the length score of a route to safely prune unnecessary routes. Moreover, to avoid executing the Dijkstra algorithm iteratively from the same vertices, we materialize search results of the Dijkstra algorithm and reuse them to search the PoI vertices. By using BSSR with optimization techniques, we can perform the SkySR query efficiently.

5.2 Bulk SkySR algorithm

Bulk SkySR algorithm (BSSR) finds all SkySRs by finding simultaneously sequenced routes with checking dominance on demand. The naive solution must execute OSR queries for all super-category sequences of S_q one by one because it only searches for the PoIs that perfectly match the given category. In contrast, BSSR searches for all PoIs that semantically match the given category.

The basic process of BSSR is simple as shown in Algorithm 1: (i) start searching the PoI vertices that match the first category from start point v_q and insert the route found into priority queue Q_b which stores all found routes (line 4), (ii) fetch a route from Q_b (line 6), (iii) search for the next PoI vertices that semantically match the next category c_d from PoI vertex p_d which is the end of the fetched route, and insert the fetched route with each of the found PoI vertices into Q_b (lines 7–9), and (iv) if Q_b is not empty, return to (ii), otherwise output the minimal set of sequenced route \mathcal{S} (line 10). In steps (i) and (iii), we find PoI vertices from the end of the fetched route using a Dijkstra algorithm modified for the SkySR query as described in Section 5.2.2.

Algorithm 1: Bulk SkySR algorithm

```

1 procedure BSSR( $v_q, S_q$ )
2  $\mathcal{S} \leftarrow \phi$ ;
3 priority_queue  $Q_b \leftarrow \phi$ ;
4  $\text{mDijkstra}(\phi, c_S[1], v_q, Q_b, \mathcal{S})$ ;
5 while  $Q_b$  is not empty do
6    $\mathbf{R} \leftarrow Q_b.\text{dequeue}()$ ;
7    $c_d \leftarrow c_S[|\mathbf{R}| + 1]$ ;
8    $p_d \leftarrow p_{\mathbf{R}}[|\mathbf{R}|]$ ;
9    $\text{mDijkstra}(\mathbf{R}, c_d, p_d, Q_b, \mathcal{S})$ ;
10 return  $\mathcal{S}$ ;
11 end procedure

```

5.2.1 Branch-and-bound. We search for sequenced routes simultaneously to reduce the search space. Our idea to safely reduce the search space is to exploit the branch-and-bound algorithm, which can reduce unnecessary search space. This section

describes the theoretical background of using the branch-and-bound algorithm. We use the following three lemmas to reduce the search space:

LEMMA 5.1. *Let \mathcal{S} be a minimum set of sequenced routes while searching for SkySRs and \mathcal{S}' be the minimum set of sequenced routes after finding SkySRs. If sequenced route \mathbf{R} is dominated by a sequenced route in \mathcal{S} , \mathbf{R} cannot be included in \mathcal{S}' .*

proof: From Definition 4.2, we search for a set of SkySRs, which are not dominated by the other sequenced routes. If we find a sequenced route not dominated by any sequenced routes in \mathcal{S} , we update \mathcal{S} by inserting the new sequenced route and deleting a sequenced route dominated by the new one. Therefore, any sequenced routes in \mathcal{S} after the update are not dominated by any sequenced routes in \mathcal{S} prior to the update. As a result, sequenced routes in \mathcal{S}' are not dominated by any sequenced routes in \mathcal{S} . In other words, \mathbf{R} is not included in \mathcal{S}' if we have sequenced route \mathbf{R}' in \mathcal{S} such that $l(\mathbf{R}') \leq l(\mathbf{R})$ and $s(\mathbf{R}') \leq s(\mathbf{R})$. \square

LEMMA 5.2. *Let $\mathcal{E}(\mathbf{R})$ be a set of super-routes of \mathbf{R} starting from the same start point. For any route \mathbf{R}' in $\mathcal{E}(\mathbf{R})$, the length and semantic scores $l(\mathbf{R}')$ and $s(\mathbf{R}')$ cannot be less than $l(\mathbf{R})$ and $\underline{s}(\mathbf{R})$, respectively.*

proof: Let \mathbf{R}' be a route included in $\mathcal{E}(\mathbf{R})$. Since we have $D(u_i, u_j) \geq 0$, the following property holds for a route \mathbf{R} from Equation (1) of Definition 3.5.

$$\begin{aligned} & D(v_q, p_{R'}[1]) + \sum_{i=1}^{|\mathbf{R}'|-1} D(p_{R'}[i], p_{R'}[i+1]) \\ &= D(v_q, p_R[1]) + \sum_{i=1}^{|\mathbf{R}'|-1} D(p_R[i], p_R[i+1]) \\ & \quad + \sum_{i=|\mathbf{R}|}^{|\mathbf{R}'|-1} D(p_{R'}[i], p_{R'}[i+1]) \\ & \geq D(v_q, p_R[1]) + \sum_{i=1}^{|\mathbf{R}'|-1} D(p_R[i], p_R[i+1]). \end{aligned}$$

Therefore, we have $l(\mathbf{R}) \leq l(\mathbf{R}')$. $\underline{s}(\mathbf{R})$ is the possible minimum semantic score of \mathbf{R} when it becomes a sequenced route. Thus, even if PoI vertices are added to \mathbf{R} , we have $\underline{s}(\mathbf{R}) \leq s(\mathbf{R}')$. As a result, we have $l(\mathbf{R}) \leq l(\mathbf{R}')$ and $\underline{s}(\mathbf{R}) \leq s(\mathbf{R}')$. \square

In terms of the branch-and-bound algorithm, Lemma 5.1 and 5.2 give us the upper and lower bounds of the scores of a route, respectively. We can prune routes according to the following lemma.

LEMMA 5.3. (pruning condition) *If (i) \mathbf{R} is a sequenced route included in the set \mathcal{S} of sequenced routes and (ii) $l(\mathbf{R}) \leq l(\mathbf{R}')$ and $s(\mathbf{R}) \leq \underline{s}(\mathbf{R}')$, any routes in $\mathcal{E}(\mathbf{R}')$ cannot be included in \mathcal{S} .*

proof: If we have $l(\mathbf{R}) \leq l(\mathbf{R}')$ and $s(\mathbf{R}) \leq \underline{s}(\mathbf{R}')$, \mathbf{R}' is not included in \mathcal{S} (Lemma 5.1). From Lemma 5.2, the scores of \mathbf{R}' cannot become less than $l(\mathbf{R}')$ and $\underline{s}(\mathbf{R}')$ even if we expand \mathbf{R}' . Therefore, any routes in $\mathcal{E}(\mathbf{R}')$ cannot be included in \mathcal{S} because \mathbf{R}' is dominated by or equivalent to the sequenced route with $l(\mathbf{R})$ and $s(\mathbf{R})$. \square

Lemma 5.3 gives us the length score *threshold* for a route, and, if the length score of a route is greater than this threshold, we can prune the given route. We define the length score threshold of a route as follows:

Definition 5.4. The threshold $\bar{l}(\mathbf{R})$ of the length score of route \mathbf{R} is given by the following equation:

$$\bar{l}(\mathbf{R}) = \min_{\mathbf{R}' \in \mathcal{S}} \{l(\mathbf{R}') | \underline{s}(\mathbf{R}) \geq s(\mathbf{R}')\}. \quad (3)$$

If $\bar{l}(\mathbf{R}) \leq l(\mathbf{R})$, we can safely prune \mathbf{R} because it cannot be included in the result. Thus, we can reduce the search space

without sacrificing the exactness of the result. Equation (3) has a small computation cost because \mathcal{S} includes only a small number of sequenced routes as shown in Section 7.

5.2.2 The modified Dijkstra Algorithm. We search the next PoI vertices that semantically match the next PoI category using the modified Dijkstra algorithm. The modified Dijkstra algorithm can prune unnecessary routes based on Lemma 5.3. Moreover, based on the following lemma, it terminates unnecessary traversal of the graph and avoids inserting unnecessary routes.

LEMMA 5.5. *Let $\mathbf{R} = \langle p_R[1], \dots, p_R[i], p_R[i+1], p_R[i+2], \dots, p_R[|\mathbf{R}|] \rangle$ be a route and $p_{i:i+1}$ be a PoI vertex on a path between $p_R[i]$ and $p_R[i+1]$. Route \mathbf{R} must be dominated by or equivalent to another route if we have $\text{sim}(c_S[i+1], c_{p_{i:i+1}}) \geq \text{sim}(c_S[i+1], c_{p_R[i+1]})$.*

proof: Let $\mathbf{R}' = \langle p_{R'}[1], \dots, p_{R'}[i], p_{i:i+1}, p_{R'}[i+2], \dots, p_{R'}[|\mathbf{R}'|] \rangle$ be a route such that the difference between \mathbf{R} and \mathbf{R}' is only in $p_{i:i+1}$ and $p_R[i+1]$. Since the PoI vertex $p_{i:i+1}$ is on the path between $p_R[i]$ and $p_R[i+1]$, we have $l(\mathbf{R}) \geq l(\mathbf{R}')$ based on triangle inequality (i.e., $D(p_{i:i+1}, p_R[i+1]) + D(p_R[i+1], p_R[i+2]) \geq D(p_{i:i+1}, p_R[i+2])$). Moreover, if $\text{sim}(c_S[i+1], c_{p_{i:i+1}}) \geq \text{sim}(c_S[i+1], c_{p_R[i+1]})$, we have $s(\mathbf{R}) \geq s(\mathbf{R}')$. Therefore, \mathbf{R} is dominated by or equivalent to \mathbf{R}' because $l(\mathbf{R}) \geq l(\mathbf{R}')$ and $s(\mathbf{R}) \geq s(\mathbf{R}')$. \square

Lemma 5.5 gives us two properties for the SkySR query: (i) even if we find a PoI vertex that passes through another PoI vertex that has a better category similarity, we can ignore the PoI vertex, and (ii) if we find a PoI vertex that perfectly matches the given category, we do not need to traverse the graph through the PoI vertex. As a result, using Lemma 5.3 and 5.5, we can efficiently find the next PoI vertices.

Algorithm 2 shows the pseudocode for the modified Dijkstra algorithm, which is used to find PoI vertices that semantically match c_d from p_d . In priority queue Q_d for the modified Dijkstra algorithm, the top vertex is the closest vertex to p_d . The queue is initialized to p_d (line 3). The closest vertex to p_d is dequeued from Q_d (line 5). \mathbf{R}_t is a route expanded from \mathbf{R}_d , which is \mathbf{R}_d with fetched vertex u (line 7). If the length score of \mathbf{R}_t is greater than or equal to the threshold of \mathbf{R}_d , the modified Dijkstra algorithm terminates the process (Lemma 5.3) (line 8). We check whether (i) u semantically matches c_d and (ii) u does not proceed through another PoI vertex whose category similarity is greater than or equal to that of u (line 9). If we satisfy the above conditions and the length score of \mathbf{R}_t is less than its threshold (line 10), we insert \mathbf{R}_t into the priority queue or the set of sequenced routes (lines 10–12). Otherwise, we skip the process to insert \mathbf{R}_t (Lemma 5.3 and 5.5). The neighbor vertices of u are inserted into Q_d unless u perfectly matches c_d (Lemma 5.5) (lines 13–17).

5.3 Optimization techniques

In this section, we propose four optimization techniques for BSSR. Section 5.3.1 explains an initial search for sequenced routes and proposes NNinit. We then explain tightening the upper and the lower bounds in Section 5.3.2 and Section 5.3.3, respectively. Furthermore, in Section 5.3.4 we propose an *on-the-fly caching technique* to reuse previous search results of the modified Dijkstra algorithm.

5.3.1 Initial search. We prune unnecessary routes efficiently using the branch-and-bound algorithm. However, we cannot calculate the threshold of \mathbf{R} if there are no sequenced routes in \mathcal{S} whose semantic scores are not greater than that of $\underline{s}(\mathbf{R})$ based

Algorithm 2: Modified Dijkstra algorithm to find the next PoI vertices matching c_d from p_d

```

1 procedure mDijkstra( $R_d, c_d, p_d, Q_b, S$ )
2  $dist[u] = \inf$  for all  $u \in \mathbb{V} \cup \mathbb{P}, dist[p_d] = 0$ ;
3 priority_queue  $Q_d \leftarrow \{p_d\}$ ;
4 while  $Q_d$  is not empty do
5    $u \leftarrow Q_d.dequeue$ ;
6   if  $u$  is already visited then continue;
7    $R_t \leftarrow R_d \oplus u$ ;
8   if  $l(R_t) \geq \bar{l}(R_d)$  then break;
9   if  $u \in \mathbb{P}_{t_{c_d}}$  and  $u$  is not through the PoI vertex whose category
similarity is higher than that of  $u$  then
10    if  $l(R_t) < \bar{l}(R_t)$  then
11      if  $R_t$  is a sequenced route then  $S.update(R_t)$ ;
12      else  $Q_b.enqueue(R_t)$ ;
13    if  $u \notin \mathbb{P}_{c_d}$  then
14      for each  $u'$  for  $e(u, u') \in \mathbb{E}$  do
15        if  $dist[u] + w(u, u') < dist[u']$  then
16           $dist[u'] = dist[u] + w(u, u')$ ;
17           $Q_d.enqueue(u')$ ;
18 end procedure

```

on Equation (3). Therefore, initially, we search for the sequenced route whose semantic score is 0. However, the length score of the sequenced route can be large if its semantic score is 0. To tighten the threshold, we also search for sequenced routes whose semantic scores are greater than 0 because the length scores of them are less than that of the sequenced route with a semantic score of 0. We initially find several sequenced routes to tighten the upper bound.

We propose NNinit, which searches for several sequenced routes efficiently. NNinit performs a nearest neighbor search repeatedly to find PoI vertices that perfectly match the given categories. With this process, we can find a sequenced route whose semantic score is 0. Moreover, NNinit can find the PoI vertex that semantically matches the given category during the nearest neighbor search. When we find the last visited PoI vertex, we may find PoI vertices that semantically match the last category in S_q . Therefore, we can obtain sequenced routes whose semantic scores are greater than 0 and length scores are small. As a result, NNinit can find several sequenced routes without incurring additional cost, and one of the sequenced routes has a semantic score of 0.

We present the pseudocode for NNinit in Algorithm 3. Here, priority queue Q is initialized to start point v_q (line 3). NNinit repeats the Dijkstra algorithm $|S_q|$ times to find sequenced routes (line 4). The Dijkstra algorithm is executed to search for the closest PoI vertex that perfectly matches $c_{S_q}[i]$ from the initial vertex (the first initial vertex is v_q) (lines 5–19). Here, the closest vertex to the initial vertex is dequeued from Q (line 7). If the algorithm finds a PoI vertex that perfectly matches $c_{S_q}[i]$, this vertex is added to R and Q is initialized to the PoI vertex (lines 12–15). When it finds the last PoI vertex that semantically matches $c_{S_q}[|S_q|]$, it inserts the sequenced route into S (lines 9–11). Finally, we obtain a set of sequenced routes, and one of the sequenced routes in S has a semantic score of 0.

Example 5.6. We show an example of NNinit using Example 1.1, which searches an Asian restaurant, an A&E place, and a gift shop in this order from start point v_q . NNinit executes the Dijkstra algorithm three times because the size of category sequence is three. First, NNinit searches PoI vertices that perfectly match Asian restaurant from v_q . Then, it finds p_2 that is the closest PoI

Algorithm 3: Initial search for finding sequenced routes with a small cost

```

1 procedure NNinit( $v_q, S_q$ )
2  $S \leftarrow \phi, R \leftarrow \phi$ ;
3 priority_queue  $Q \leftarrow \{v_q\}$ ;
  /* execute Dijkstra algorithm  $|S_q|$  times */
4 for  $i : 1$  to  $|S_q|$  do
5    $dist[u] = \inf$  for all  $u \in \mathbb{V} \cup \mathbb{P}, dist[Q.top] = 0$ ;
6   while  $Q$  is not empty do
7      $u \leftarrow Q.dequeue$ ;
8     if  $u$  is already visited then continue;
9     if  $i = |S_q|$  and  $u \in \mathbb{P}_{t_{c_{S_q}[i]}}$  then
10       $R' \leftarrow R \oplus u$ ;
11       $S.update(R')$ ;
12     if  $u \in \mathbb{P}_{c_{S_q}[i]}$  then
13       $R \leftarrow R \oplus u$ ;
14       $Q \leftarrow \{u\}$ ;
15      break;
16     for each  $u'$  for  $e(u, u') \in E$  do

```

that perfectly match Asian restaurant to v_q . Next, it searches the closest PoI vertex that perfectly matches A&E to p_2 and then finds p_5 . From the next search, NNinit inserts sequenced routes to S when it finds PoI vertices that semantically match gift shop. NNinit finds p_7 whose category is Shop&Service (i.e., semantically match) and thus inserts $\langle p_2, p_5, p_7 \rangle$ to S . After finding p_7 , it finds p_8 that perfectly matches gift shop and inserts $\langle p_2, p_5, p_8 \rangle$ to S . Finally NNinit returns S including $\{\langle p_2, p_5, p_8 \rangle, \langle p_2, p_5, p_7 \rangle\}$. The length score of $\langle p_2, p_5, p_7 \rangle$ is 12, which is less than the length score of $\langle p_2, p_5, p_8 \rangle$ of 15.

5.3.2 Tightening upper bound: Arranging routes in the priority queue. We use the upper bound to prune unnecessary routes. The upper bound is computed from the obtained sequenced routes. To tighten the upper bound, it is important to efficiently find sequenced routes that have small length and semantic scores. BSSR extends a route at the top of the priority queue to search for a sequenced route, as shown in Algorithm 1. Note that priority queues in existing algorithms conventionally consider only distances (i.e., a distance-based priority queue). If we use a distance-based priority queue, BSSR preferentially extends a route with a small length score. Although we must increase the size of a route to $|S_q|$ to find a sequenced route, a route that has a small length score likely has a small size. Therefore, it is difficult to search for sequenced routes efficiently using a distance-based priority queue.

To search for sequenced routes efficiently, we preferentially extend a route that has a large size. Here, since many routes in the priority queue could have the same size, we must consider an additional priority, which is expected to affect performance. If multiple routes in the priority queue are the same size, we preferentially extend the route with the smallest semantic score. We can reduce the search space by searching for sequenced routes in ascending order of semantic score. Moreover, if routes are the same size and have the same semantic score, we preferentially extend the route with the smallest length score. As a result, we can efficiently obtain sequenced routes with small length and semantic scores.

5.3.3 Tightening lower bound: Possible minimum length score.

As described in Section 5.2.1, we use the length scores of routes as the lower bound, i.e., we prune a route if the length score of the route is not less than the threshold. Note that the length score of the route increases as the route size increases. This indicates that it is difficult to prune routes before the route size increases. Our approach to tighten the lower bound of the route is to estimate the increase of the length score. However, if we carelessly estimate a future length score, we may sacrifice the exactness of the result.

The basic idea of this estimation is to calculate the *possible minimum distance*. Here, we compute the smallest distance among any pair of PoI vertices in sets of PoI vertices. We use the following two minimum distances, *semantic-match minimum distance* \underline{l}_s and *perfect-match minimum distance* \underline{l}_p :

Definition 5.7. (minimum distance) The semantic-match minimum distance \underline{l}_s and perfect-match minimum distance \underline{l}_p are given by the following equations:

$$\underline{l}_s(\mathbf{R}) = \sum_{i=|\mathbf{R}|-1}^{|\mathbf{S}_q|-1} \underline{l}_s[i], \text{ where } \underline{l}_s[i] = \min_{p_i \in \mathbb{P}_{t_i}, p_{i+1} \in \mathbb{P}_{t_{i+1}}} D(p_i, p_{i+1}). \quad (4)$$

$$\underline{l}_p(\mathbf{R}) = \sum_{i=|\mathbf{R}|-1}^{|\mathbf{S}_q|-1} \underline{l}_p[i], \text{ where } \underline{l}_p[i] = \min_{p_i \in \mathbb{P}_{t_i}, p_{i+1} \in \mathbb{P}_{c_{i+1}}} D(p_i, p_{i+1}). \quad (5)$$

In Equations (4) and (5), \mathbb{P}_{t_i} and \mathbb{P}_{c_i} denote the set of PoI vertices associated with a category tree of $c_{S_q}[i]$ and the set of PoI vertices whose category is $c_{S_q}[i]$, respectively.

We compute the semantic-match minimum distance based on the distance to the PoI vertices that semantically match the next category. We can safely add the semantic-match minimum distance to the current length score without restriction. However, the semantic-match minimum distance is much less than the threshold. Thus, it could be difficult to improve pruning performance; thus, we use the perfect-match minimum distance to increase pruning performance. The perfect-match minimum distance is computed based on the distance to the PoI vertices that perfectly match the next category. We can improve pruning performance using the perfect-match minimum distance compared to the semantic-match minimum distance because the perfect-match minimum distance is much greater than the semantic-match minimum distance; therefore, the perfect-match minimum distance tightens the lower bound more than the semantic-match minimum distance. However, we can use the perfect-match minimum distance only in a special case, i.e., where a route must pass only PoIs that perfectly match the given categories so as not to be dominated. The perfect-match minimum distance works well if the number of sequenced route in \mathbf{S} is large because the constraint is usually satisfied by increasing the number of sequenced route in \mathbf{S} .

LEMMA 5.8. *Let \mathbf{R}' and \mathbf{R}'' be sequenced routes in \mathbf{S} and \mathbf{R} be a route such that (i) $l(\mathbf{R}) \geq l(\mathbf{R}')$ and $s(\mathbf{R}) < s(\mathbf{R}')$ and (ii) $l(\mathbf{R}) < l(\mathbf{R}'')$ and $s(\mathbf{R}) \geq s(\mathbf{R}'')$. Let δ be the minimum increment of a semantic score². We can prune \mathbf{R} if we have (a) $l(\mathbf{R}) \geq l(\mathbf{R}')$ and $s(\mathbf{R}) + \delta \geq s(\mathbf{R}')$ and (b) $l(\mathbf{R}) + \underline{l}_p(\mathbf{R}) \geq l(\mathbf{R}'')$ and $s(\mathbf{R}) \geq s(\mathbf{R}'')$.*

proof: First, we consider case (a). If we have $l(\mathbf{R}) \geq l(\mathbf{R}')$ and $s(\mathbf{R}) + \delta \geq s(\mathbf{R}')$, \mathbf{R} is dominated by or equivalent to \mathbf{R}' if its semantic score increases. Therefore, \mathbf{R} must only pass through PoI vertices that perfectly match the given categories not to be dominated. If \mathbf{R} passes through only PoI vertices that perfectly

²The least increase of the semantic score is computed from the category tree. Specifically, we can compute the least increase from the category that is most similar (but not equal) to the next category.

match the given categories, the length score of \mathbf{R} increases by at least $\underline{l}_p(\mathbf{R})$. For case (b), if we have $l(\mathbf{R}) + \underline{l}_p(\mathbf{R}) \geq l(\mathbf{R}'')$ and $s(\mathbf{R}) \geq s(\mathbf{R}'')$, \mathbf{R} is dominated by or equivalent to \mathbf{R}'' if its length score increases by $\underline{l}_p(\mathbf{R})$. As a result, if we have two routes \mathbf{R}' and \mathbf{R}'' , such as (i) $l(\mathbf{R}) \geq l(\mathbf{R}')$ and $s(\mathbf{R}) + \delta \geq s(\mathbf{R}')$ and (ii) $l(\mathbf{R}) + \underline{l}_p(\mathbf{R}) \geq l(\mathbf{R}'')$ and $s(\mathbf{R}) \geq s(\mathbf{R}'')$, \mathbf{R} is dominated by or equivalent to at least one of \mathbf{R}' and \mathbf{R}'' . \square

To compute the estimation of the lower bound, we compute two types of possible minimum distances \underline{l}_s and \underline{l}_p . A naive approach computes all minimum distances from the PoI vertices that semantically match $c_{S_q}[i]$ to $c_{S_q}[i+1]$ for $1 \leq i \leq |\mathbf{S}_q| - 1$ by iteratively executing the Dijkstra algorithm. However, this has a high computational cost. To reduce the cost, we execute a *multi-source multi-destination Dijkstra algorithm*. In this algorithm, all start points are inserted into the same priority queue. Then, the algorithm dequeues vertices in the same manner as the conventional Dijkstra algorithm. Here, the process is terminated if the top of the priority queue becomes one of the destinations. This approach only needs $|\mathbf{S}_q| - 1$ times to compute the possible minimum distance. The multi-source multi-destination Dijkstra algorithm guarantees the minimum distance by the following lemma:

LEMMA 5.9. *The multi-source multi-destination Dijkstra algorithm guarantees the minimum distance from the start points to the destinations.*

proof: We first insert multiple start points into the priority queue, and their distances from the start points are initialized as 0. If we find a vertex, it is inserted into the queue and the distance to the vertex is updated from the closest start point to the vertex. The vertex with the smallest distance from the start point in the priority queue is dequeued from the priority queue. If the top vertex in the priority queue is one of the destinations, there are no destinations with smaller distance than the top one. Therefore, we can guarantee the minimum distance from the start points to the destinations. \square

Algorithm 4 shows the pseudocode to compute the semantic-match minimum distance. The estimation of the lower bound is executed after line 4 in Algorithm 1. Here, we initialize \mathbb{P}_1 and \mathbb{P}_{i+1} (lines 3–4). $\bar{l}(\phi)$ denotes the threshold for a route whose semantic score is 0. The difference between computing the semantic-match and perfect-match minimum distances is whether the PoI vertices in \mathbb{P}_{i+1} semantically or perfectly match the given category.

Example 5.10. We show an example to compute the semantic-match minimum distance using Example 1.1. \mathbb{P}_1 , \mathbb{P}_2 , and \mathbb{P}_3 include $\{p_1, p_2, p_6, p_{10}, p_{11}\}$, $\{p_5, p_9, p_{12}\}$, and $\{p_3, p_4, p_7, p_8, p_{13}\}$, respectively. First, PoI vertices in \mathbb{P}_1 are inserted to priority queue Q , and the set of destinations is \mathbb{P}_2 . By processing the Dijkstra algorithm, we compute possible minimum distance $\underline{l}_s[1] = 2$ (from p_6 to p_9). Next, we search PoI vertices that semantically match A&E to gift shop. Then, we compute $\underline{l}_s[2] = 1$ (from p_{12} to p_{13}). Finally, we obtain semantic-match minimum distance $\underline{l}_s = \{2, 1\}$. We can compute the perfect-match minimum distance in the same way and obtain $\underline{l}_p = \{3, 1\}$, which is greater than \underline{l}_s .

5.3.4 Reuse of the temporal result: On-the-fly caching technique. Although BSSR efficiently prunes unnecessary routes, it may iteratively execute the modified Dijkstra algorithm at the same vertex because, in Algorithm 1 (line 8), p_d could be the

Algorithm 4: Computing possible minimum distance

```
1 procedure EstimationLowerbound( $v_q, S_q$ )
2 for  $i : 1$  to  $|S_q| - 1$  do
3    $\mathbb{P}_i \leftarrow \{p | p \in \mathbb{P}_{c_{S_q}[i]} \text{ and } D(v_q, p) < \bar{l}(\phi)\};$ 
4    $\mathbb{P}_{i+1} \leftarrow \{p | p \in \mathbb{P}_{c_{S_q}[i+1]} \text{ and } D(v_q, p) < \bar{l}(\phi)\};$ 
5    $dist[u] = \inf$  for all  $u \in \mathbb{V} \cup \mathbb{P}$ ,  $dist[p] = 0$  for all  $p \in \mathbb{P}_i$ ;
6   priority_queue  $Q \leftarrow \{p\} \in \mathbb{P}_i$ ;
7   while  $Q$  is not empty do
8      $u \leftarrow Q.dequeue$ ;
9     if  $u$  is already visited then continue;
10    if  $u \in \mathbb{P}_{i+1}$  then
11       $l_s[i] = dist[u]$ ;
12      break;
13    for each  $u'$  for  $e(u, u') \in E$  do
14      if  $dist[u] + w(u, u') < dist[u']$  then
15         $dist[u'] = dist[u] + w(u, u')$ ;
16         $Q.enqueue(u')$ ;
17 return  $l_s$ ;
18 end procedure
```

same as the former executions of the modified Dijkstra algorithms. Thus, we reuse the result starting at the same PoI vertex by materializing the result of the modified Dijkstra algorithm (i.e., keeping PoI vertices matching c_d and distances from p_d to the PoI vertices), which we refer to as *on-the-fly caching*.

After finding SkySRs, on-the-fly caching frees the results of the modified Dijkstra algorithms (this is why we call it *on-the-fly*), because the search space rarely overlaps across different inputs (i.e., S_q and v_q differ).

5.4 Theoretical Analysis

In this section, we theoretically analyze the cost and correctness of the proposed BSSR.

THEOREM 1. (Time complexity) *Let γ be a ratio of pruning and α be a ratio of the size of a graph to find the SkySRs. The time complexity of BSSR is $O(\gamma(\alpha|\mathbb{P}|)^{|S_q|} \alpha(|\mathbb{E}| + (|\mathbb{V}| + |\mathbb{P}|) \log(\alpha(|\mathbb{V}| + |\mathbb{P}|))))$.*

proof: The time complexity of the Dijkstra algorithm is $O(|\mathbb{E}| + |\mathbb{V}| \log |\mathbb{V}|)$ if the number of vertices is $|\mathbb{V}|$. In our setting, we have $|\mathbb{V}| + |\mathbb{P}|$ vertices because we have two types of vertices. In addition, we do not need to search the whole graph by reducing the graph size according to the threshold. Therefore, the time complexity of the modified Dijkstra algorithm is $O(\alpha(|\mathbb{E}| + (|\mathbb{V}| + |\mathbb{P}|) \log(\alpha(|\mathbb{V}| + |\mathbb{P}|))))$. The time complexity of BSSR depends on the number of times the modified Dijkstra algorithms is executed. The number of modified Dijkstra algorithms is equal to all the potential routes $|\mathbb{P}|^{|S_q|}$. Recall that we can prune the number of routes using the branch-and-bound algorithm. Finally, the time complexity of BSSR is $O(\gamma(\alpha|\mathbb{P}|)^{|S_q|} \alpha(|\mathbb{E}| + (|\mathbb{V}| + |\mathbb{P}|) \log(\alpha(|\mathbb{V}| + |\mathbb{P}|))))$. \square

In our approach, γ and α depend on the upper and lower bounds. These are affected by the graph structure, the category trees, and the ratio of PoI vertices, and the time complexity of BSSR depends on these factors.

THEOREM 2. (Space complexity) *Let γ be the pruning ratio, and α be the ratio of the size of the graph to find the SkySRs. The space complexity of BSSR is $O(|\mathbb{E}| + |\mathbb{V}| + |\mathbb{P}| + \gamma|S_q|(\alpha|\mathbb{P}|)^{|S_q|})$.*

proof: We store the whole graph of size $O(|\mathbb{E}| + |\mathbb{V}| + |\mathbb{P}|)$. We also store routes into the priority queue and \mathcal{S} , and the maximum

number of routes is $|\mathbb{P}|^{|S_q|}$. We can prune the number of routes using the branch-and-bound algorithm. The size of the routes is proportional to $|S_q|$. Therefore, the space complexity of BSSR is $O(|\mathbb{E}| + |\mathbb{V}| + |\mathbb{P}| + \gamma|S_q|(\alpha|\mathbb{P}|)^{|S_q|})$. \square

If the number of routes in the priority queue is small, the graph size becomes the main factor related to the memory usage. Otherwise, the number of routes in the priority queue is the main factor.

THEOREM 3. (Correctness) *BSSR guarantees the exact result.*

proof: BSSR prunes routes based on the upper and lower bounds. BSSR safely prunes routes dominated by or equivalent to the obtained sequenced routes. As a result, BSSR does not sacrifice the exactness of the search result. \square

5.5 Running Example

We demonstrate BSSR with optimization techniques using Example 1.1. Table 4 shows routes in priority queue Q_b and sequenced routes in \mathcal{S} . To compute category similarity and semantic score, we use Equations (6) and (7), respectively.

First, we process NNinit, and \mathcal{S} initially includes $\{\langle p_2, p_5, p_8 \rangle, \langle p_2, p_5, p_7 \rangle\}$. 1st step: BSSR starts to find PoI vertices that semantically match Asian restaurant from v_q with the threshold of 15. Then, it finds p_1, p_2, p_6, p_{10} , and p_{11} . Both p_2 's and p_{10} 's category similarities are 1, and their lengths are 6 and 8, respectively. Thus, p_2 comes the top in Q_b . 2nd step: BSSR searches PoI vertices that semantically match Arts&Entertainment from p_2 , and finds p_5 . Since $\langle p_2, p_{12} \rangle$ passes through p_5 and $l(\langle p_2, p_9 \rangle)$ is more than 15, both routes are not inserted to Q_b . 3rd step: as the top route is $\langle p_2, p_5 \rangle$, BSSR searches PoI vertices that semantically match gift shop from p_5 . BSSR does not find any routes due to the threshold. 4th step: BSSR fetches $\langle p_{10} \rangle$ from Q_b and inserts two routes $\langle p_{10}, p_5 \rangle$ and $\langle p_{10}, p_{12} \rangle$ to Q_b . 5th step: BSSR fetches $\langle p_{10}, p_{12} \rangle$ and finds sequenced route $\langle p_{10}, p_{12}, p_{13} \rangle$. Since $\langle p_{10}, p_{12}, p_{13} \rangle$ dominates $\langle p_2, p_5, p_8 \rangle, \langle p_2, p_5, p_8 \rangle$ is deleted from \mathcal{S} . 6th step: The top route $\langle p_{10}, p_5 \rangle$ is deleted from Q_b because its length score is not smaller than the threshold of 13. 7th step: BSSR fetches $\langle p_1 \rangle$ and inserts $\langle p_1, p_5 \rangle$ and $\langle p_1, p_9 \rangle$. 8th step: BSSR fetches $\langle p_1, p_9 \rangle$ and finds a sequenced route $\langle p_1, p_9, p_8 \rangle$. $\langle p_1, p_9, p_8 \rangle$ is inserted to \mathcal{S} , and $\langle p_2, p_5, p_7 \rangle$ is deleted from \mathcal{S} . 9th step: $\langle p_1, p_5 \rangle$ is deleted due to the threshold. 10th step: BSSR fetches $\langle p_6 \rangle$ and finds a route $\langle p_6, p_9 \rangle$. 11th step: BSSR finds a sequenced route $\langle p_6, p_9, p_8 \rangle$, and the route dominates $\langle p_1, p_9, p_8 \rangle$. 12th step: The distance from p_{11} to the PoI vertices that match A&E is larger than the threshold. Finally, BSSR returns the set of SkySRs \mathcal{S} .

6 VARIATIONS AND EXTENSIONS

The SkySR query has a number of variations and extensions. We discuss some of these in the following.

Directed graphs: The SkySR query can be easily applied to directed graphs. We only need to use the Dijkstra algorithm for directed graphs. Here, no modification of the main idea is required.

PoI with multiple categories: To treat PoIs with multiple categories, we can change the definitions of sequenced routes and category similarity. Specifically, we change condition (ii) in Definition 3.4 to state that at least one $c_{p_i}[j]$ ($1 \leq j \leq k_i$) semantically matches $c_S[i]$ for $1 \leq i \leq |S|$, where $c_{p_i}[j]$ is the j -th category of p_i and k_i is the number of categories associated with p_i . The category similarity is either the highest or the average value among the category similarities.

Table 4: Example of BSSR algorithm

1	$Q_b: \langle p_2 \rangle, \langle p_{10} \rangle, \langle p_1 \rangle, \langle p_6 \rangle, \langle p_{11} \rangle$ $S: \langle p_2, p_5, p_8 \rangle, \langle p_2, p_5, p_7 \rangle$
2	$Q_b: \langle p_2, p_5 \rangle, \langle p_{10} \rangle, \langle p_1 \rangle, \langle p_6 \rangle, \langle p_{11} \rangle$ $S: \langle p_2, p_5, p_8 \rangle, \langle p_2, p_5, p_7 \rangle$
3	$Q_b: \langle p_{10} \rangle, \langle p_1 \rangle, \langle p_6 \rangle, \langle p_{11} \rangle$ $S: \langle p_2, p_5, p_8 \rangle, \langle p_2, p_5, p_7 \rangle$
4	$Q_b: \langle p_{10}, p_{12} \rangle, \langle p_{10}, p_5 \rangle, \langle p_1 \rangle, \langle p_6 \rangle, \langle p_{11} \rangle$ $S: \langle p_2, p_5, p_8 \rangle, \langle p_2, p_5, p_7 \rangle$
5	$Q_b: \langle p_{10}, p_5 \rangle, \langle p_1 \rangle, \langle p_6 \rangle, \langle p_{11} \rangle$ $S: \langle p_{10}, p_{12}, p_{13} \rangle, \langle p_2, p_5, p_7 \rangle$
6	$Q_b: \langle p_1 \rangle, \langle p_6 \rangle, \langle p_{11} \rangle$ $S: \langle p_{10}, p_{12}, p_{13} \rangle, \langle p_2, p_5, p_7 \rangle$
7	$Q_b: \langle p_1, p_9 \rangle, \langle p_1, p_5 \rangle, \langle p_6 \rangle, \langle p_{11} \rangle$ $S: \langle p_{10}, p_{12}, p_{13} \rangle, \langle p_2, p_5, p_7 \rangle$
8	$Q_b: \langle p_1, p_5 \rangle, \langle p_6 \rangle, \langle p_{11} \rangle$ $S: \langle p_{10}, p_{12}, p_{13} \rangle, \langle p_1, p_9, p_8 \rangle$
9	$Q_b: \langle p_6 \rangle, \langle p_{11} \rangle$ $S: \langle p_{10}, p_{12}, p_{13} \rangle, \langle p_1, p_9, p_8 \rangle$
10	$Q_b: \langle p_6, p_9 \rangle, \langle p_{11} \rangle$ $S: \langle p_{10}, p_{12}, p_{13} \rangle, \langle p_1, p_9, p_8 \rangle$
11	$Q_b: \langle p_{11} \rangle$ $S: \langle p_{10}, p_{12}, p_{13} \rangle, \langle p_6, p_9, p_8 \rangle$
12	$Q_b:$ $S: \langle p_{10}, p_{12}, p_{13} \rangle, \langle p_6, p_9, p_8 \rangle$

Complex category requirement: We can specify more detailed category requirements, such as *conjunction*, *disjunction*, and *negation*. For example, we can specify that a PoI category is “American restaurant” or “Mexican restaurant” (disjunction), but not “Taco Place” (negation). If PoI vertices are associated with more than two categories, we can specify a conjunction such as “Cafe” and “Bakery”. Note that the time complexity of our algorithm does not change if we specify a detailed requirement because the detailed requirements are equivalent to increasing the number of categories.

Skyline trip planning query: The proposed algorithm can be applied to the trip planning query without category order. For searching routes without category order, the proposed algorithm searches PoI vertices that semantically match a category in a given set of categories. Then, if the algorithm finds PoI vertices, it deletes the categories that are already included in the routes to find next PoI vertices. Note that we need to modify some definition and scoring functions for routes without category order. By this procedure, we can find skyline routes efficiently.

SkySR with destination: Note that we can specify the destination. The simple way to calculate a SkySR with a destination is to add the distance from the last visited PoI vertex to the destination to the length score after finding the sequenced route. To improve efficiency, we traverse PoI vertices from both the destination and the start point.

7 EXPERIMENTAL STUDY

We perform experiments to evaluate the effectiveness of the proposed algorithm. All algorithms are implemented in C++ and run on an Intel(R) Xeon(R) CPU E5620 @ 2.40GHz with 32 GB of RAM.

7.1 Experimental settings

Algorithm. We compare the proposed BSSR and algorithms that iteratively find OSRs using the Dijkstra-based solution and the PNE approach (denoted Dij and PNE, respectively), as described in Section 3. We evaluate performance with respect to (i) response time, and (ii) maximum resident set size (RSS) to represent memory usage.

Table 5: Summary of dataset

Dataset	Area	$ V $	$ E $	$ C $
Tokyo	Tokyo	401,893	174,421	499,397
NYC	New York city	1,150,744	451,051	1,722,350
Cal	California	21,048	87,365	108,863

Dataset. We conduct experiments using various maps (Tokyo, New York city, and California). Table 5 summarizes each dataset. For the Tokyo and NYC datasets, the road network is extracted from OpenStreetMap³ and the PoI information is extracted from Foursquare. Each PoI is embedded on the closest edge in the same way as [10] and is associated with the Foursquare category trees. Note that the number of category trees in Foursquare is 10. For the Cal dataset, the road network and PoI information are available online⁴. The number of categories in the Cal dataset is 63⁵. For each dataset, we use distances based on longitude and latitude as edge weights and treat the graphs as undirected graphs. The graphs are implemented using adjacency lists.

For each dataset, we generate 100 searches, in which the size of a sequence is $|S_q|$. The start points are selected randomly from vertices in the maps. The categories of sequences are selected randomly from the leaf nodes in the category trees with the constraint that they have different category trees. Since the number of PoI vertices associated with each category is significantly biased, we select only categories that have a large number of PoI vertices.

Here, category similarity is calculated based on the *Wu and Palmer similarity measure* [19] and the semantic score is calculated as the product of the category similarities of the sequence members. Specifically, we calculate the category similarity and semantic score using the following equations:

$$\text{sim}(c, c') = \max_{c_i \in a(c')} \frac{2 \cdot d(c_m)}{d(c) + d(c')}, \quad (6)$$

$$s(\mathbf{R}) = 1 - \prod_{i=1}^{\min(|R|, |S_q|)} \text{sim}(c_{PR[i]}, c_{S_q}[i]), \quad (7)$$

where $a(c)$, $d(c)$, and c_m denote the set of ancestor categories of c (including c), the depth of c , and the deepest common ancestor category of c and c_i , respectively.

7.2 Overview of results

First, we present an overview of the performance of all algorithms. Figure 3 shows the response time with various category sequence sizes, and Table 6 shows the RSS for a category sequence of size four. Here, “BSSR w/o Opt” denotes BSSR without optimization techniques. In Figure 3, there are missing bars for the case of size of sequence 5, because the executions were not finished after a month.

BSSR achieves the least response time with all datasets and reduces the search space by exploiting the branch-and-bound algorithm and the proposed optimization techniques. By comparing BSSR and BSSR w/o Opt, we confirm that the optimization techniques increase efficiency. When the size of the category sequence is small, PNE finds SkySRs efficiently because it can search for sequenced routes efficiently if the category sequence size is small. On the other hand, as category sequence size increases, the response time of PNE and Dij increases significantly.

If the category sequence size is large, BSSR achieves better performance than PNE and Dij even if we do not use optimization techniques. By comparing Dij to PNE, it can be seen that their performance depends on the datasets and the category sequence size. Although the PNE approach was proposed to be a more sophisticated algorithm than the Dijkstra-based solution [16], PNE requires more time than Dij for the NYC and Cal datasets, which implies that it is not effectively robust to datasets. In terms of RSS, BSSR and PNE achieve nearly the same performance. These two algorithms do not store many routes in the priority queue; therefore, RSS is highly dependent on the graph size. On the other hand, as Dij stores many routes in the priority queue, RSS is significantly larger than those of the other algorithms. Although we do not show the routes returned by each algorithm due to space limitations, all algorithms output the same routes. As a result, BSSR achieves the fastest response time with small memory usage without sacrificing the exactness of the result.

7.3 Optimization Techniques

The optimization techniques improve the efficiency of BSSR. Here, we evaluate each optimization technique.

Initial Search: We show the search spaces with and without an initial search for the first modified Dijkstra algorithm to evaluate the effect of the initial search. Moreover, we evaluate NNinit in terms of response time. Table 7 shows the weight sum, which

Table 8: Effect of priority queue for various $|S_q|$

Dataset	Approach	2	3	4	5
Tokyo	Proposed	3750	17600	112000	397000
	Distance-based	3890	23500	189000	1760000
NYC	Proposed	13800	108000	172000	637000
	Distance-based	14800	165000	444000	1520000
Cal	Proposed	4900	24800	84900	383000
	Distance-based	5300	34900	168000	899000

represents the search space, the response time of NNinit, and the number of sequenced routes found by NNinit for various category sequence sizes. In addition, we show the ratio of the length score of the sequenced route with the largest semantic score among the sequenced routes found in the initial search to the length score of the sequenced route whose semantic score is 0 in the initial search. The weight sum with the initial search is significantly smaller than that without the initial search. We can avoid traversing the whole graph using the initial search; thus, this can significantly reduce the search space of BSSR. Moreover, since the response time of NNinit is significantly less than that of BSSR (Figure 3), we confirm that NNinit can reduce the search space efficiently. Note that the number of sequenced routes found by the initial search is not large. On the other hand, the length score of the sequenced route with the largest semantic score is much smaller than that of the sequenced route whose semantic score is 0. As a result, NNinit reduces the search space significantly without increasing total response time.

Tightening Upper Bound: The priority queue aims at efficiently tightening the upper bound to reduce the search space. Here, we show the total number of vertices visited by BSSR, which is highly related to the response time. Table 8 shows the total number of vertices visited by the proposed priority queue and distance-based priority queue for various category sequence sizes. The number of vertices visited by the proposed priority queue is less than that of the distance-based priority queue. In particular, as the size of the category sequences increases, the performance gap increases because, as the category sequence size increases, the distance-based priority queue cannot find sequenced routes efficiently. Thus, the upper bound is rarely updated. On the other hand, the proposed priority queue can update the upper bound efficiently because the route with the largest size is dequeued preferentially. Thus, the proposed priority queue is more suitable than the distance-based approach for finding SkySRs.

Tightening Lower Bound: To tighten the lower bound, we propose two types of possible minimum distances, i.e., semantic-match and perfect-match minimum distances. If the minimum possible distance is large, we can prune routes even if the routes

Figure 4: Effect of minimum possible distances

(a) Tokyo

(b) NYC

(c) Cal

Figure 5: Effect of on-the-fly caching for various $|S_q|$

Figure 6: Number of SkySRs for various $|S_q|$

include a small number of PoI vertices. Figure 4 shows the ratios of the possible minimum distances to the sum weights of the initial search when we set the category sequence size to five. The semantic-match and perfect-match minimum distances in the Tokyo dataset effectively reduce the search space by tightening the lower bound. However, different from the Tokyo dataset, the possible minimum distances in the NYC and Cal datasets are small. Since the PoI vertices in the two datasets are relatively concentrated in a small area, the possible minimum distances become small. The effect of the possible minimum distances highly depends on the skews of locations of the PoI vertices.

On-the-fly Caching: On-the-fly caching can reuse the results of former modified Dijkstra algorithm executions; thus, the number of executions of the Dijkstra algorithm decreases. Figure 5 shows the numbers of executions of modified Dijkstra algorithms by BSSR with all optimization techniques and those except for on-the-fly caching. The number of executions of the Dijkstra algorithms decreases using on-the-fly caching. In particular, when the category sequence size increases, the performance gap increases because, as the category sequence size increases, we have more opportunities to reuse former results. Thus, we confirm that on-the-fly caching is effective to reduce the number of executions of the Dijkstra algorithms.

7.4 Number of skyline sequenced routes

Figure 6 shows the number of SkySRs obtained with each dataset for various $|S_q|$. As shown, the Cal dataset returns the largest number of SkySRs. The response time and RSS obtained with the Tokyo and NYC datasets are much greater than those of the Cal dataset, which implies that the number of SkySRs does not affect response time and RSS significantly. Moreover, if we use a complete real-world dataset, we may not require a ranking function because the number of SkySRs would be small.

Table 9: Example SkySRs in Tokyo

Distance	Sequenced route
7451 meters	Beer Garden → Sushi Restaurant → Sake Bar
1295 meters	Bar → Sushi Restaurant → Sake Bar

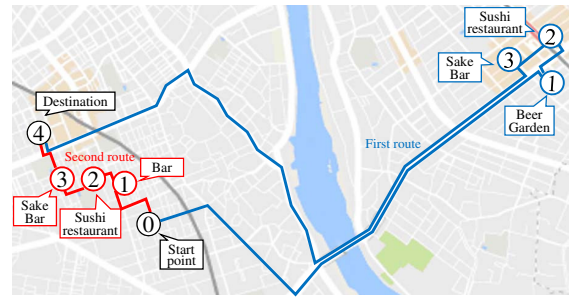

Figure 7: Visualization of routes in Tokyo: black circles (with 0 and 4) denote a start point and a destination, respectively. Blue and red circles denote sequences of PoIs for the first and second routes in Table 9, respectively, and their numbers indicate the order of PoIs to be visited.

7.5 Usecase

We show an example of SkySRs in Tokyo. We assume that we plan to go to places for dinner and drinks. We want to visit a “Beer garden”, a “Sushi restaurant”, and a “Sake bar” from our current location and finally go to our hotel. Table 9 and Figure 7 show two representative SkySRs from the four identified SkySRs. Note that the other two routes are similar to either of the representative routes. In the Foursquare category trees, “Bar” includes “Beer Garden” and “Sake bar”, and “Japanese restaurant” includes “Sushi restaurant”. Thus, we find routes using “Bar” and/or “Japanese restaurant”. The second route is much shorter than the first route that perfectly matches the user requirement, and the difference between them is only whether they pass a “Bar” or “Beer garden”. The best route depends on the users and situations (e.g., weather); thus, we confirm that SkySRs are useful to help users make decisions.

8 USER STUDY

We developed a prototype SkySR query service⁶ using OpenStreetMap and the Santander Open Data platform from Santander, Spain⁷. Figure 8 shows a screenshot of the prototype system, which outputs one of the SkySR route. We performed a test in July, 2017. To gather users for this test, the Santander municipality arranged meetings with different groups of people

⁶<https://ss.festival.ckp.jp/OuRouteSuggestion/dispSearchRoute/index>. The default language is Spanish.

⁷<http://datos.santander.es>

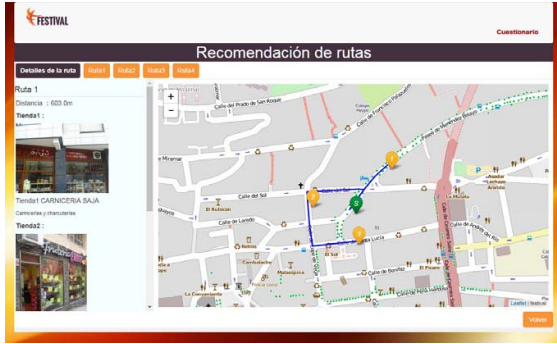

Figure 8: Screenshot of the prototype system

Figure 9: Ratios of answers for each question

to present the service: municipal staff (computing, convention and tourism municipal services), students from vocational training departments who are developing webpages and apps, and citizens. We also provided a leaflet that shows the concept of the SkySR query and how to use the service. In this test, users freely used the service and answered a questionnaire (25 respondents). The questionnaire included the following three questions.

Q1 What do you think about this service?

Answer. 1. I love it, 2. I like it, 3. I do not like it.

Q2 Would you recommend it to anyone?

Answer. 1. Yes, 2. Maybe, 3. No.

Q3 Do you think that it is a good idea for the city: citizens, tourists, commercial sectors?

Answer. 1. Yes, 2. Maybe, 3. No.

We summarize the ratios of answers for each question in Figure 9. As shown, more than 80% of the users liked the service. In addition, the questionnaire shows that the service is valuable for the city. From the user experiment, we confirm that the SkySR query is useful for users and cities.

9 CONCLUSION

In this paper, we have first introduced a semantic hierarchy for trip planning. We then proposed the skyline sequenced route (SkySR) query, which finds all preferred routes from a start point according to a user's PoI requirements. In addition, we have proposed an efficient algorithm for the SkySR query, i.e., BSSR, which simultaneously searches for all SkySRs by a single traversal of a given graph. To optimize the performance of BSSR, we proposed four optimization techniques. We evaluated the proposed approach using real-world datasets and demonstrated that it comprehensively outperforms naive approaches in terms of response time without increasing memory usage or sacrificing the exactness of the result. Moreover, we developed a SkySR

query service using open data, and conducted a user test, which confirmed that SkySR queries are useful for both users and cities.

In future work, we would like to extend the proposed approach in several directions. First, because we assume a forest structure for the category classification in this paper, a more complex classification may provide better granularity. Second, because we have not used any preprocessing techniques such as indexing, we plan to propose a suitable preprocessing method for the SkySR query. Finally, although the SkySR query proposed in this paper considers two scores (length and category similarity), it could be extended to consider many attributes of a PoI (e.g., text, keywords, and ratings) and the cost/quality of a graph (e.g., route popularity, tolls, and the number of traffic lights).

ABSTRACT

Mutual Information (MI) is an established measure for the dependence of two variables and is often used as a generalization of correlation measures. Existing methods to estimate MI focus on static data. However, dynamic data is ubiquitous as well, and MI estimates on it are useful for stream mining and advanced monitoring tasks. In dynamic data, small changes (e.g., insertion or deletion of a value) may often invalidate the previous estimate. In this article, we study how to efficiently adjust an existing MI estimate when such a change occurs. As a first step, we focus on the well-known nearest-neighbor based estimators for static data and derive a tight lower bound for their computational complexity, which is unknown so far. We then propose two dynamic data structures that can update existing estimates asymptotically faster than any approach that computes the estimates independently, i.e., from scratch. Next, we infer a lower bound for the computational complexity of such updates, irrespective of the data structure and the algorithm, and present an algorithm that is only a logarithmic factor slower than this bound. In absolute numbers, these solutions offer fast and accurate estimates of MI on dynamic data as well.

1 INTRODUCTION

Motivation. Finding and quantifying dependencies between variables is an essential task in data analysis. Conventional methods to detect (in)dependent attributes, like correlation coefficients and covariance matrices, are limited in the types of dependencies they detect. *Mutual Information* (MI) in turn is a notion from Information Theory that captures both linear and arbitrary non-linear dependencies. However, MI is defined on the probability density of the data. This makes exact computation impossible on samples. Nevertheless, existing MI estimators yield good results even for small samples [13]. In consequence, a wide range of applications, such as Feature Selection [22], Text Analysis [7] and Computer Vision [23], uses MI.

A popular choice are estimators based on nearest-neighbor distances [9, 16, 17]. This is because such estimators essentially are non-parametric and yield very good results [13, 14, 21, 29]. Nearest-neighbor based estimation of MI is often perceived as equivalent to the concrete estimation formula by Kraskov et al. (KSG)[17]. However, the KSG is just one estimation formula for MI using the nearest-neighbor entropy estimator by Kozachenko and Leonenko [16]. There exists at least one other MI estimator using a different formula, while relying on the same entropy estimator (3KL)[9]. In the following, the term *estimator* names

concrete formulas that estimate the MI value (e.g., KSG, 3KL), and *nearest-neighbor based estimation* is the group of these estimators.

So far, algorithms to compute nearest-neighbor based MI estimates and thus their practical applications focus on static data. However, data streams are ubiquitous as well and also require suitable analysis methods. The problem studied in this article is nearest-neighbor based estimation of MI on dynamic data. In this setting, an elementary task called *update* is the incremental maintenance of an estimate when adding or deleting a point.

With dynamic data, scalability with the number of data points is crucial. A good, data-independent measure is the computational complexity of the respective algorithms. In order to evaluate the efficiency of a new solution, it also is important to know the complexity of the problem. That is, a lower bound for any algorithm that computes such estimates, independent of the concrete approach. So far, no lower bound for nearest-neighbor based MI estimation is known, be it for updating an existing estimate, be it for computing the estimate on static data.

Challenges. Designing the estimators envisioned with controlled complexity is challenging. Two reasons for this are as follows: First, while nearest-neighbor based estimation of entropy depends on distances to the nearest neighbor, this does not imply that it has the same computational complexity as nearest-neighbor search. Put differently, it may be possible to obtain the same results using different methodologies. Consequently, one must prove the complexity based only on the result and not hinge on the complexity of certain tasks that seem mandatory in the context at first sight, such as nearest-neighbor search.

Second, to design a dynamic data structure that answers certain queries faster than any static algorithm, it is necessary to identify expensive computations whose results are relatively easy to maintain in the presence of updates. This means that the time required to incrementally maintain the results after a change must be limited in all cases. But this is not obvious here. At the same time, availability of these results must significantly speed up the query.

Our Contributions. Our work focuses on the time required to maintain an estimate of MI on dynamic data. We concentrate on the computational efficiency of nearest-neighbor based estimators on static data and the implications for dynamic estimation. We present solutions for dynamic data that maintain an estimate with the same estimation quality as static estimators, but with less time required. Specifically, our contributions are as follows:

Computational complexity of nearest-neighbor based estimators. In Section 4 we provide a complexity analysis of nearest-neighbor based MI estimators. Using a proof by reduction, we establish a lower bound in the algebraic computation tree model for any algorithm estimating MI using 3KL or KSG. To our knowledge, we are the first to prove any lower bound for the time complexity of such estimators. The lower bounds we prove are tight. This means that there already exist algorithms that have this asymptotically

optimal running time. Additionally, we use this result to infer lower bounds for the maintenance of KSG and 3KL estimates on dynamic data.

Dynamic data structures. In this article, we present two dynamic data structures. The first one is DEMI, which estimates nearest-neighbor based MI on a dynamic data set, see Section 5. This data structure holds a set of data points and some intermediate computation results we use for the estimation. The data structure allows insertion and deletion of data points and querying the estimate using all data points stored. Both the 3KL and the KSG estimator can use this data structure. We prove that updating an estimate using DEMI is asymptotically faster than the lower bound for static estimates, i.e., computing the estimate from scratch. To our knowledge, we are first to present a way of maintaining a KSG estimate on dynamic data that requires asymptotically less time than static estimation and preserves the estimate without any approximation.

Near-optimal computation time. The second data structure we present, ADEMI, integrates existing state-of-the-art data structures and algorithms into DEMI to reduce computation time, see Section 6. While the structure does not offer a speedup when maintaining the KSG estimate, we can maintain the 3KL estimate in polylogarithmic time. In particular, we are only a logarithmic factor slower than the lower bound shown in Section 4.

Systematic experimental evaluation. Finally, we evaluate our approaches experimentally, using a broad variety of dependency types and noise levels, in Section 7. We show that both KSG and 3KL converge to the true MI values with a good rate of convergence. This is a stark contrast to another recently published estimator for MI on sliding windows [3]. Additionally, we show that our data structures perform very well when maintaining MI estimates on large samples.

2 FUNDAMENTALS

We begin by revisiting the foundations of MI and its estimation.

Mutual Information. Introduced by Shannon [26], the notion of *entropy* is a measure for the expected information from observing the value of a random variable X , noted as $H(X)$. The expected information for observed values of two random variables X and Y is the natural extension *joint entropy* $H(X, Y)$. This gives way to the notion of *Mutual Information*

$$I(X; Y) = H(X) + H(Y) - H(X, Y), \quad (1)$$

which describes the information shared between both variables. Using the definition of entropy for continuous random variables in Equation 1 yields the differential definition of MI

$$I(X; Y) = \int_Y \int_X p(x, y) \log \left(\frac{p(x, y)}{p(x)p(y)} \right) dx dy \quad (2)$$

where $p(x)$, $p(y)$ and $p(x, y)$ are the marginal and joint probability density functions of X and Y , respectively [8]. Using the natural logarithm, MI is then measured in the *natural unit of information* (nat).

Nearest-Neighbor based Estimation. Kozachenko and Leonenko [16] presented a nearest-neighbor based estimator for (joint) entropies for a given sample. They used the distance to the k -th nearest neighbor as a means to approximate the density of the distribution for that region. They also have proven that this method yields a consistent estimator for entropy independent of the choice of k . ‘Consistent’ means that, with increasing sample

Figure 1: Illustration of the notation used for the 3KL.

size, the estimate converges towards the true entropy value. Their method is as follows:

Let $Q = \{q_1, \dots, q_n\} \subseteq \mathbb{R}^d$ be a set of points in a d -dimensional euclidean space, and let $\epsilon_Q^k(q_i)$ be the distance between q_i and its k -th nearest neighbor in Q using the L_∞ -norm, also known as maximum distance. Using the notation by Kraskov et al. [17], the entropy estimator by Kozachenko and Leonenko [16] is

$$\hat{H}(Q) = \psi(n) - \psi(k) + \log(2^d) + \frac{d}{n} \sum_{i=1}^n \log(\epsilon_Q^k(q_i)), \quad (3)$$

where ψ is the digamma function. That is, $\psi(x) = \sum_{m=1}^{x-1} (\frac{1}{m}) - C$, for $x \geq 1$ with $C \approx 0.577$ being the Euler-Mascheroni-Constant.

We now say how this entropy estimator is used to estimate MI. Let $P = \{p_1 = (x_1, y_1), \dots, p_n = (x_n, y_n)\} \subseteq \mathbb{R}^2$ be a sample of a random variable with two attributes. Note that we use P for the sample whose MI value we are interested in. This may be the original, full data set as well as the set of the most recent points of a data stream or any other subsample. Additionally, let $X = \{x_1, \dots, x_n\}$ and $Y = \{y_1, \dots, y_n\}$ be the sets of all values of the respective attribute in the sample. We use $\epsilon_P^k(p_i)$, $\epsilon_X^k(x_i)$ and $\epsilon_Y^k(y_i)$ to refer to the distance of p_i , x_i and y_i to its k -th nearest neighbor in P , X and Y , respectively. Figure 1 illustrates an exemplary set P , with $k = 1$ and p_i , x_i and y_i marked as squares. Inserting Equation 3 into Equation 1 yields the MI estimator

$$\widehat{I_{3KL}}(P) = \psi(n) - \psi(k) + \frac{1}{n} \sum_{i=1}^n \log \left(\frac{\epsilon_X^k(x_i) \cdot \epsilon_Y^k(y_i)}{(\epsilon_P^k(p_i))^2} \right). \quad (4)$$

Because this estimator estimates each of the three entropies in Equation 1 separately with the estimator by Kozachenko and Leonenko, we call the estimator 3KL. This estimator has also been used by Evans [9] for MI estimation on static data. Additionally, because each term in Equation 1 is estimated using a consistent estimator, the 3KL also is a consistent estimator.

Varying numbers of nearest neighbors. A different approach to use Equation 3 for MI estimation was proposed by Kraskov et al. [17]. While the 3KL uses the same k when estimating $\hat{H}(X)$, $\hat{H}(Y)$ and $\hat{H}(P)$ to obtain a compact formula, Kraskov et al. adjust k for every point such that the logarithmic term is 0. The idea is to make the distances $\epsilon_P^k(p_i)$, $\epsilon_X^k(x_i)$ and $\epsilon_Y^k(y_i)$ of a point to its nearest neighbors in X , Y and P identical. To achieve this, the parameter k for $\epsilon_X^k(x_i)$ and $\epsilon_Y^k(y_i)$ has to be set accordingly and may be different for each point. Specifically, each nearest neighbor p_j of p_i in P should result in x_j being a nearest neighbor

Figure 2: Illustration of the notation used for the KSG.

of x_i in X and y_j being a nearest neighbor of y_i in Y . To this end, the k -th nearest neighbor distance $\epsilon_P^k(p_i)$ is determined and afterwards k_x and k_y for $\epsilon_X^{k_x}(x_i)$ and $\epsilon_Y^{k_y}(y_i)$ is set accordingly. Figure 2 features an illustration of the notation that follows, using the same exemplary set P and k as Figure 1. As before, the set kNN of k nearest neighbors of a point $p_i \in P$ using the L_∞ -norm is determined first. Let $\delta_x^k(p_i) = \max_{p_j \in kNN} |x_i - x_j|$ be the greatest distance between x_i and any other x -value among its k nearest neighbors. Then the *marginal count* $C_x^k(p_i)$ is the number of elements in X as close to x_i as this distance, i.e.,

$$C_x^k(p_i) = |\{x \in X \setminus \{x_i\} : |x_i - x| \leq \delta_x^k(p_i)\}|. \quad (5)$$

Another marginal count $C_y^k(p_i)$ is defined analogously using y_i and $\delta_y^k(p_i)$. When these marginal counts are used as k per point in the estimator $\hat{H}(X)$ and $\hat{H}(Y)$, the distances $\epsilon_X(x_i)$, $\epsilon_Y(y_i)$ and $\epsilon_P(p_i)$ in Equation 4 (mostly) cancel out. However, one has to adjust the formula for using a different k , i.e., the marginal counts, for each point. The resulting estimator, called KSG due to its inventors Kraskov, Stögbauer and Grassberger, is

$$\widehat{I}_{KSG}(P) = \psi(n) + \psi(k) - \frac{1}{k} - \frac{1}{n} \sum_{i=1}^n \psi(C_x^k(p_i)) + \psi(C_y^k(p_i)). \quad (6)$$

While there exist many other approaches to estimate MI, we focus on nearest-neighbor based estimation due to its performance in comparative studies [13, 14, 21, 29]. Because these studies consider only the KSG, we use the same distributions in Section 7 to assess the estimation quality of the 3KL.

Another point is that it is generally recommended [13, 14, 17] to use a small k , that is $k < 10$. The choice of k has only been studied extensively for the KSG but not for the 3KL. However, because Equation 3 is consistent for any k [16], the 3KL is the sum of three consistent estimators and thus consistent for any k as well. Consequently, we assume $k < 10$ in this work, i.e., k is a constant for asymptotic considerations.

3 RELATED WORK

Data Streams. Data streams, a constantly growing form of dynamic data, are ubiquitous. Because data streams grow over time, and memory and storage is limited, it is impossible to store all data points. This means that information is lost over time.

Nevertheless, there exist space-efficient estimators for entropy of discrete distributions on streams. With Equation 1, entropy estimators can also be used to estimate MI, but with accumulating error. The estimator of Chakrabarti et al. [5] provides multiplicative approximations of entropy on insert-only streams. In contrast, the estimator by Harvey et al. [10] offers multiplicative and

additive approximations of entropy on streams with insertions and deletions, but requires knowledge about the maximum length of the stream. However, both estimators are restricted to discrete distributions. Estimating MI on discrete distributions is easier, because their relative count of points is a good estimator for the probability. Estimating the density of continuous distributions in turn is not trivial.

The estimation of MI of continuous distributions on streams has received less attention. The MISE framework [12] offers estimates of MI between continuous variables for any time interval on data streams. While both MISE and our approach offer nearest-neighbor based MI estimation, the difference is as follows: Results with MISE are approximations of the KSG estimate for consecutive subsets of the data. We in turn provide exactly the estimates of KSG and 3KL on a dynamic data set. Maintaining an accurate KSG estimate for a dynamic set of data points, e.g., the last 1000 data points, would incur prohibitively high (and growing) resource consumption with MISE. This is because it cannot explicitly delete points. In consequence, the target application and the optimizations are too different to allow for a fair comparison.

Sliding Windows. A common approach to process data streams are sliding windows. Maintaining only a fixed number of points ensures a fixed problem size that allows for bounded resource consumption. By construction, this technique rules out the usage of any information outside the window, but allows for accurate computations on data within it. There already are very good general approaches for sliding-window aggregation [27]. However, no competitive MI estimator is known so far that can be aggregated and thus used with this framework. Most MI estimators have stronger relations to concrete items than to collective values, e.g., distances to the nearest neighbor instead of distances to the mean. In consequence, previous analytics tasks that use MI estimates over a sliding window [15, 24] had to recompute the estimate from scratch for each window.

There is little work regarding algorithmic optimization of the computation time for such tasks. A very recent work by Boidol and Hapfelmeier [3] has introduced an estimator that approximates the 3KL inside a sliding window. In contrast, our approach allows for arbitrary insertions and deletions, and we provide the exact results of the 3KL and KSG. To show the difference between their approximation and accurate 3KL estimates, we include their method in our experiments in Section 7.

Computational Complexity. There has been little research regarding the computational complexity of the KSG and 3KL. Several proposals to compute the KSG appear in the original KSG article [17] with the claimed time complexity $O(n)$ for their fastest, so-called “box-assisted” algorithm on smooth distributions. Vajmelka et al. [28] compare their own approach with the box-assisted algorithm and cite [25] for different conditions for a linear runtime of the box-assisted algorithm. In the end, the best universal time complexity of their presented algorithms is $\Theta(n \log n)$. The same complexity is given for the algorithm computing the 3KL by Evans [9]. In the following section we prove that this limit is not a coincidence, i.e., we prove that no algorithm computing these estimators can have a time complexity lower than $O(n \log n)$.

4 LOWER BOUNDS

In this section we present our first contribution, the lower bounds for computing and maintaining estimates using the KSG and 3KL.

All existing approaches to compute the 3KL and KSG follow the original description in the sense that they first compute the nearest neighbors of all points. In the case of the KSG, the marginal counts C_x^k and C_y^k are computed afterwards. However, it is not known if this is the only approach to compute $\widehat{I_{3KL}}(P)$ and $\widehat{I_{KSG}}(P)$, or if it is computationally optimal. For instance, there could be a different formula for either of these estimators that does not require explicit computation of the nearest neighbors. Consequently, the complexity of computing the 3KL and KSG can only be based on the result and not on intermediate steps such as determining the nearest neighbors. The problems whose complexities we want to study in general, i.e., without confinement to specific algorithms, are the following ones.

Problem 1 (3KL-ESTIMATION). For a set $P \subseteq \mathbb{R}^2$ of points, determine $\widehat{I_{3KL}}(P)$.

Problem 2 (KSG-ESTIMATION). For a set $P \subseteq \mathbb{R}^2$ of points, determine $\widehat{I_{KSG}}(P)$.

In the following, we show the complexity of Problem 1. By reducing a problem with known complexity to 3KL-ESTIMATION, we prove that it has a lower bound of $\Omega(n \log n)$ in the algebraic computation tree model [1]. For brevity, all formal proofs in this article are available in Appendix A. We use the algebraic computation tree model because it allows us to prove bounds without assuming any statistical properties of the data. This is important because we want general-purpose estimation of MI. If knowledge regarding the data or its distribution was known, it could be used to model the density function in Equation 2.

THEOREM 4.1. *The problem 3KL-ESTIMATION has time complexity $\Omega(n \log n)$.*

PROOF. The formal proof is available in Appendix A.1. \square

This lower bound matches the running time of the algorithm presented by Evans [9] to solve 3KL-ESTIMATION. Consequently, this algorithm is already asymptotically optimal, and the lower bound is tight.

COROLLARY 4.2. *The computational complexity of 3KL-ESTIMATION is $\Theta(n \log n)$.*

We use the same approach to prove a lower bound for KSG-ESTIMATION. With the algorithms presented by Vejmelka et al. [28] this lower bound is tight as well.

THEOREM 4.3. *The problem KSG-ESTIMATION has a time complexity in $\Omega(n \log n)$.*

PROOF. The formal proof is available in Appendix A.2. \square

COROLLARY 4.4. *The computational complexity of KSG-ESTIMATION is $\Theta(n \log n)$.*

As a next step, we consider dynamic data. The distinctive feature of dynamic data is that the data changes over time. For a set P of points, all changes can be modeled using insertion of new points and deletion of existing points. For instance, moving a point from (x, y) to (x', y') can be modeled with one deletion of (x, y) and one insertion of (x', y') . To maintain an estimate of MI with the 3KL or KSG, we need to adjust the estimate according to such insertions or deletions. We see this as a problem for a dynamic data structure and thus allow storage of some auxiliary information about P , noted as *state* S_P of a dynamic data structure. The formal problem is then:

Problem 3 (3KL-UPDATE). Let $P \subseteq \mathbb{R}^2$ be a set of points, S_P the state for P and $p \in \mathbb{R}^2$ a point. Determine $\widehat{I_{3KL}}(P \cup \{p\})$ and $S_{P \cup \{p\}}$ if p is inserted and $\widehat{I_{3KL}}(P \setminus \{p\})$ and $S_{P \setminus \{p\}}$ if p is deleted using only S_P and p .

Problem 4 (KSG-UPDATE). Let $P \subseteq \mathbb{R}^2$ be a set of points, S_P the state for P and $p \in \mathbb{R}^2$ a point. Determine $\widehat{I_{KSG}}(P \cup \{p\})$ and $S_{P \cup \{p\}}$ if p is inserted and $\widehat{I_{KSG}}(P \setminus \{p\})$ and $S_{P \setminus \{p\}}$ if p is deleted using only S_P and p .

Because these problems can be used to solve 3KL-ESTIMATION and KSG-ESTIMATION, respectively, we can use the previous results to infer lower bounds for their time complexities. If we start with an empty set P and incrementally insert n points, the total time required cannot generally be asymptotically faster than $\Omega(n \log n)$ by Theorem 4.1 and Theorem 4.3. Because this includes n insertions, the time complexity of individual insertions is in $\Omega(\log n)$.

COROLLARY 4.5. *The problem 3KL-UPDATE has a time complexity in $\Omega(\log n)$.*

COROLLARY 4.6. *The problem KSG-UPDATE has a time complexity in $\Omega(\log n)$.*

In this section we have established formal problem descriptions for the tasks of estimating and maintaining MI estimates using the 3KL and KSG. Furthermore, we have proven lower bounds for the time required to solve these problems. These bounds are tight for computing estimates on static data. This means that no asymptotic speed-up is achievable. In contrast, we are not aware of any data structures or algorithms that solve the problems of maintaining 3KL or KSG estimates when points are inserted or deleted. In the following sections, we present two data structures for these tasks, evaluate their time complexity and compare them to the lower bounds presented in this section.

5 ESTIMATING MUTUAL INFORMATION ON DYNAMIC DATA

Naturally, the simplest solution to KSG-UPDATE and 3KL-UPDATE is storing exactly P in S_P and computing $\widehat{I_{3KL}}(\cdot)$ and $\widehat{I_{KSG}}(\cdot)$, respectively, with every change. The result from the previous section is that any such approach would require $\Omega(n \log n)$ time for 3KL-UPDATE and KSG-UPDATE. In the following we show that this is not optimal and present a more efficient solution.

We propose the data structure DEMI (Dynamic Estimation of Mutual Information) that focuses on updating an estimate of the 3KL or KSG for a single insertion or deletion. First, we present how this data structure works with 3KL estimates. In Section 5.2 we describe the differences when maintaining a KSG estimate. In more detail, we describe the changes to the 3KL estimate that can occur by inserting or deleting a point. Then we describe which information our data structure stores and how it determines the changes in the 3KL estimate efficiently. Lastly, we evaluate the space complexity of our data structure as well as the time complexity of adding or deleting a point.

5.1 Updating 3KL Estimates

Let $P = \{p_1 = (x_1, y_1), \dots, p_n = (x_n, y_n)\} \subseteq \mathbb{R}^2$ be the set of points in our sample and let $X = \{x_1, \dots, x_n\}$ and $Y = \{y_1, \dots, y_n\}$ be the set of values per attribute. When we insert a point $p_{n+1} = (x_{n+1}, y_{n+1}) \in \mathbb{R}^2$, let $P' = P \cup \{p_{n+1}\}$, $X' = X \cup \{x_{n+1}\}$ and $Y' = Y \cup \{y_{n+1}\}$ be the sets including

Data Structure 1: DEMI

```
struct {  
  | real  $x, y$   
  | real  $\epsilon_p^k, \epsilon_X^k, \epsilon_Y^k$   
} DemiPoint;  
  
struct {  
  | DemiPoint[ ]  $P_D$   
  | BST<DemiPoint*>  $T_x, T_y$   
  | real  $base, sum$   
} state;
```

p_{n+1}, x_{n+1} and y_{n+1} , respectively. Considering Equation 4, the change from $\widehat{I_{3KL}}(P)$ to $\widehat{I_{3KL}}(P')$ consists of three partial changes:

- (1) $\psi(n)$ increases to $\psi(n+1) = \psi(n) + \frac{1}{n}$,
- (2) the arithmetic mean includes $n+1$ logarithms instead of n ,
- (3) and the nearest-neighbor distances $\epsilon_p^k(p_i)$, $\epsilon_X^k(x_i)$ and $\epsilon_Y^k(y_i)$ may change for any $i \in \{1, \dots, n\}$.

While Change (1) is trivial, Change (2) requires the computation of $\epsilon_p^k(p_{n+1})$, $\epsilon_X^k(x_{n+1})$ and $\epsilon_Y^k(y_{n+1})$. However, Change (3) could require the re-evaluation of all nearest-neighbor distances. Clearly, these changes apply analogously if p_1 is removed from P instead of inserting p_{n+1} . Following these observations, we propose a dynamic data structure that determines these changes efficiently and evaluate its computation complexity.

Overview. Our data structure, DEMI, is given in Data Structure 1. For each point $p_i \in P$ of our sample, we store its attributes x_i, y_i and k -th nearest-neighbor distances $\epsilon_p^k(p_i)$, $\epsilon_X^k(x_i)$ and $\epsilon_Y^k(y_i)$ as a *DemiPoint*. In addition, we store references to all DemiPoints, ordered by the x -component and y -component of the point, in binary search trees (BST) T_x and T_y , respectively. Using self-balancing BST like red-black-trees, we can insert, delete and search items in logarithmic time. Additionally, we also maintain the values $base = \psi(|P|) - \psi(k)$ and $sum = \sum_{i=1}^n \log \left(\frac{\epsilon_X^k(x_i) \cdot \epsilon_Y^k(y_i)}{(\epsilon_p^k(p_i))^2} \right)$. The collection of all stored data is the state S_P of our data structure for the sample P . Because we store a constant amount of information per point, the space complexity of DEMI is $\Theta(n)$. Given State S_P , one can query the 3KL estimate on the set P in constant time as $\widehat{I_{3KL}} = base + \frac{sum}{|P|}$. However, this data structure requires adjustment of S_P after every change of P .

Insertion Algorithm. To insert a point p_{n+1} into a state S_P , illustrated in Algorithm 2, we distinguish two phases of the update. First (Lines 1-6), we add p_{n+1} as a DemiPoint to P_D and update $base$ and sum accordingly. Second (Lines 7-18), we determine which nearest-neighbor distances change and adjust sum according to the changes. We now describe these steps in more detail, together with the computational complexity of elementary operations, to allow for an easier evaluation. We discuss possible improvements in Section 6.

To add p_{n+1} to S_P , we first compute its k -th nearest neighbor in P' by linear search and derive the k -th nearest-neighbor distance $\epsilon_p^k(p_{n+1})$ ($O(n)$, Line 1). To determine the k -th nearest neighbor distances $\epsilon_X^k(x_{n+1})$ and $\epsilon_Y^k(y_{n+1})$ we can use the binary search tree and evaluate the distance to the next k and preceding k elements ($O(k \cdot \log n)$, Line 2). With this information we construct the DemiPoint for p_{n+1} and insert it into P_D ($O(1)$,

Algorithm 2: INSERT(S_P, p_{n+1})

```
1 Compute  $\epsilon_p^k(p_{n+1})$   $O(n)$   
2 Compute  $\epsilon_X^k(x_{n+1})$  and  $\epsilon_Y^k(y_{n+1})$   $O(k \cdot \log n)$   
3 Insert  $p_{n+1}$  into  $P_D$   $O(1)$   
4 Reference  $p_{n+1}$  in  $T_x, T_y$   $O(\log n)$   
5  $base \leftarrow base + \frac{1}{n}$   $O(1)$   
6  $sum \leftarrow sum + \log \left( \frac{\epsilon_X^k(x_{n+1}) \cdot \epsilon_Y^k(y_{n+1})}{(\epsilon_p^k(p_{n+1}))^2} \right)$   $O(1)$   
7  $A \leftarrow \{p_i \in P: \max(|x_i - x_{n+1}|, |y_i - y_{n+1}|) < \epsilon_p^k(p_i)\}$   $O(n)$   
8  $B \leftarrow \{p_i \in P: |x_i - x_{n+1}| < \epsilon_X^k(x_i)\}$   $O(n)$   
9  $C \leftarrow \{p_i \in P: |y_i - y_{n+1}| < \epsilon_Y^k(y_i)\}$   $O(n)$   
10 forall  $p_i \in A$  do  
11   | Compute  $\epsilon_p^k(p_i)$   $O(|A| \cdot n)$   
12   |  $sum \leftarrow sum + \log((\epsilon_p^k(p_i))^2) - \log((\epsilon_p^k(p_i))^2)$   $O(|A|)$   
13 forall  $p_i \in B$  do  
14   | Compute  $\epsilon_X^k(x_i)$   $O(|B| \cdot k \cdot \log n)$   
15   |  $sum \leftarrow sum - \log(\epsilon_X^k(x_i)) + \log(\epsilon_X^k(x_i))$   $O(|B|)$   
16 forall  $p_i \in C$  do  
17   | Compute  $\epsilon_Y^k(y_i)$   $O(|C| \cdot k \cdot \log n)$   
18   |  $sum \leftarrow sum - \log(\epsilon_Y^k(y_i)) + \log(\epsilon_Y^k(y_i))$   $O(|C|)$ 
```

Line 3). References to this point are then inserted into T_x and T_y ($O(\log n)$, Line 4). Then, we add the appropriate terms to $base$ and sum ($O(1)$, Lines 6 and 7), respectively.

Next, we find all previous nearest-neighbor distances that changed, by linear search. For each $i \in \{1, \dots, n\}$ we test whether p_{n+1}, x_{n+1} and y_{n+1} is closer than $\epsilon_p^k(p_i)$, $\epsilon_X^k(x_i)$ and $\epsilon_Y^k(y_i)$, respectively. This takes time in $O(n)$ and yields the sets A, B and C (Lines 7-9), respectively. For each point $p_i \in A$ we compute $\epsilon_p^k(p_i)$ analogously to $\epsilon_p^k(p_{n+1})$, which takes $O(n)$ each. Then we adjust sum accordingly ($O(1)$, Line 12). The sets A and B are handled in an analogous way, using $\epsilon_X^k(x_i)$ and $\epsilon_Y^k(y_i)$, respectively, instead (Lines 13-18). Note that these distances can be computed in time $O(k \cdot \log n)$ each, instead of $O(n)$, analogous to $\epsilon_X^k(x_{n+1})$ and $\epsilon_Y^k(y_{n+1})$.

Computational Complexity. The total runtime for inserting a point into our structure therefore is in $O(k \cdot n + |A| \cdot n + (|B| + |C|) \cdot k \cdot \log n)$. In the following theorem we show that $|A|, |B|$ and $|C|$ are in $O(k)$, because there are at most $8 \cdot k$ points for which p_{n+1} is one of the k nearest neighbors. Consequently, our insertion time is in $O(k \cdot n + k^2 \cdot \log n)$. Since k is suggested to be a small constant, e.g. less than 10, in the literature, we can assume k to be constant. This means that an insertion is in $O(n)$. This results in the total time complexity of $O(n)$. Because deleting a point changes the estimate analogously, we can use an analogous algorithm with the same complexity, i.e., $O(n)$.

THEOREM 5.1. *Let $P \subseteq \mathbb{R}^2$ be a set of points. For any point $p \in P$ there exist at most $8k$ points $q \in P$ such that p is one of the k nearest neighbors of q using the L_∞ -norm.*

PROOF. The formal proof is available in Appendix A.3. \square

As context for the update time of $O(n)$, Theorem 4.1 proves that any algorithm requires time in $\Omega(n \log n)$ to compute the 3KL from scratch. As a result, updating an estimate using DEMI is asymptotically faster than recomputing it, independently of the method used. In Section 6 we show how the time for updates

Data Structure 3: DEMI-KSG

```
struct {  
  real  $x, y$   
  real  $\epsilon_p^k, \delta_x^k, \delta_y^k$   
  int  $C_x^k, C_y^k$   
} DemiPointKSG;  
  
struct {  
  DemiPointKSG[ ]  $P_D$   
  BST<DemiPointKSG* >  $T_x, T_y$   
  real  $base, sum$   
} state;
```

on the 3KL can be improved even further. However, we will first discuss how we use the same approach to update KSG estimates.

5.2 Updating KSG Estimates

In this section, we describe how we achieve the same results, that is linear space and linear time for updates, using KSG estimates instead of 3KL estimates. As with the 3KL, we decompose the KSG estimate into $\widehat{I_{KSG}} = base + \frac{sum}{|P|}$. Comparing Equation 4 and Equation 6, it follows that $base$ and sum need to maintain different values when maintaining 3KL or KSG estimates. The change for $base$, that is $base = \psi(|P|) + \psi(k) - \frac{1}{k}$ instead of $base = \psi(|P|) - \psi(k)$, does not have any influence on the overall procedure. However, the change from $sum = \sum_{i=1}^n \log \left(\frac{\epsilon_x^k(x_i) \cdot \epsilon_y^k(y_i)}{(\epsilon_p^k(p_i))^2} \right)$ to $sum = -\sum_{i=1}^n \psi(C_x^k(p_i)) + \psi(C_y^k(p_i))$ has stronger implications. Most notably, we do not require explicit nearest neighbor distances per point but need marginal counts. We need to update a marginal count $C_x^k(p_i)$ if and only if the nearest neighbors of p_i in P changes, or a point (x, y) with $|x - x_i| \leq \delta_x^k(p_i)$ is inserted or deleted, see Figure 2. As a consequence, per point p_i we do not store $\epsilon_x^k(x_i)$ and $\epsilon_y^k(y_i)$ but the distances to the furthest x - and y -values among the k nearest neighbors in P , i.e., $\delta_x^k(p_i)$ and $\delta_y^k(p_i)$. Additionally we track the marginal counts $C_x^k(p_i)$ and $C_y^k(p_i)$. These slight changes are displayed in Data Structure 3. Furthermore, this means that we still store a constant amount of information per point, and the space complexity of the data structure remains $\Theta(n)$.

Updating the data structure follows the same principles as before, that is, we include the new point into the data structure and evaluate its impact on other marginal counts afterwards. In the following we describe the changes in specific steps between the update algorithm for 3KL estimates and KSG estimates, that is, Algorithm 2 and Algorithm 4.

Tracking marginal counts, instead of nearest-neighbor distances, per attribute allows for faster updates, because the counts only need increments and decrements ($O(1)$ each, Lines 16 and 18), instead of recomputation. However, a change of nearest neighbors does also invalidate the marginal counts and requires computing them and correct adjustment of sum (Lines 11-14). Computing marginal counts from scratch can be done with linear search ($O(n)$ each, Lines 2 and 13).

Regarding the time complexity of Algorithm 4, it is important to note that B and C are not sets of points with changed nearest neighbors. As a consequence, only the size of A has an upper bound of $8 \cdot k$ by Theorem 5.1. In the worst case, B and C contain all points, that is, $|B| \leq n$ and $|C| \leq n$. The total time complexity

Algorithm 4: INSERT-KSG(S_P, p_{n+1})

```
1 Compute  $\delta_x^k(p_{n+1}), \delta_y^k(p_{n+1})$  and  $\epsilon_{p'}^k(p_{n+1})$   $O(n)$   
2 Compute  $C_x^k(p_{n+1})$  and  $C_y^k(p_{n+1})$   $O(n)$   
3 Insert  $p_{n+1}$  into  $P_D$   $O(1)$   
4 Reference  $p_{n+1}$  in  $T_x, T_y$   $O(\log n)$   
5  $base \leftarrow base + \frac{1}{n}$   $O(1)$   
6  $sum \leftarrow sum - \psi(C_x^k(p_{n+1})) - \psi(C_y^k(p_{n+1}))$   $O(1)$   
7  $A \leftarrow \{p_i \in P: \max(|x_i - x_{n+1}|, |y_i - y_{n+1}|) < \epsilon_{p'}^k(p_i)\}$   $O(n)$   
8  $B \leftarrow \{p_i \in P: |x_i - x_{n+1}| < \delta_x^k(p_i)\}$   $O(n)$   
9  $C \leftarrow \{p_i \in P: |y_i - y_{n+1}| < \delta_y^k(p_i)\}$   $O(n)$   
10 forall  $p_i \in A$  do  
11    $sum \leftarrow sum + \psi(C_x^k(p_i)) + \psi(C_y^k(p_i))$   $O(|A|)$   
12   Compute  $\delta_x^k(p_i), \delta_y^k(p_i)$  and  $\epsilon_{p'}^k(p_i)$   $O(|A| \cdot n)$   
13   Compute  $C_x^k(p_i)$  and  $C_y^k(p_i)$   $O(|A| \cdot n)$   
14    $sum \leftarrow sum - \psi(C_x^k(p_i)) - \psi(C_y^k(p_i))$   $O(|A|)$   
15 forall  $p_i \in B$  do  
16    $sum \leftarrow sum - \frac{1}{C_x^k(p_i)}$ ;  $C_x^k(p_i) \leftarrow C_x^k(p_i) + 1$   $O(|B|)$   
17 forall  $p_i \in C$  do  
18    $sum \leftarrow sum - \frac{1}{C_y^k(p_i)}$ ;  $C_y^k(p_i) \leftarrow C_y^k(p_i) + 1$   $O(|C|)$ 
```

therefore is $O(n + |A| \cdot n) = O(k \cdot n)$. As before, k is taken as constant, which yields the time complexity $O(n)$. This is asymptotically faster than recomputing the estimate by Theorem 4.3.

6 POLYLOGARITHMIC UPDATES

Because DEMI relies only on simple algorithms like linear search and binary search trees during insertions and deletions, faster solutions might exist. In this section we determine which parts of our insertion algorithm have a high computational cost and present solutions for these tasks. There are two factors that lead to the linear time complexity of Algorithm 2.

- (1) Computing the nearest neighbors, with linear search
- (2) Finding the points whose nearest neighbors changed by linear search

6.1 Geometric Structures

Computing the nearest neighbors. Computing the k nearest neighbors of a point is a classic problem of computational geometry, which has received a lot of research. While there exist many solutions, most of them are built for static data and are not compatible with the incremental changes in dynamic data. But there also exist solutions that allow for insertions and deletions. Chan [6] proposed a dynamic data structure that computes nearest neighbors in two-dimensional spaces with sub-linear times for insertion, deletion and queries. However, the computational complexity of deletions is $O(\log^6 n)$, which is quite high. Kapoor and Smid [11] provide an alternative based on dynamic range trees [30]. With dynamic fractional cascading [20] the time complexities for insertions, deletions and querying the nearest neighbor of a point are in $O(\log n \log \log n)$. To query two nearest neighbors, we can query one nearest neighbor, delete this point from the tree, query the new nearest neighbor and insert the deleted point. Querying the k nearest neighbors can thus easily be achieved through a sequence of k queries, $k - 1$ deletions, and $k - 1$ insertions, with total time in $O(k \cdot \log n \log \log n)$.

Finding the points whose nearest neighbors have changed. Finding all points whose nearest neighbors have changed is also a geometric problem, that is, finding the reverse nearest neighbors of the inserted or deleted point. For each point $p = (x, y)$ with nearest neighbor distance ϵ , all nearest neighbors of p (using the L_∞ -norm) are within the square $[x - \epsilon, x + \epsilon] \times [y - \epsilon, y + \epsilon] \subseteq \mathbb{R}^2$. To find all points whose nearest neighbors contain a point p' , the task is to determine which squares contain p' . One data structure to solve this problem is the segment tree by Bentley [2]. The technique of dynamic fractional cascading is also applicable for segment trees [20] and yields the time complexities for insertions and deletions in $O(\log n \log \log n)$. Queries require time in $O(\log n \log \log n + m)$, where m is the number of squares returned.

6.2 Improving DEMI

To achieve sublinear time complexity for updates, we integrate a two-dimensional dynamic range tree and a two-dimensional dynamic segment tree into DEMI. We call this the augmented version of DEMI (ADEMI). The insertion algorithm is nearly identical to Algorithm 2, except for changes in time complexities and insertions and deletions to the integrated tree structures. In consequence, we only mention the changes relative to Algorithm 2 in this section. The full data structure and insert algorithm can be found in Appendix B.

Using the dynamic range tree, Line 1 requires only time in $O(k \cdot \log n \log \log n)$, and Line 11 requires time in $O(|A| \cdot k \cdot \log n \log \log n)$. Using the dynamic segment tree, Line 7 can be done in time $O(\log n \log \log n + |A|)$. Additionally, B and C can only contain elements that are at most k positions before and after x_{n+1} and y_{n+1} in T_x and T_y , respectively. Consequently, Lines 8–9 can also be done using the binary search trees in time $O(k \cdot \log n)$.

Additionally, we need to maintain the integrated tree structures. Specifically, we insert p_{n+1} into the dynamic range tree and insert the square of its nearest neighbors, that is,

$$\begin{aligned} \text{square}(p_{n+1}, P') &= [x_{n+1} - \epsilon_{p'}^k(p_{n+1}), x_{n+1} + \epsilon_{p'}^k(p_{n+1})] \\ &\quad \times [y_{n+1} - \epsilon_{p'}^k(p_{n+1}), y_{n+1} + \epsilon_{p'}^k(p_{n+1})], \end{aligned} \quad (7)$$

into the dynamic segment tree. The dashed lines in Figure 1 illustrate this square. Both insertions require time in $O(\log n \log \log n)$. Finally, for each point $p_i \in A$ we delete its old square of nearest neighbors $\text{square}(p_i, P)$ from the dynamic segment tree and insert the new square $\text{square}(p_i, P')$. This requires time in $O(|A| \cdot \log n \log \log n)$.

For an overview of the new time complexity, the updated insertion algorithm can be found in Appendix B. Because $|A|, |B|, |C| \in O(k)$, the total time complexity of an insertion is $O(k^2 \cdot \log n \cdot \log \log n)$. As before, k can be assumed to be a small constant, which leads to an insertion time of $O(\log n \log \log n)$. Deleting a point is completely analogous to insertions in (A)DEMI, and the used tree structures have the same complexity for insertions and deletions. Consequently, deletions in ADEMI also have a deletion time of $O(\log n \log \log n)$. Since the time complexity of queries is in $O(1)$, ADEMI solves problem 3KL-UPDATE in time $O(\log n \log \log n)$. This means that ADEMI is a nearly optimal, since its time complexity is only a factor $\log \log n$ higher than the lower bound from Corollary 4.6.

The drawback of ADEMI is an increased space complexity. The space complexity of the two-dimensional range tree and segment tree are $O(n \log n)$ and $O(n \log^2 n)$, respectively. Additionally, the improvements to the time complexity cannot be used

when maintaining KSG estimates. This is because the number of points whose marginal counts change during an update has no bound lower than n . Additionally, the impact of incrementing or decrementing a marginal count on the overall estimate depends on the current count, which can be any value between k and n . As a consequence, it remains unclear whether any dynamic data structure can solve KSG-UPDATE in sublinear time, or whether there exists a stronger lower bound.

7 EXPERIMENTS

In this section we empirically validate the estimation quality and time efficiency of our approach. To this end, we use data with known MI values and show that the 3KL converges to these values even with small samples. We also do so for the KSG. For brevity we only present the results for $k = 4$, since this value offers good rates of convergence for both the KSG and 3KL and follows the general recommendation of small values for k . Additionally, we compare the runtimes for maintaining 3KL estimates using ADEMI, DEMI and repeated estimation from scratch (REFS). For REFS we compute Equation 4 repeatedly with a state-of-the-art static approach [9], i.e., using sorting and space-partitioning trees for nearest-neighbor searches. While we have already proven a clear hierarchy regarding their asymptotic scalability, the complexity classes neglect constant factors. So it remains interesting how their concrete runtimes compare.

Setup. All approaches are implemented in C++ and compiled using the Gnu Compiler (v. 5.4) with optimization (-O3) enabled. We use the non-commercial ALGLIB¹ implementation of KD-Trees as space-partitioning trees in REFS. We conduct all experiments on Ubuntu 16.04.2 LTS using a single core of an AMD Opteron™ Processor 6212 clocked at 2.6 GHz and 128GB RAM.

7.1 Data

For our evaluation, we use synthetic and real data sets. In particular, we use the dependent distributions with noise used for comparing MI estimators [13]. These distributions have a noise parameter σ_r , which we vary from 0.1 to 1.0. Thus, we use 10 distributions for each of these dependency types. Additionally, we use the uniform distributions used to compare MI with the maximal information coefficient [14] as well as independent uniform and normal distributions. As real data sets, we use sensor data of randomly charged and discharged batteries [4] and time series of household power consumption [18]. Monitoring MI on such data could be useful to monitor the condition of battery cells for maintenance or to infer knowledge about the behavior of the households inhabitants. In the following, we briefly describe the different distributions and data sets.

Linear. To construct the point $p_i \in P$, we draw the value x_i from the normal distribution $N(0, 1)$. Additionally, we draw some noise r_i from the normal distribution $N(0, \sigma_r)$, where σ_r is the noise parameter of the distribution. This yields the point $p_i = (x_i, x_i + r_i)$.

Quadratic. This distribution is generated analogously to the linear distribution, except that the point is $p_i = (x_i, x_i^2 + r_i)$.

Periodic. For each point $p_i \in P$, we draw the value x_i from the uniform distribution $U[-\pi, \pi]$. Additionally, we draw some noise r_i from the normal distribution $N(0, \sigma_r)$, where σ_r is the noise parameter. This yields the point $p_i = (x_i, \sin(x_i) + r_i)$.

¹ALGLIB (www.alglib.net), Sergey Bochkanov

Figure 3: An overview of the uniform distributions used.

Chaotic. This distribution uses the classical Hénon Map, that is,

$$\begin{aligned} h_{x_{i+1}} &= 1 - \alpha \cdot h_{x_i}^2 + h_{y_i} \\ h_{y_{i+1}} &= \beta \cdot h_{x_i}, \end{aligned}$$

with $\alpha = 1.4$, $\beta = 0.3$ and $(h_{x_0}, h_{y_0}) = (0, 0)$. For a point p_i we additionally independently draw noise r_{x_i}, r_{y_i} from the distribution $N(0, \sigma_r)$, where σ_r is the noise parameter. Each point $p_i \in P$ is then $p_i = (h_{x_i} + r_{x_i}, h_{y_i} + r_{y_i})$.

Uniform. The uniform distributions A to H we use are illustrated in Figure 3. Note that the striped areas contain twice as many points as the dotted areas. For these distributions, each striped area with size $0.25 \cdot 0.25$ contains 25% of all points, while dotted areas of the same size contain 12.5% of all points. The distribution A simply draws values v_i from $U[0,1]$ and constructs the points $p_i = (v_i, v_i)$.

Independent. Lastly, we use the distributions U_{IND} and N_{IND} , where each point consists of two values drawn independently and identically distributed from $U[0, 1]$ and $N(0, 1)$, respectively.

Battery Data. This data set, available at the NASA Prognostics Center of Excellence [4], monitors voltage, current and temperature of battery cells during random loads. We use the data corresponding to battery cell “RW9” and use each combination of the attributes as bivariate sample.

Power Consumption. This data set, available at the UCI Machine Learning Repository [18], monitors the power consumption of a household in France. We use each combination of *global active power*, *global reactive power* and *voltage* as a bivariate sample.

Data Precision. The nearest-neighbor based entropy estimator, and by consequence the 3KL and KSG, expects samples from continuous distributions and require samples without duplicate values. Because of the limited precision of the battery and the power consumption data, we add noise to the sample. Kraskov et al. also have observed this issue and recommend the addition of low intensity noise, e.g., a normal distribution with variance 10^{-10} , to eliminate duplicate points [17]. However, we think that filling the missing precision with uniform noise is a better compensation for rounded or imprecise data. Figure 4 illustrates both approaches with the number of duplicates per value of an imprecise data set in parentheses. For our experiments we use the second approach.

7.2 Quality of Estimation

To evaluate the quality of estimation, we use all data sets with well-defined MI values. That is, all synthetic data sets except the chaotic distributions, whose probability densities are unknown,

Figure 4: Avoiding duplicates in a sample by adding minimal noise (top) or filling the missing precision uniformly (bottom).

Figure 5: Average difference of estimates to true MI values depending on sample size.

and the uniform distribution A, whose MI is infinite. We use these distributions to evaluate the consistency and the rate of convergence of the KSG, 3KL and the estimator used by DIMID [3]. Specifically, we are interested in the difference between the estimated MI and true value for the distribution as well as the variance of estimates for samples of the same distribution. Since the behavior has turned out to be very homogeneous across the different distributions, we restrict our presentation to selected results.

Development with sample size. For each distribution we created samples with sample sizes between 10 and 10000 and 1000 repeats per size. Figure 5 graphs the average difference between the estimate and the true MI value of the respective distribution. Additionally, Figure 6 shows the standard deviation of estimates of the same distribution and sample size, averaged across all distributions. One can see in these diagrams, that both the 3KL and the KSG converge quickly to the true values and have only small variance. In contrast, the approximate estimator in DIMID has a strong variance and difference. We think the reason is the random projection used by that estimator. It may retain enough information such that estimates are comparable to each other, as shown in their work [3]. However, we think that the projection loses too much information regarding the joint probability density to allow for good MI estimates.

Different dependency types. We also studied whether the quality of estimation changes for different dependency types. As we have seen in the previous paragraph, both the 3KL and KSG are very consistent even with moderate sample sizes. As a result we will use a small sample size, i.e. 100, to highlight differences. Figure 7 shows the average estimation error and standard deviation of estimates using 3KL, KSG and DIMID for each dependency type. While the variance of both KSG and 3KL are comparable

Figure 6: Standard deviation of estimates depending on sample size.

Figure 7: Average difference (left) and standard deviation (right) of estimates to true MI values on distribution type.

for all dependency types, the difference to the true value is imbalanced for the KSG but not the 3KL. Unfortunately, we do not have any explanation for this difference. As before, we notice strong differences between the DIMID approximation and the results of KSG and 3KL.

7.3 Runtime Analysis

We have benchmarked runtimes of our data structures for all data sets. Because we are not aware of any competitor that offers good MI estimates on dynamic data, we compare our performance to naïve recomputation of the estimate when an update occurs. We compare the runtime to maintain 3KL estimates using DEMI and ADEMI as well as repeated recomputation (REFS). We use a slight simplification of the ADEMI trees, compared to the description in Section 6. Specifically, we did not implement dynamic fractional cascading and relied only on the technique of Willard [30] for insertion and deletion of nodes. The reason is that dynamic fractional cascading provides a small asymptotic benefit, i.e. reducing a factor $\log n$ to $\log \log n$, but requires a lot of overhead. As a result, the structure labeled ADEMI in this section has insertion and deletion time in $O(\log^2 n)$ instead of $O(\log n \log \log n)$.

By design, both DEMI and ADEMI require only constant time for querying the current MI value, but require more time to update the data structure during insertions and deletions. The repeated static estimation REFS has inverse properties, i.e., constant time insertions and deletions but expensive queries. To provide a good overview we use the task of monitoring the MI of a changing data set of fixed size. That is, each update consists of deleting one point, inserting a different point and querying

Figure 8: Average time for an update depending on sample size for the synthetic distributions.

Figure 9: Average time for an update depending on sample size for the used real data set.

the current MI estimate. For these experiments we averaged the time required per update using 1000 updates per distribution and sample size.

Figure 8 shows the average update time required across all synthetic distributions per sample size. The same graph based on the real data sets instead of the synthetic distributions is Figure 9. As expected, the time complexity of each approach translates directly to asymptotic scaling with sample sizes, that is, steepness of the curve in the double log plot. To highlight this, the graphs include different asymptotic functions with dashed and dotted lines. An interesting result is that ADEMI has by far the worst performance for small windows and by far the best performance for large ones. Our explanation is as follows: The maintenance of the range trees and even more so the segment trees is expensive, even if it scales favorably. For instance, when inserting a square into a two-dimensional segment tree, $8 \cdot (1 + \log n)$ nodes are created in the tree. This is a lot even for small n but does not increase significantly for large n .

7.4 Discussion

To summarize this section, we confirmed the estimation quality of 3KL and KSG across all dependency types tested. Additionally, we compared the performance of DEMI, ADEMI and REFS both on synthetic and real data. As expected, DEMI consistently outperforms the SE. The evaluation of ADEMI depends on the context and application. While it is slow for small window sizes, it barely slows down for larger sizes. On the one hand, this means that it is often recommendable to use DEMI if the data size is small. On the other hand, ADEMI can be used for very data-intensive

tasks such as monitoring high-throughput streams. A problem with stream monitoring often is the multiplicative cost of high temporal resolutions: A stream with frequent items permits less time to process a new item, and a window with fixed time length contains more items. This leads to increased time to process a new item. As we have seen, the second factor is nearly negligible when using ADEMI.

8 CONCLUSIONS

In this work we have studied the efficiency of estimating mutual information using nearest-neighbor distances. We have considered the estimator by Kraskov et al. [17](KSG) and the direct application of the entropy estimator [9, 16](3KL). We have investigated the computational complexity of these estimators on static data and have proven a tight lower bound for both in the algebraic computation tree model. Next, we have turned to the maintenance of 3KL and KSG estimates on dynamic data and have examined possible optimizations and limitations. We have inferred a lower bound for the computational complexity of this task. We also have presented two dynamic data structures DEMI and ADEMI that maintain 3KL and KSG estimates. We have proven that both data structures require asymptotically less time to update their estimate than the lower bound to recompute it. Additionally, for maintenance of 3KL estimates, the time complexity of ADEMI is near optimal. Finally, we have validated the performance of our approach empirically. We have shown that the 3KL has a good rate of convergence for various dependencies. We also have benchmarked our data structure using both synthetic and real data and have shown that ADEMI is very fast for large data sets.

Future Work. In this work we have focused on exact computations of nearest-neighbor based MI estimators for dynamic data. It remains open whether our approach offers the best trade-off between estimation quality and computation time.

For one, it would be interesting which results one could achieve by binning the data and using estimators for discrete distributions [5, 10]. However, it is unclear how the bin width should be chosen, given the evolving nature of a stream. If the bin width needs adjustment, this is computationally expensive or reduces the quality of estimation if there is no adjustment.

It would also be interesting to study which provable quality one might achieve with approximations. While there exist approximations of static estimators [3, 12], there are no bounds for additive or multiplicative errors. But these would be very important because there exists a lot of work comparing static estimators. In addition, empirical assessments of new estimators often cover only some of the dependencies that MI quantifies.

A FORMAL PROOFS

A.1 Proof of Theorem 4.1

THEOREM 4.1. *The problem 3KL-ESTIMATION has time complexity $\Omega(n \log n)$.*

PROOF. The proof is by reduction from the problem INTEGERELEMENTDISTINCTNESS. Given a multiset $A = \{a_1, \dots, a_n\}$ of integers, are there two indices $i \neq j$ such that $a_i = a_j$ are duplicates. The problem INTEGERELEMENTDISTINCTNESS has a known lower bound of $\Omega(n \log n)$ in the algebraic computation tree model [19]. For an instance A of INTEGERELEMENTDISTINCTNESS, we construct an instance of 3KL-ESTIMATION P as follows. For $a_i \in A$, the set P contains two points $p_i = (i, a_i + \frac{1}{4+i})$ and

Figure 10: An illustration of the construction of P in Appendix A.1.

$p_{n+i} = p_i + (0.25, 0.25)$. Note that p_i and p_{n+i} are closer than any other pair, because i and a_i are integers. Additionally, we add the offset $\frac{1}{4+i}$ to the y -coordinates, because duplicates in A would otherwise lead to a nearest-neighbor distance of 0 and thus $\log(0)$ in Equation 4. Figure 10 features an example for this construction for the INTEGERELEMENTDISTINCTNESS instance $A = \{1, 2, 4, 3, 1\}$. The point p_1 is highlighted as circle and its nearest-neighbor distances are highlighted.

CLAIM 1. *A contains a duplicate if and only if $\widehat{I}_{3KL}(P) \neq \psi(|P|) - \psi(1)$ for $k = 1$.*

SUBPROOF. Let $i, j \in \{1, \dots, n\}$ be two integers with $i \neq j$. Based on the construction of P , it follows that $|x_i - x_j| = |x_{n+i} - x_{n+j}| \geq 1$. Additionally, it is $|x_i - x_{n+i}| = |y_i - y_{n+i}| = 0.25$. Using the reverse triangle inequality, it is $|x_i - x_{n+j}| \geq |x_i - x_j| - |x_j - x_{n+j}| \geq 0.75$. This holds for any $i \neq j$, which means that p_i is the nearest neighbor of p_{n+i} and vice versa, because we use the L_∞ norm. As a consequence the nearest neighbor distances are $\epsilon_P^1(p) = 0.25$ for all $p \in P$ and $\epsilon_X^1(x) = 0.25$ for all $x \in X$. Note that this means that the nearest neighbor distances in P and X are independent of the existence of duplicates in A .

If A does not contain any duplicates, it follows that $|y_i - y_j| = |y_{n+i} - y_{n+j}| \geq \frac{4}{5}$, since A only contains integers and the difference between $\frac{1}{4+i}$ and $\frac{1}{4+j}$ is less than 0.2. By the same arguments as above it follows that $|y_i - y_{n+j}| \geq 0.55$ and that $\epsilon_Y^1(y) = 0.25$ for all $y \in Y$. We can then use these values in Equation 4, which yields:

$$\widehat{I}_{3KL}(P) = \psi(|P|) - \psi(1) + \frac{1}{|P|} \sum_{m=1}^{|P|} \log \left(\frac{0.25 \cdot 0.25}{(0.25)^2} \right) = \psi(|P|) - \psi(1). \quad (8)$$

Conversely, if A contains the duplicates $a_i = a_j$, it is $|y_i - y_j| = |\frac{1}{4+i} - \frac{1}{4+j}| \leq 0.2$ and $|y_i - y_{n+j}| \geq |0.25 - \frac{1}{4+j}|$ and thus $\epsilon_Y^1(y_i) \leq 0.2$. Additionally, because of $j \neq i$ it also is $\epsilon_Y^1(y_i) > 0$. It follows that

$$\log \left(\frac{\epsilon_Y^1(y_i) \cdot \epsilon_X^1(x_i)}{(\epsilon_P^1(p_i))^2} \right) < 0 \Rightarrow \frac{1}{|P|} \sum_{m=1}^{|P|} \log \left(\frac{\epsilon_X^1(x_m) \cdot \epsilon_Y^1(y_m)}{\epsilon_P^1(p_m)^2} \right) < 0 \quad (9)$$

and analogously to Equation 8 we obtain $\widehat{I}_{3KL}(P) < \psi(|P|) - \psi(1)$. This concludes the subproof. ■

It is clear that P can be constructed in time $O(|A|)$, which means $|P| \in O(|A|)$. After computing $\widehat{I}_{3KL}(P)$, the result is only compared to a sum over $|P|$ numbers, because $\psi(|P|) - \psi(1) = \sum_{m=1}^{|P|-1} \frac{1}{m}$ by definition of the digamma function. Note that this

Figure 11: An illustration of the construction of P in Appendix A.2.

reduction works analogously for any fixed $k > 0$ by placing $k - 1$ points evenly spaced on the diagonal between each pair p_i and p_{n+i} . Because k is fixed, the size of P increases only by a constant factor. Therefore, the complexity of the reduction is in $O(n)$. This means that determining $\widehat{I_{3KL}}(P)$ has a lower bound of $\Omega(n \log n)$. \square

A.2 Proof of Theorem 4.3

THEOREM 4.3. *The problem KSG-ESTIMATION has a time complexity in $\Omega(n \log n)$.*

PROOF. Similarly to the Proof of Theorem 4.1, see Appendix A.1, we reduce the problem to INTEGERELEMENTDISTINCTNESS. For any instance A of INTEGERELEMENTDISTINCTNESS, we construct an instance of KSG-ESTIMATION P as follows. For $a_i \in A$, the set P contains two points $p_i = (i, a_i)$ and $p_{n+i} = (i + 0.25, a_i + 0.25)$. We use 0.25 because it means that this pair of points is closer than any other pair, because i and a_i are integers. Figure 11 features an example for this construction for the INTEGERELEMENTDISTINCTNESS instance $A = \{1, 4, 2, 5, 3, 2\}$. The dashed lines in the figure illustrate the areas of the marginal counts $C_x^1(p_3)$ and $C_y^1(p_3)$.

CLAIM 2. *A contains a duplicate if and only if $\widehat{I_{KSG}}(P) \neq \sum_{m=1}^{|P|-1} \left(\frac{1}{m}\right) - 1$ for $k = 1$.*

SUBPROOF. Let $i, j \in \{1, \dots, n\}$ be two integers with $i \neq j$. Based on the construction of P , it follows that $|x_i - x_j| = |x_{n+i} - x_{n+j}| \geq 1$. Additionally, it is $|x_i - x_{n+i}| = |y_i - y_{n+i}| = 0.25$. Using the reverse triangle inequality, it is $|x_i - x_{n+j}| \geq |x_i - x_j| - |x_j - x_{n+j}| \geq 0.75$. This holds for any $i \neq j$, which means that p_i is the nearest neighbor of p_{n+i} and vice versa, because we use the L_∞ norm. As a consequence, the marginal counts $C_x^1(p)$ are 1 for all $p \in P$, independent of the existence of duplicates in A .

If A does not contain any duplicates, it follows that $|y_i - y_j| = |y_{n+i} - y_{n+j}| \geq 1$, since A only contains integers. By the same arguments as above it follows that $|y_i - y_{n+j}| \geq 0.75$ and that $C_y^1(p) = 1$ for all $p \in P$. We can then use these values in Equation 6 and because of $\psi(x) = \sum_{m=1}^{x-1} \left(\frac{1}{m}\right) - C$ it is:

$$\widehat{I_{KSG}}(P) = \psi(1) + \psi(|P|) - \frac{1}{1} - \frac{1}{|P|} \sum_{m=1}^{|P|} \psi(1) + \psi(1) = \sum_{m=1}^{|P|-1} \left(\frac{1}{m}\right) - 1 \quad (10)$$

Conversely, if A contains the duplicates $a_i = a_j$, it is $|y_i - y_j| = 0$ and $|y_i - y_{n+j}| = 0.25$ and thus $C_y^1(p_i) \geq 3$. Because of $\psi(x+1) = \psi(x) + \frac{1}{x} > \psi(x)$ for all $x \geq 0$, it is, analogously to Equation 10, $\widehat{I_{KSG}}(P) < \sum_{m=1}^{|P|-1} \left(\frac{1}{m}\right) - 1$. This concludes the subproof. \blacksquare

Figure 12: The partitioning of Q in Appendix A.3.

Figure 13: An example for Q_{RU} .

It is clear that P can be constructed in time $O(|A|)$, which means $|P| \in O(|A|)$. Note that this reduction works analogously for any fixed $k > 0$ by placing $k - 1$ points evenly spaced on the diagonal between each pair p_i and p_{n+i} . Because k is fixed, the size of P increases only by a constant factor. After computing $\widehat{I_{KSG}}(P)$, the result is only compared to a sum over $|P|$ numbers. Therefore the complexity of the reduction is in $O(n)$. This means that determining $\widehat{I_{KSG}}(P)$ has a lower bound of $\Omega(n \log n)$. \square

A.3 Proof of Theorem 5.1

THEOREM 5.1. *Let $P \subseteq \mathbb{R}^2$ be a set of points. For any point $p \in P$ there exist at most $8k$ points $q \in P$ such that p is one of the k nearest neighbors of q using the L_∞ -norm.*

PROOF. Let $p = (x, y) \in P$ be a point and $Q \subseteq P$ be the set of points such that for each point $q \in Q$, p is one of the k nearest neighbors of q . We separate Q into eight sets based on their relative location to p , as illustrated in Figure 12. There are four axis-aligned rays $Q_L, Q_R, Q_U, Q_D \subseteq Q$ centered at p such that points on any of these rays share one component with p and differ in the other one. Additionally, there are four quadrants $Q_{RU}, Q_{LU}, Q_{LD}, Q_{RD} \subseteq Q$ centered at p excluding the axis-aligned rays. Because p cannot be its own nearest neighbor, these eight sets partition Q . To prove the lemma we proceed to show that each of these eight sets contains at most k points.

Let $r = (x_r, y_r)$ be the most distant point to p in the axis-aligned ray Q_R , that is, $|x - x_r| = \max_{(x_i, y_i) \in Q_R} |x - x_i|$. Then all other points in Q_R are on the line between p and r and thus closer to r than p . This means that Q_R cannot contain more than k points, because p would not be a nearest neighbor of r otherwise. By symmetry, this result also holds for the sets Q_L, Q_U, Q_D .

Similarly, Let $r = (x_r, y_r)$ be the most distant point to p in the quadrant Q_{RU} and let Δ be that distance. More formally, it is

$$\Delta = \max(|x - x_r|, |y - y_r|) = \max_{(x_i, y_i) \in Q_{RU}} \max(|x - x_i|, |y - y_i|).$$

An exemplary illustration can be found in Figure 13 with the set $Q_{RU} = \{s, r\}$. For any other point $q_i = (x_i, y_i) \in Q_{RU}$ with $q_i \neq r$ it is $x < x_i \leq x + \Delta$ and $y < y_i \leq y + \Delta$, because r is the point most distant to p . Figure 13 illustrates this by delimiting the area in which all points of Q_{RU} lie with dashed lines. Because of $x_r > x$ and $y_r > y$, it follows that $|x_r - x_i| < \Delta$ and $|y_r - y_i| < \Delta$. This means that q_i is a nearest neighbor of r . Figure 13 shows this by highlighting the area of nearest neighbors of r with dotted lines. Analogously to the axis-aligned rays, Q_{RU} cannot contain more than k points, because p would not be a nearest neighbor of r otherwise. By symmetry, this result also holds for the sets Q_{LU}, Q_{LD}, Q_{RD} . \square

ABSTRACT

Cliques are commonly used for social network analysis tasks, as they are a good representation of close-knit groups of people. For this reason (as well as for others), the problem of enumerating, i.e., finding, all maximal cliques in a graph has received extensive treatment. However, considering only complete subgraphs is too restrictive in many real-life scenarios where “almost cliques” may be even more useful. Hence, the notion of an s -clique, a clique relaxation that allows every node to be at distance at most s from every other node, has been introduced. *Connected s -cliques* add the natural requirement of connectivity to the notion of an s -clique.

This paper presents efficient algorithms for finding all maximal connected s -cliques in a graph. We present a provably efficient algorithm, which runs in polynomial delay. In addition, we present several variants of the well-known Bron-Kerbosch algorithm for maximal clique generation. Extensive experimentation over both real and synthetic datasets shows the efficiency of our algorithms, and their scalability with respect to graph size, density, and choice of s .

1 INTRODUCTION

Maximal cliques have long been considered a key component in the analysis of social networks [34]. Cliques are indeed highly cohesive sets of nodes, and as such are used to detect close-knit overlapping communities [13, 29, 36]. For this reason (among others), there has been extensive work on algorithms for finding all maximal cliques in a given graph, e.g., [1, 6, 8, 11, 17].

While the notion of a clique captures a completely cohesive group of nodes within a graph, this definition is often overly restrictive. In practice, it is obvious that sets of nodes can represent cohesive groups even if several links are missing; for example, within a community not all pairs of people will be friends. In addition, as networks are often built from observation of empirical data, there may be real-life links that are missing within the data captured. Searching for groups of nodes that are cliques will miss highly related groups of nodes for which links have been omitted from the dataset. To overcome these limitations, relaxations to the notion of a clique have been studied [30].

One useful relaxation to the notion of a clique, called an s -clique, was introduced over 65 years ago [24] to describe and measure connectivity in social groups. Given a graph G , we say that a set of nodes U is an s -clique, where s is a (typically small) natural number, if every pair of nodes $u, v \in U$ is at distance at most s one from another in G . In particular, when $s = 1$, the notions of a clique and an s -clique coincide. An s -clique is *maximal* if it cannot be extended with additional nodes, while retaining the required distances property. Unlike cliques, s -cliques may be

Figure 1: Example of a small social network G .

unconnected. Connected s -cliques add the natural requirement of connectivity.

Example 1.1. Consider the example of a small social network G in Figure 1. Graph G contains six maximal cliques, namely $\{a, b, c\}$, $\{b, c, d\}$, $\{d, e, f\}$, $\{e, f, h\}$, $\{d, g\}$, $\{g, h\}$, where a is a shorthand for Ann, b is a shorthand for Bob, and so on. This graph contains three maximal 2-cliques $\{a, b, c, d\}$, $\{b, c, d, e, f, g\}$ and $\{d, e, f, g, h\}$. Intuitively, the 2-cliques seem to better capture the graph communities, as they are a bit coarser. They also highlight the fact that d is a bridge between the communities.

Graph G contains two maximal 3-cliques $\{a, b, c, d, e, f, g\}$ and $\{b, c, d, e, f, g, h\}$, which (by their symmetric difference) indicate the people who, if linked, could help merge the communities. Thus, such a link might be suggested to Ann and Hal. Finally, we note that there is a single maximal 4-clique in G , as the diameter of G is four.

This paper studies the problem of enumerating (i.e., finding) all maximal connected s -cliques in a graph. Maximal clique enumeration has been shown to be useful in other areas (beyond social network analysis), e.g., finding subgraphs common to a set of input graphs [19], genome mapping and protein clustering in bioinformatics [14, 25], clustering for wireless sensor networks [4], and statistical analysis of financial networks [5]. As s -cliques are relaxations of cliques, they allow significantly greater flexibility, and may be useful for the above applications, e.g., to find subgraphs that are “almost common” to input graphs (i.e., that appear in slight variations in the various input graphs), to integrate genome mappings based on very similar subportions or to cluster protein sequences while allowing more flexibly for missing information.

An algorithm for enumerating maximal connected s -cliques can be used for new and interesting applications, such as link prediction in social networks [22], since missing direct links in large s -cliques are prime candidates for link suggestion. Note that large cliques could not be used for this purpose, as they are missing no links at all, by definition. Similarly, another possible application would be to help identify hidden connections in a social network, by finding maximal s -cliques that may form unidentified communities. We leave the development of such applications to future work, and focus in this paper on algorithms for efficiently enumerating all maximal s -cliques from a given graph.

The main contributions of this paper are three new algorithms for enumerating all maximal connected s -cliques from a given graph G . While it may seem from Example 1.1 that graphs have a small (polynomial) number of maximal s -cliques, this is in fact not always the case. As we demonstrate later, a graph may have exponentially many maximal s -cliques. (This was already well known for $s = 1$, and is true for larger values of s as well.) Hence, we cannot hope to derive a polynomial time algorithm for the problem at hand, as it may take exponential time to simply print the output. Instead, our first algorithm guarantees polynomial delay between results, i.e., the time to produce the first result, between every pair of subsequent results, and from the final result until completion, is polynomial.

The other two algorithms we present are adaptations of the well-known Bron-Kerbosch method, originally developed for finding all maximal cliques, to the problem at hand. While Bron-Kerbosch clique enumeration does not run in polynomial delay, it is known to be the fastest method, in practice, for maximal clique enumeration (when used with some specific optimizations). Hence, adapting this method to s -cliques is of interest. Optimizations for our adaptations, including pivoting and checking for feasibility, are studied. Extensive experimentation, over both real and synthetic datasets, proves the efficiency of our techniques, as well as their suitability for use over social network data.

2 RELATED WORK

Due to their numerous uses, the problem of finding all maximal cliques of a graph has received extensive attention. In the worst case, there can be exponentially many maximal cliques in a graph. In fact, [26] shows that the maximal number of cliques in graph with n nodes is $O(3^{n/3})$. Thus, the focus is on finding maximal cliques in time that is efficient with respect to the input and output. One well-known algorithm is that of Bron-Kerbosch [6], which, with the *pivoting* improvement of [32], guarantees a worst-time complexity of $O(3^{n/3})$ for graphs of size n . Hence the total time spent is no worse than required to return all maximal cliques on the graph with the most possible cliques.

Additional work on maximal clique enumeration has focused on output-efficient algorithms, i.e., algorithms whose runtime is a function of the number of maximal cliques in the given input graph [1, 17]. Several works have studied enumeration over sparse graphs [7, 12], as such graphs tend to be common in practice. Recent work has also focused on maximal clique enumeration over uncertain graphs [38], and over massive networks [9, 11].

Enumeration of maximal graphs for several relaxations of the notion of a clique has also been studied. The problem of mining all maximal k -plexes was studied in [3, 35], and enumeration of maximal c -isolated cliques was studied in [15]. There has also been work on mining quasi-cliques (i.e., densest subgraphs) in a single graph [23, 33, 37], and over a set of graphs [16], as well as mining locally dense subgraphs [31].

Among clique relaxations, both quasi-cliques and s -clubs appear to be most related to s -cliques. Formally, *quasi-cliques* are parameterized by a value γ , i.e., a subset S of nodes in a graph G is a γ -quasi-clique if every node in S is connected to at least $\gamma(|S| - 1)$ nodes in S . It has been shown [16] that there is a strong relationship between the parameter γ , and the diameter of the induced subgraph of G on S . For example, if $\frac{1}{2} \leq \gamma \leq \frac{|S|-2}{|S|-1}$, then the induced subgraph on S will have diameter at most 2. At first glance, it would seem then that this property can be utilized to

enumerate (connected) s -cliques, e.g., by enumerating γ -quasi-cliques with an appropriate (s -dependent) choice of γ . In fact, this is not the case, and previous algorithms for γ -quasi-cliques do not enumerate s -cliques. The difference is subtle, as every pair of nodes in an s -club S is of distance at most s in G , but may be of larger distance in the graph induced by S .

A subset U of nodes in a graph G is an s -club, if the diameter of U is at most s , i.e., if there is a path between every two nodes in U that only traverses nodes in U , that is of length at most s . This definition is different from that of s -cliques, where the distance between nodes is determined by the shortest path in the entire graph G . Similar to the maximum clique problem, the problem of finding an s -club of maximum size is also NP-complete [2]. However, unlike cliques and s -cliques, s -clubs are not hereditary (i.e., a subgraph of an s -club is not necessarily an s -club), and indeed s -club maximality testing is NP-complete [28]. Since maximal s -clubs cannot be efficiently recognized, enumerating maximal s -clubs cannot be achieved in polynomial delay (unlike enumerating maximal connected s -cliques, as we show in this paper).

The enumeration problem for connected s -cliques has not yet been studied. However, the optimization problem for s -cliques, i.e., the NP-complete problem of finding an s -club of maximal size, was studied in [2]. Enumerating s -cliques with given labels, over a labeled graph, is also NP-complete problem, and is studied in [18]. Finally, [28] has shown that for graphs with some special properties, the notions of connected s -cliques and s -clubs coincide.

3 FORMAL FRAMEWORK

Graphs and Induced Subgraphs. We use G, H (possibly with subscripts or superscripts) to denote simple undirected graphs. We use $V(G)$ to denote the nodes of G and $E(G)$ to denote the edges of G . Note that an edge is a pair $\{v, u\}$ where v and u are two different nodes in $V(G)$.

We will often be interested in *induced subgraphs* of a given graph G . Formally, a subset of nodes $U \subseteq V(G)$ defines the *induced subgraph* $G[U]$ of G consisting of precisely the set of nodes U , and the edges in $E(G)$ that are incident only on nodes in U . In notation, we have $V(G[U]) = U$ and $E(G[U]) = E(G) \cap U^2$. We say that H is an induced subgraph of G if $H = G[U]$, for some U , and denote this fact by $H \sqsubseteq G$.

We use $dist_G(u, v)$ to denote the number of edges on the shortest path between u and v in G and $N_G^i(v)$ to denote the set

$$N_G^i(v) := \{u \mid dist_G(v, u) \leq i \text{ and } u \neq v\}$$

of the nodes at distance at most i from v in G . We use $N_G(v)$ for the special case where $i = 1$, i.e., $N_G(v)$ contains all direct neighbors of v . Extending this notation, we use $N_G^{v,i}(V)$ and $N_G^{\exists,i}(V)$ to denote the set of nodes at distance at most i from all and at least one, respectively, v in V , i.e.,

$$N_G^{v,i}(V) := \{u \mid \forall v \in V, dist_G(v, u) \leq i \text{ and } u \notin V\},$$

$$N_G^{\exists,i}(V) := \{u \mid \exists v \in V, dist_G(v, u) \leq i \text{ and } u \notin V\}.$$

If G is clear from the context, we will omit the subscript.

Example 3.1. Consider graph G from Figure 1. Let $V = \{e, h\}$. We have:

$$\begin{aligned} N^{\exists,1}(V) &= \{d, f, g\} & N^{v,1}(V) &= \{f\} \\ N^{\exists,2}(V) &= N^{\exists,1}(V) \cup \{b, c\} & N^{v,2}(V) &= N^{\exists,1}(V). \end{aligned}$$

Figure 2: Graph G' .

Cliques and s -Cliques. A set of nodes U in a graph G is a *clique* if all pairs $u, v \in U$ are adjacent one to another in G . Cliques are useful in many problem areas, as they represent fully cohesive portions of G . As discussed earlier, in many scenarios, the requirement that a set of nodes form a clique may be overly restrictive.

Previous work [30] has studied various relaxations of the notion of a clique. In the following, let s be an integer and U be a set of nodes in a graph G . We say that

- U is an s -clique if, for all $u, v \in U$, it holds that $\text{dist}_G(u, v) \leq s$.
- U is a *connected s -clique* if U is an s -clique and the induced graph $G[U]$ is connected.

When $s = 1$, cliques coincide with both s -cliques and connected s -cliques.

Example 3.2. Consider graph G from Figure 1. The set of nodes $\{a, b, c, d, e, f, g\}$ is a (connected) 3-clique, but is not a 2-clique, e.g., $\text{dist}_G(a, f) = 3 > 2$. The set of nodes $\{a, b, c, d\}$ is a connected 2-clique, and the set $\{a, d\}$ is a 2-clique, but is not a connected 2-clique.

We say that U is a *maximal (connected) s -clique* in G , if U is a (connected) s -clique, and for all U' such that $U \subseteq U'$, it holds that U' is not a (connected) s -clique. It is natural to focus on *maximal (connected) s -cliques*. Indeed, every (connected) s -clique is contained in some maximal (connected) s -clique. Hence, maximal (connected) s -cliques can be viewed as a succinct representation for all (connected) s -cliques.

Example 3.3. Consider graph G' , from Figure 2. Let

$$\begin{aligned} V &= \{v_1, v_2, v_3\} & U &= \{u_{1,2}, u_{1,3}, u_{2,1}, u_{2,3}, u_{3,1}, u_{3,2}\} \\ V' &= \{v'_1, v'_2, v'_3\} & W &= \{w, w'\} \end{aligned}$$

Now, it is easy to observe that every subset C of $V \cup V'$ that does not contain both v_i and v'_i for some $i \leq 3$ is a 2-clique. Such 2-cliques are not maximal, however. A subset $C \subseteq V \cup V' \cup W$ will be a maximal connected 2-clique if (1) C contains precisely one among v_i, v'_i for each $i \leq 3$, and (2) C contains w, w' . Thus, for example, $\{v_1, v_2, v'_3\}$ is a 2-clique (but not maximal nor connected), and $\{v_1, v_2, v'_3, w, w'\}$ is a maximal connected 2-clique in G . Note that there are additional ways to form maximal connected 2-cliques, when taking nodes from U . For example, $\{v_1, v'_2, w, w', u_{1,2}\}$ is also a maximal connected 2-clique.

We can now formally state our problem of interest: *Given a graph G and an integer s , enumerate (i.e., find, one after another) all maximal connected s -cliques in G .* As larger s -cliques can, naturally, be more interesting, we will also briefly consider a

Figure 3: Graph H and corresponding graph H^2 .

related problem, i.e., that of finding maximal s -cliques of size at least k , for some given number k .

REMARK 1. We do not consider enumeration of maximal s -cliques that are not necessarily connected. This is because enumeration of maximal s -cliques over a graph G can be reduced to maximal clique enumeration: Define G^s as the graph containing an edge between nodes u, v if they are of distance at most s in G . Then, the maximal cliques in G^s are precisely the maximal s -cliques in G . However, this reduction is not applicable for connected s -cliques, as cliques in G^s can correspond to unconnected sets in G . Hence, enumeration of maximal connected s -cliques is more difficult, as the following example demonstrates.

Consider the graphs H, H^2 in Figures 3 (a) and (b). The graph H^2 contains an edge between every pair of nodes in H that are of distance at most 2 one from another. Every 2-clique in H is a clique (in the standard sense) in H^2 . Observe, for example, that the sets $C_1 = \{v_1, v_2, v_6\}$ and $C_2 = \{v_1, v_3, v_5\}$ are 2-cliques in H and cliques in H^2 . Unlike the set C_1 , the set C_2 is not a connected 2-clique. Indeed no two nodes in C_2 are connected in H , and thus, C_2 forms an unconnected subgraph of H . This cannot be seen when looking at H^2 alone; the information about connectedness is lost in the given graph transformation.

We note that due to the fact that the number of sets in the result can be exponential in the size of G , the problem of enumerating all maximal connected s -cliques cannot be solved in polynomial time. Hence, exponential time may be needed just to print the output. Therefore, we focus on finding algorithms whose runtime is either provably efficient with respect to the output size (e.g., polynomial delay) or of high efficiency in practice.

Example 3.4. We demonstrate a graph with exponentially many maximal connected s -cliques for $s = 2$. It is easy to extend this idea to derive a graph with exponentially many maximal connected s -cliques for other values of s . Let n be an integer. Let

$$\begin{aligned} V &= \{v_i \mid i \leq n\} & U &= \{u_{i,j} \mid i \neq j \leq n\} \\ V' &= \{v'_i \mid i \leq n\} & W &= \{w, w'\} \end{aligned}$$

be sets of nodes. We add edges $\{v_i, u_{i,j}\}, \{u_{i,j}, v'_j\}$ for all $i \neq j \leq n$, as well as edges $\{v_i, w\}, \{v'_i, w'\}$ for all $i \leq n$. Finally, we add the edge $\{w, w'\}$. Graph G' from Figure 2 has precisely this structure, for $n = 3$.

Every pair of nodes v_i, v'_j where $i \neq j$ have distance 2 one from another, while v_i, v'_i have distance 3. Nodes w, w' are at distance at most 2 from every node in the graph. Thus, it is easy to see that every choice of nodes including precisely one among v_i, v'_i , for all $i \leq n$, as well as nodes w, w' , yields a maximal connected 2-clique. (Note that nodes $u_{i,j}$ cannot be added to such sets.) Thus, the graph derived has at least 2^n maximal connected 2-cliques, while it has only $2n + n(n-1) + 2$ nodes, i.e., the number of maximal connected 2-cliques is exponential in the size of the graph.

Figure 4: An polynomial delay algorithm for enumerating all maximal connected s -cliques.

4 A POLYNOMIAL DELAY ALGORITHM

We present a provably efficient algorithm for enumerating all maximal connected s -cliques in a given graph G . This algorithm is inspired by the general purpose algorithm for enumerating maximal subgraphs satisfying some connected-hereditary property, appearing in [10]. Our algorithm, called POLYDELAYENUM, appears in Figure 4.

The algorithm POLYDELAYENUM uses two data structures:

- Q , a queue, containing maximal connected s -cliques that must still be processed. Later, in Section 6, we will also consider using a priority queue for Q .
- I , an index containing maximal connected s -cliques that have already been generated. In order to achieve the required runtime, access to I (both insertions and membership checks) must be in time that is at most logarithmic in the size of I . Thus, for example, I can be implemented as a BTree.

POLYDELAYENUM uses a sub-procedure, called EXTENDMAX, which is given, as input, a set C , a graph G and the integer s . We note that the set C provided as input is always a connected s -clique. EXTENDMAX returns a set C' such that

- $C \subseteq C'$ (this is ensured as C' is created by adding nodes to C);
- C' is a connected s -clique (as we only add a node that is connected to and of distance at most s from the nodes presently in C);
- C' is maximal in G , with respect to the above two properties (as we continue to add nodes as long as possible).

For example, when calling EXTENDMAX with the empty set (Line 3 of POLYDELAYENUM), a single maximal connected s -clique is returned. In general, the output of EXTENDMAX may differ, depending on the order in which we iterate over the nodes of G . In the special case that G is almost a connected s -clique, i.e., contains a single node that contradicts this property (as occurs in the

invocation of EXTENDMAX in Line 10 of POLYDELAYENUM), there is only one possible output for EXTENDMAX.

Now, POLYDELAYENUM begins by finding a single maximal connected s -clique, using EXTENDMAX, and adding this set to both Q and I (Lines 1–5). While Q is not empty, we remove a maximal connected s -clique C from Q , and print C (Lines 6–8). Now, for each node v that is a neighbor of some node in C , we proceed as follows. First (Line 10) we find the s -clique C' containing v that is maximal with respect to $G[C \cup \{v\}]$. Next (Line 11), we extend this set so as to derive an s -clique C'' that is maximal with respect to G . If we have not created C'' yet (i.e., $C'' \notin I$), we add it to Q and I (Lines 12–14). We note that a key aspect of the algorithm is the fact that EXTENDMAX is called twice, consecutively (Lines 10 and 11) with different graphs as input. The first invocation guides the creation of a new connected s -clique C' to contain portions from C . The second invocation ensures maximality with respect to the input graph G .

Example 4.1. Consider calling POLYDELAYENUM with the graph G from Figure 1 and $s = 2$. At first, an arbitrary 2-clique will be created, such as $C = \{a, b, c, d\}$. This set C will be added into the queue Q . When removed from the queue (Line 7), we will print C and then iterate over the set $N_G^{\exists,1}(C) = \{e, f, g\}$. Consider the case where we choose $v = e$ (in Line 9). We will call EXTENDMAX($\{e\}, G[C \cup \{e\}], 2$), deriving the set $C' = \{b, c, d, e\}$. There is only one way to extend C' in order to derive a maximal connected 2-clique. This extension will be returned from the next call to EXTENDMAX in Line 11, $C'' = \{b, c, d, e, f, g\}$, and inserted into the queue. Execution will proceed similarly, first for all other neighbors of C , which will return the same result C'' , that will not be enqueued again. Then, the next graph dequeued will be C'' , that will form the last s -clique $\{d, e, f, g, h\}$ when h is added.

The following result holds. (In practice, the delay between answers is typically lower than the theoretical result.)

THEOREM 4.2. *Given a connected graph G and an integer s , the algorithm POLYDELAYENUM prints every maximal connected s -clique in G , precisely once. In addition, the delay before printing the first answer, and between every two consecutive answers, and from the time the last answer is printed until termination, is $O(|V(G)|^3)$.*

PROOF. We start by showing correctness of the algorithm. First, it is immediate from the structure of EXTENDMAX that every set printed must be a maximal connected s -clique. Second, observe that every set is printed at most once, as we only insert C into Q if it was not already generated in the past (i.e., does not appear in I). It remains to show that every maximal connected s -clique is indeed printed.

Let v be an arbitrary node in G . Then, there is some set C , printed by POLYDELAYENUM, that contains v . (This can be shown by induction on the distance of v from the closest node in the first set generated by POLYDELAYENUM.)

We can now prove that every maximal connected s -clique is printed. Let C_* be some maximal connected s -clique. Let C_m be the set printed by POLYDELAYENUM for which the largest connected component in $C_* \cap C_m$ is maximal. (If there are ties, choose C_m arbitrarily among all such sets.) If $C_m = C_*$, we have indeed printed C_* . Suppose otherwise. Observe first that $C_m \cap C_*$ cannot be empty, as POLYDELAYENUM must print some set containing each node in C_* . Now, since $C_m \neq C_*$, there is some node $v \in C_* - C_m$, such that v is connected to the largest connected component in $C_m \cap C_*$. After dequeuing C_m from Q in Line 7, we will iterate over the node v in Line 9. Then, Line 10 will return a

Algorithm CLIQUES(R, P, X)

1. **if** $P = \emptyset$ and $X = \emptyset$
2. **then** PRINT(R)
3. **for** $v \in P$
4. **do** CLIQUES($R \cup \{v\}, P \cap N(v), X \cap N(v)$)
5. $P \leftarrow P - \{v\}$
6. $X \leftarrow X \cup \{v\}$

Figure 5: Bron-Kerbosch algorithm for enumerating maximal cliques.

set C' containing v , as well as the largest connected component in $C_m \cap C_*$ (since these together form a connected s -clique). This set will be enlarged to C'' in Line 11. Now, C'' is either inserted into Q (and eventually printed) or was already inserted in Q (and eventually printed). Observe that the largest connected component in $C'' \cap C_*$ must be larger than that in $C_m \cap C_*$, which contradicts the maximality of choice of C_m . Hence, it must be $C_m = C_*$, and C_* is indeed printed.

We will now show that the delay is $O(|V(G)|^3)$. First, note that by a preprocessing step we can compute $N_G^s(v)$ for every node $v \in V(G)$ in time $O(|V(G)|^3)$. In addition, EXTENDMAX runs in $O(|V(G)|^2)$, since it traverses each edge at most once, in increasing distance from the set C . Now, the delay before printing the first answer is determined by (1) the preprocessing step which finds the distances between nodes and (2) running EXTENDMAX in Line 3. Therefore the delay before printing the first answer is $O(|V(G)|^3)$.

The delay between every two consecutive answers, and from the time the last answer is printed until termination, is determined by the runtime of a single iteration of the while loop in Line 6 in POLYDELAYENUM, because in each iteration a single answer is printed and the last answer is printed in the last iteration. In each iteration, the for loop in Line 9 goes over the set $N_G^{\leq 1}(C)$, that is of size $O(|V(G)|)$, and for each node v in the set calls EXTENDMAX, which runs in $O(|V(G)|^2)$. In total we derive that each iteration runs in $O(|V(G)|^3)$. \square

5 ADAPTATION OF BRON-KERBOSCH ALGORITHM

We start by reviewing the Bron-Kerbosch algorithm for enumerating maximal cliques. We then present strategies and optimization techniques to adapt this algorithm for enumerating maximal connected s -cliques.

5.1 Maximal Cliques

The Bron-Kerbosch algorithm for enumerating maximal cliques appears in Figure 5. This algorithm, called CLIQUES, recursively searches for all maximal cliques. When called with sets R, X and P , it searches for all maximal cliques containing all nodes in R , possibly some nodes in P , and no nodes in X . In particular, in the first invocation, we send the empty set for R and X , and the set $V(G)$ for P .

Throughout the execution, R is always a clique. The sets P and X are disjoint, and always satisfy that $P \cup X$ contains precisely every node that is connected to all nodes in R (i.e., those can potentially be used to extend R). Therefore, when P and X are both empty, R is a maximal clique. Otherwise, if P is not empty, the algorithm attempts to add each node $v \in P$ in turn to R , updating P and X to contain only nodes that are connected to

v (in addition to being connected to the rest of R). After the recursive call that includes v , the node v is added to X , so as to create additional unseen cliques—those that exclude v . (Cliques containing v will be produced in the recursive call.)

The algorithm CLIQUES, as presented in Figure 5, runs quite poorly in practice. To improve the runtime, [32] presented a technique called *pivoting* to reduce the branching factor of the recursion, by iterating over only a subset of P . In particular, instead of iterating over P , their algorithm:

- first, chooses a *pivot* node $u \in P \cup X$.
- then, iterates only over the nodes v in $P - N(u)$.

The intuition behind this improvement is that, for any node u , every maximal clique must either contain u , or contain some node that is not a neighbor of u . (Otherwise, if the maximal clique contains only neighbors of u , it must also contain u .) Hence, it is sufficient to iterate over the nodes in P , other than the neighbors of u . The pivot node is chosen so as to minimize the set $P - N(u)$. This optimization ensures a worst case runtime of $O(3^{n/3})$, which is order of the largest number of cliques possible in a graph of n nodes. Previous work has shown that this improvement causes the algorithm to run very well in practice.¹

5.2 Maximal Connected s -Cliques

We adapt the Bron-Kerbosch algorithm to return all maximal connected s -cliques, instead of all maximal cliques. There are, perhaps, two different natural approaches to adapt the algorithm CLIQUE to this new setting:

- (1) **R is always a connected s -clique:** In the CLIQUE algorithm, we have seen that R is always a clique. It is natural to adapt this algorithm so as to preserve the invariant that R is always a connected s -clique. This approach is taken in CsCLIQUES1 in Figure 6. Thus, when choosing a node v with which to extend R (Line 3), we will only choose nodes from P that are adjacent to some node in R . After choosing v , we perform a recursive call, with v added to R and we intersect sets P and X with the nodes of distance at most s from v . Thus, throughout the algorithm, P and X always contain precisely the nodes at distance at most s from every node in R . Only such nodes may possibly be used to extend R in the future.

Note the final change in the algorithm, in the condition for printing R (Line 1). We print R only if it is maximal, i.e., there are no nodes at distance at most s from R (i.e., nodes in P or X) that are adjacent to R .

- (2) **R is always an s -clique, but may be unconnected:** In the second adaptation, we do not require R to be connected. In the algorithm CsCLIQUES2 in Figure 7, the set R may be unconnected. To observe this, see that in Line 3 we can add any node v from P to R , even if v is not adjacent to R . Thus, R will be an s -clique throughout the execution, but may be unconnected. This requires an additional change to the condition for printing R in Line 1—we print R only if it is connected.

Example 5.1. Consider using CsCLIQUES1 to find all maximal connected 2-cliques for graph H in Figure 3. When first called, $R = X = \emptyset$, $P = \{v_1, \dots, v_6\}$ and $s = 2$. Since, R is empty, we iterate over all nodes in P . Suppose the first node chosen is v_1 .

¹Additional optimizations to the algorithm have been considered in the past, such as iterating over v in the outermost recursion according to a degeneracy ordering of G [12] and early recognition of special branching cases [27]. Such optimizations can also be included in our algorithm.

Algorithm CsCLIQUES1(R, P, X, s)

1. **if** $P \cap N^{\exists,1}(R) = \emptyset$ and $X \cap N^{\exists,1}(R) = \emptyset$
2. **then** PRINT(R)
3. **for** $v \in P \cap N^{\exists,1}(R)$
 - ▷ If $R = \emptyset$, then take $N^{\exists,1}(R) = G(V)$
4. **do** CsCLIQUES1($R \cup \{v\}, P \cap N^s(v), X \cap N^s(v), s$)
5. $P \leftarrow P - \{v\}$
6. $X \leftarrow X \cup \{v\}$

Figure 6: Adaptation of Bron-Kerbosch algorithm for enumerating all maximal connected s -cliques. Throughout the execution, R is always a connected s -clique.

Algorithm CsCLIQUES2(R, P, X, s)

1. **if** $P \cap N^{\exists,1}(R) = \emptyset$ and $X \cap N^{\exists,1}(R) = \emptyset$ and R is connected
2. **then** PRINT(R)
3. **for** $v \in P$
4. **do** CsCLIQUES2($R \cup \{v\}, P \cap N^s(v), X \cap N^s(v), s$)
5. $P \leftarrow P - \{v\}$
6. $X \leftarrow X \cup \{v\}$

Figure 7: Adaptation of Bron-Kerbosch algorithm for enumerating all maximal connected s -cliques. Throughout the execution, R is always an s -clique, but may be unconnected.

In the recursive call to CsCLIQUES1, we will have $R = \{v_1\}$, $P = \{v_2, v_3, v_5, v_6\}$ and $X = \emptyset$. When a recursive call is made for the second node v_2 , we will have $R = \{v_2\}$, $P = \{v_3, v_4, v_6\}$ and $X = \{v_1\}$. (Note that v_1 was removed from P in Line 5 and added to X in Line 6, in the previous iteration.) Now, consider the execution of CsCLIQUES1($\{v_2\}, \{v_3, v_4, v_6\}, \{v_1\}, 2$). We will iterate over nodes that are neighbors of $\{v_2\}$ in $\{v_3, v_4, v_6\}$, i.e., only over v_3 . This will cause a single recursive call to CsCLIQUES1($\{v_2, v_3\}, \{v_4\}, \{v_1\}, 2$), which will eventually produce the maximal connected 2-clique $\{v_2, v_3, v_4\}$.

We contrast this execution with the execution of algorithm CsCLIQUES2. At first, the algorithms will proceed in the same fashion, as $R = \emptyset$ and both algorithms will iterate over all nodes in the graph. However, consider the execution of the recursive call to CsCLIQUES2($\{v_2\}, \{v_3, v_4, v_6\}, \{v_1\}, 2$). Instead of iterating only over neighbors of v_2 in $\{v_3, v_4, v_6\}$, we will iterate over all nodes in this set. Assuming the order of iteration is $v_3 < v_4 < v_6$, this will cause two additional recursive calls: CsCLIQUES2($\{v_2, v_4\}, \emptyset, \{v_3\}, 2$) and CsCLIQUES2($\{v_2, v_6\}, \emptyset, \{v_3, v_4\}, 2$). Neither of these calls will produce maximal connected s -cliques.

When comparing these two approaches, it is immediately obvious that CsCLIQUES2 does extra work that is avoided by CsCLIQUES1, as CsCLIQUES2 can create many sets that will never be printed, as they are unconnected. The algorithm CsCLIQUES1 completely avoids this by ensuring that R is connected throughout its execution. Notwithstanding the fact that CsCLIQUES1 would seem to be much superior to CsCLIQUES2, in fact, we will see that the latter is much more amenable to optimizations (including the pivoting technique). This will be discussed further in Section 5.3. However, before discussing this further, we prove correctness of both algorithms.

In order to prove correctness, let $<$ be an arbitrary ordering of the nodes in G . We assume that the iteration over (the subset of) P in Line 3 of both CsCLIQUES1 and CsCLIQUES2 follows this ordering, i.e., if $v, v' \in P$ (resp. $v, v' \in P \cap N^{\exists,1}(R)$) and $v < v'$, then we will choose to iterate over v before iterating over v' . The ordering $<$ implies two types of total orderings over nodes in a connected s -clique C . Let $\omega_2(C) = v_1, \dots, v_k$ be the total ordering over C , defined by $<$. Let $\omega_1(C) = u_1, \dots, u_k$ be the total ordering over C , defined as follows:

- $u_1 = v_1$;
- for all $i > 1$, it holds that $u_i = v_j$ where v_j in the first node according to $\omega_2(C)$ that is not already among u_1, \dots, u_{i-1} , for which $G[\{u_1, \dots, u_i\}]$ is connected.

Example 5.2. Consider graph G' from Figure 2. Let $<$ be the total ordering that orders the nodes as seen in the graph from left to right, top to bottom, i.e.,

$$v_1 < \dots < w < u_{1,2} < \dots < u_{3,2} < v'_1 < \dots < w'.$$

Consider the set $C = \{v_1, v'_2, w, w', u_{1,2}\}$. Then, we have $\omega_1(C) = v_1, w, u_{1,2}, v'_2, w'$.

We consider the *execution tree* \mathcal{T}_i formed by (recursive) calls to CsCLIQUES $_i$, for $i = 1, 2$. To be precise, this tree has nodes of the form (R, P, X) where R, P, X are subsets of $V(G)$. An edge from a node (R, P, X) to a node (R', P', X') is labeled by a node v . This tree is defined recursively as follows: The root of \mathcal{T}_i is $(\emptyset, V(G), \emptyset)$. A node (R, P, X) has a child (R', P', X') with a connecting edge labeled v if the call to CsCLIQUES $_i$ with parameters (R, P, X) results in a recursive call with parameters (R', P', X') when the node v is chosen in Line 3.

Given a series of nodes $\bar{u} = u_1, \dots, u_n$, we say that \bar{u} is a path in \mathcal{T}_i if there is a path of edges starting from the root of \mathcal{T}_i with labels u_1, \dots, u_n (precisely in that order). A node (R, P, X) in \mathcal{T}_i is an *output node* if R is printed by CsCLIQUES $_i$, during the call with parameters (R, P, X) .

Several important properties of \mathcal{T}_i hold.

LEMMA 5.3. *Let G be a graph and let \mathcal{T}_i be the execution tree derived by calling CsCLIQUES $_i(\emptyset, V(G), \emptyset, s)$. Let (R, P, X) be a node in \mathcal{T}_i .*

- (1) *The set R is an s -clique;*
- (2) *If $i = 1$, the set R is connected;*
- (3) *$P \cup X = N^{V,s}(R)$;*
- (4) *Let u_1, \dots, u_k be the path to (R, P, X) in execution tree \mathcal{T}_i . If u_1, \dots, u_k is a prefix of $\omega_i(C)$ for some maximal connected s -clique C , then $C - R \subseteq P$;*
- (5) *For every other node (R', P', X') in \mathcal{T}_i it holds that $R \neq R'$;*
- (6) *If C is a maximal connected s -clique, then $\omega_i(C)$ is a path in \mathcal{T}_i .*

PROOF. We show Properties 1–4 by induction on the depth (i.e., distance from the root) of the node (R, P, X) . For base case of distance 0, i.e., the root node, all four properties are immediate. (For Property 3, note that $R = \emptyset$, and thus, every node in G is of distance at most s from all nodes in R . Indeed $P = V(G)$).

Now, assume that Properties 1–4 hold for nodes of distance at most k from the root. We prove the required for nodes at distance $k + 1$. Let (R, P, X) be a node at distance $k + 1$ from the root, and let (R', P', X') be its parent. Let v be the label of the edge from (R', P', X') to (R, P, X) . By the induction hypothesis, R' is an s -clique, if $i = 1$, R' is connected, and every node in P' is of distance at most s from all nodes in R' . Since v is chosen from

P' , and is chosen so as to be connected to R' , if $i = 1$, it follows immediately that R satisfies Properties 1 and 2.

Let $S' = N^{\vee, s}(R')$. By the induction hypothesis, $S' = P' \cup X'$. During the loop of Line 3, before the recursive call $\text{CsCLIQUESi}(R, P, X, s)$, we remove nodes from P' and add them to X' . Thus, when node v is chosen in Line 3, it still holds that $S' = P' \cup X'$. Let S be the set of nodes that are of distance at most s from all nodes in R' . Clearly, $S = S' \cap N^s(v)$. Now, since $P = P' \cap N^s(v)$ and $X = X' \cap N^s(v)$, it follows that $S = P \cup X$, as required in Property 3.

Finally, suppose that u_1, \dots, u_{k+1} is a prefix of $\omega_i(C)$ for some maximal connected s -clique C . This implies that also u_1, \dots, u_k is also a prefix of $\omega_i(C)$. Hence, $C - R' \subseteq P'$. Since we only choose, in Line 3, a node that is in P' (and hence, by Property 3 is of distance at most s from every node in R') and if $i = 1$, we only continue with nodes that are connected to R , it follows that no node in C is removed from P in Line 5. Otherwise, this would contradict the minimality of choice of u_{k+1} in the definition of $\omega_i(C)$. Hence, it follows that $C - R \subseteq P$, as required in Property 4.

Now, we show Property 5. Let (R'', P'', X'') be the lowest common ancestor of (R, P, X) and (R', P', X') . We consider two cases:

- Case 1: (R'', P'', X'') is the node (R, P, X) . (The case in which (R'', P'', X'') is the node (R', P', X') is identical.) In this case, Let v be the node on the outgoing edge of (R, P, X) on the path leading to (R', P', X') . Clearly, $v \notin R$ and $v \in R'$, and therefore $R \neq R'$.
- Case 2: Neither node among (R, P, X) and (R', P', X') is an ancestor of the other. Let v and v' be the nodes on the outgoing edges of (R'', P'', X'') on the paths leading to (R, P, X) and (R', P', X') , respectively. Suppose, without loss of generality, that the node v was chosen before v' in the loop of Line 3. Clearly, R contains v . However, since v is removed from the set P'' before the recursive call with v' , it follows that v is not in R' . Hence, $R \neq R'$.

Finally, we show Property 6. Let $\omega_i(C) = u_1, \dots, u_n$. We show, by induction, that for every prefix u_1, \dots, u_k of $\omega_i(C)$, it holds that u_1, \dots, u_k is a path in \mathcal{T}_i . Obviously, this holds for the empty prefix. Assume the required for a prefix of length k , and we show that the claim holds for a prefix of length $k + 1$. By the induction hypothesis, u_1, \dots, u_k is a path in \mathcal{T}_i leading to a node (R, P, X) . Observe that $R = \{u_1, \dots, u_k\}$. By Property 4, it holds that $C - R \subseteq P$, i.e., $u_{k+1} \in P$. For $i = 1$, by the definition of $\omega_i(C)$, it holds that u_{k+1} is connected to R . Hence, at some point, the node u_{k+1} will be chosen in Line 3. Therefore, there will be a recursive call made where u_{k+1} is added, i.e., u_1, \dots, u_{k+1} is a path in \mathcal{T}_i . \square

We can now show correctness of the algorithm.

THEOREM 5.4. *Let G be a graph. Then, calling the procedure $\text{CsCLIQUESi}(\emptyset, V(G), \emptyset, s)$ will result in the printing of every maximal connected s -clique in G precisely once, and no other sets of nodes will be printed.*

PROOF. First observe that no set will be printed more than once. This follows immediately from the Property 5 of Lemma 5.3, since we print the set R , and there are no two nodes in the execution tree that contain the same set R .

Next, we show that every set that is printed is a maximal s -clique. Assume that R is printed. Let (R, P, X) be the node of \mathcal{T}_i in which R is printed. By Property 1 of Lemma 5.3, it follows that R is an s -clique. If $i = 1$, R is also connected (Property 2 of

Lemma 5.3). If $i = 2$, R must be connected if it is printed, as this is part of the requirement before printing (Line 1). Hence, R is a connected s -clique. Suppose, by way of contradiction, that R is not maximal. Then there is a node v that is connected to R and is of distance at most s from every node in R . By Property 3 of Lemma 5.3, it holds that $v \in P \cup X$. Hence, either $P \cap N(R) \neq \emptyset$ or $X \cap N(R) \neq \emptyset$, and thus, R will not be printed, in contradiction to the assumption.

Finally, we show that every maximal connected s -clique will be printed. Let C be a maximal connected s -clique. By Property 6 of Lemma 5.3, it holds that $\omega_i(C)$ is a path in \mathcal{T}_i leading to a node (R, P, X) . Assume, by way of contradiction, that this node is not an output node. It then follows that there is a node $v \in (P \cap N(R)) \cup (X \cap N(R))$, i.e., v is connected to R and is in P or X . By Property 3 of Lemma 5.3, it follows that v is of distance at most s from every node in R . Hence, $R \cup \{v\}$ is a connected s -clique. However, $R = C$, and thus, this is a contradiction to the assumption that C is maximal. Hence, it follows that if C is a maximal connected s -clique, C will be printed during execution. \square

5.3 Optimizing the Algorithm

We consider two different strategies to optimize the algorithm CsCLIQUEs2 . Unfortunately, neither of these strategies are applicable to CsCLIQUEs1 , as will be made clear.

Pivoting. As discussed earlier, a critical improvement to CLIQUEs , which renders the algorithm efficient in practice, is that of pivoting [32]. This strategy reduces the branching factor in the execution tree by avoiding iteration over the entire set P , and iterating over $P - N(u)$, for some $u \in P \cup X$, instead. Node u is called the *pivot*. This technique can be applied when generating maximal connected s -cliques, due to the following proposition.

PROPOSITION 5.5. *Let C be a maximal connected s -clique and let $u \in V(G)$ be a node. Then, one of the following conditions must hold: (1) $u \in C$, (2) $C \not\subseteq N^s(u)$ or (3) $C \cap N(u) = \emptyset$.*

PROOF. Suppose, by way of contradiction, that none of the above conditions hold. Then,

- (1) $u \notin C$;
- (2) $C \subseteq N^s(u)$;
- (3) C contains a node in $N(u)$.

It immediately follows that C is not maximal, in contradiction to the assumption, as u can be added to C (since it is close enough to all nodes in C , and has a neighbor in C). \square

It may not be immediately obvious how to utilize this property, to improve the runtime, as it states that every clique must either contain u , or contain some node that is not at distance s from u , or cannot contain any neighbor of u . Thus, if instead of iterating over P , we iterate over $P - N^s(u)$ (in a similar fashion to the pivoting of CLIQUE), we can miss maximal connected s -cliques that do not contain any node from $P - N^s(u)$ (and also contain no neighbor of u).

To overcome this problem, we will always choose the pivot as a neighbor of some node in R . To be precise, we choose a pivot node $u \in (P \cup X) \cap N^{\exists, 1}(R)$ that minimizes $P - N^s(u)$. Then, in Line 3 of CsCLIQUEs2 , instead of iterating over P , we iterate over $P - N^s(u)$. Now, every maximal connected s -clique containing R must either contain u , or must contain some node that is not within $N^s(u)$. (Otherwise, if it does not contain any node in $N^s(u)$, we could always add u , since u is connected to R and of distance at most s from every node in R .)

Figure 8: Graph used to demonstrate the reduction of Theorem 5.6

We note that this improvement cannot be integrated with CsCLIQUEs1, as it requires us to iterate over nodes that may not be neighbors of R . The algorithm CsCLIQUEs1 always preserves the invariant that R is connected, and iterating over such nodes would cause them to be added to R , thereby, losing the correctness of the invariant.

To summarize, integrating pivoting into CsCLIQUEs2 is performed by replacing Line 3 with the following two lines:

- 3.1 $u \leftarrow \arg \min_u \{|P - N^s(u)| \mid u \in (P \cup X) \cap N^{\exists 1}(R)\}$
 3.2 **for** $v \in P - N^s(u)$

Checking for Feasibility. CsCLIQUEs1 never creates a set R that is unconnected. On the other hand, CsCLIQUEs2 may go deep into the recursion tree even if a set R is being considered, for which it is not possible to add nodes and derive a connected maximal s -clique. It would be preferable to prune branches for calls of the form (R, P, X, s) if there is no connected s -clique C such that $R \subseteq C$ and $C \subseteq R \cup P$. (Recall that we will only try to add nodes from P to R .) In such cases, the branches cannot lead to a solution. Unfortunately, this cannot be verified efficiently, in the general case, as shown stated by the following theorem.

THEOREM 5.6. *Let G be a graph, $s > 1$ be an integer, and R be an s -clique. Determining whether there exists a connected s -clique C such that $R \subseteq C$ is NP-complete.*

PROOF. Membership in NP is immediate, as we can guess a set C and check whether it satisfies all requirements. We show NP-hardness by a reduction from 3-SAT.

Let ψ be a 3-SAT formula with m clauses C_1, \dots, C_m , over the variables X_1, \dots, X_k . We assume, without loss of generality, that no clause contains both a variable and its negation.

Let V_0 be the set of nodes:

$$\{c_i^k \mid i \leq m, k \leq s\} \cup \{x_i^j \mid i \leq m, j \leq 3\} \cup \{f\}$$

Let G_0 be the graph derived by taking the nodes in V_0 , and adding the following edges:

- $\{c_i^j, c_i^{j+1}\}$ for every $i \leq m$ and $j < s$;
- $\{c_i^s, x_i^j\}$ for every $i \leq m$ and $j \leq 3$;
- $\{x_i^j, c_{i+1}^1\}$ for every $i < m$ and $j \leq 3$;
- $\{x_m^j, f\}$ for every $j \leq 3$.

We say that a pair of nodes in V_0 is *conflicting* if they are of the form $x_i^j, x_{i'}^{j'}$ and the j -th literal in C_i is the negation of the j' -th literal in $C_{i'}$. Let G be the graph derived by taking the graph G_0 , and adding a path of length s (using new nodes) between every pair of non-conflicting nodes in V_0 that are at distance greater than s in G_0 .

Figure 8 (a) demonstrates graph G_0 for $s = 2, m = 3$ and the 3-SAT formula $\psi = (X_1 \vee \bar{X}_2 \vee X_3) \wedge (X_1 \vee X_2 \vee X_3) \wedge (\bar{X}_1 \vee \bar{X}_2 \vee X_3)$. Figure 8 (b) focuses on the framed subgraph in (a) and shows all the nodes and edges that will appear in G . Observe that there is no path of length $s = 2$ between x_1^2 and x_2^2 as they correspond to \bar{X}_2 and X_2 .

Now, we make several observations about the graph G .

- (1) Let U be any subset of V_0 that does not contain nodes corresponding to a literal and its negation. Then, U is an s -clique (although may be unconnected). This is immediate, since we have paths of length s between every two nodes in U .
- (2) Let U be any subset of $V(G)$ that does contain nodes corresponding to a literal and its negation. Then, U is not an s -clique. This is also apparent, from a careful analysis of the graph. We did not include paths of length s between such nodes, in the beginning. Furthermore, when adding edges between nodes in V_0 , we never create a path of length at most s between such nodes. Indeed, the use of s nodes c_1^1, \dots, c_i^s is precisely to avoid such cases.
- (3) Let U be any subset of $V(G)$ containing the nodes c_1^1, \dots, c_m^1, f . If U is an s -clique, then U must be a subset of V_0 , i.e., cannot contain the additional new nodes. To see why this is so, observe that every node that is not among V_0 is on a path of length s between two nodes in V_0 , and will be at distance greater than s from at least one node among c_1^1, \dots, c_m^1, f .

Now, consider s -clique $R = \{c_1^1, \dots, c_1^s, \dots, c_m^1, \dots, c_m^s, f\}$. We claim that there exists a connected s -clique C such that $R \subseteq C$ if and only if ψ is satisfiable. Suppose first that ψ is satisfiable, and let μ be a satisfying assignment for ψ . Let C be the set containing R , as well as all nodes corresponding to literals that are satisfied in μ . Clearly, C is an s -clique, by our first observation. In addition, since C must include at least one node x_i^j corresponding to a satisfied literal in each clause c_i , the set C is connected (as x_i^j will connect between c_i^s and c_{i+1}^1).

For the other direction, suppose there exists such a set C . By Observation 3, C can contain only nodes from V_0 , and by Observation 2, C will not contain nodes corresponding to a literal and its negation. Therefore, C defines a truth assignment for ψ , in which true is assigned to literals corresponding to nodes in C . As before, the fact that C is connected implies that the truth assignment gives the value of true to at least one literal in each C_i , i.e., ψ is satisfiable. \square

Theorem 5.6 implies that we cannot have an efficient algorithm that prunes useless branches whenever possible. Instead, we

apply a simple optimization, that is sufficient, but not complete, for pruning (i.e., branches are pruned only if they cannot lead to a result, but not all such branches will be pruned). In particular, we remove from P each node v for which the set of nodes $R \cup \{v\}$ is not completely contained in a single connected component of

$$G[R \cup \{v\} \cup (P \cap N^s(v))].$$

Intuitively, v can be added to R , only if eventually, we may find nodes in $P \cap N^s(v)$ ($= N^{v,s}(R \cup \{v\})$) that can fill in the gaps between the nodes in R to derive a single connected graph. Therefore, if we discover that this is not the case, we can remove v from P , as it can never be in a connected s -clique together with R .

Example 5.7. Consider running CsCLIQUES2 algorithm with the above feasibility check, on graph H from Figure 3 (a). When first called, $R = X = \emptyset$, $P = \{v_1, \dots, v_6\}$ and $s = 2$. Since, R is empty, we iterate over all nodes in P . Suppose the first node chosen is v_1 . In the recursive call to CsCLIQUES2, we will have $R = \{v_1\}$, $P = \{v_2, v_3, v_5, v_6\}$ and $X = \emptyset$. We will iterate over all nodes in P . In the second iteration of the loop of Lines 3-6, $v = v_3$ (v_2 was removed from P at the end of the first iteration) and $P \cap N^s(v) = v_5$. Now $R \cup \{v\} = \{v_1, v_3\}$ is not a connected component in $G[R \cup \{v\} \cup (P \cap N^s(v))]$ $= \{v_1, v_3, v_5\}$ and v_3 will be removed from P without calling the recursion.

6 FINDING LARGE RESULTS

We now consider the problem of finding large maximal connected s -cliques. In particular, assume we are given an integer $k \geq 0$, and our goal is to find all maximal connected s -cliques C such that $|C| \geq k$. When $s = 1$, s -cliques are standard cliques. For this case, it is well known that determining whether there exists a clique of size k is NP-complete. Therefore, it is interesting to consider k as a parameter of the problem and determine whether a fixed parameter algorithm exists, i.e., whether there is an algorithm that runs in time $O(f(k) \cdot |G|^{O(1)})$, for an arbitrary function f . Since k is expected to be much smaller than $|G|$, such an algorithm would be useful. Unfortunately, determining existence of a clique is known to be $W[1]$ -complete, i.e., we cannot expect to find an algorithm with time $O(f(k) \cdot n^{O(1)})$.

We now consider the case in which $s > 1$. Interestingly, determining whether there exists a s -clique of size k is fixed parameter tractable with respect to k , for both the case of connected s -cliques, and for arbitrary s -cliques. This gives hope that large maximal connected s -cliques can be enumerated with delay between answers that is exponential in k , but not in $|G|$. Unfortunately, for general s -cliques, this is not the case, as the following theorem states. (The proof has been omitted due to space limitations.) For connected s -cliques this problem is still open.

THEOREM 6.1. *Let k and $s > 1$ be integers.*

- (1) *The problem of determining whether a graph G contains a (connected) s -clique of size k is NP-complete, but is fixed parameter tractable with respect to k .*
- (2) *It is not possible to enumerate all maximal s -cliques of size at least k in a graph G with fixed parameter delay with respect to k , unless $W[1] = W[0]$.*

Our algorithms can already mine all maximal connected s -cliques of size at least k , by simply finding all maximal connected s -cliques, and then filtering out all those that do not satisfy the size bound. This process may be highly inefficient, as many smaller s -cliques will be generated. We consider optimizations that can be made to our algorithms to speed up the process

of finding all maximal connected s -cliques of size at least k . In POLYDELAYENUM, we replace the queue with a priority queue that returns larger maximal connected s -cliques first. In the algorithms CsCLIQUES1 and CsCLIQUES2, we prune (i.e., do not make recursive calls) the cases in which $|R| + |P| < k$. Clearly, in such cases it is not possible to create maximal connected s -cliques with k nodes at least.

7 EXPERIMENTAL RESULTS

Our algorithms were implemented in 32bit C++, as an extension of the SNAP library [21]. All experimentation was run on a Win7 desktop with 16GB RAM and an Intel i5-4570 processor, with 2GB of memory allocated to the program.

We run our algorithms on synthetic Erdős-Rényi (ER) graphs and scale-free (SF) graphs (which simulate social networks) of varying sizes, generated by the SNAP library. All data points in our figures are derived by generating three random graphs of the same size, and taking the average runtime in seconds. We also use several real datasets, as follows, taken from [20]. (Some of these datasets are directed graphs, but for our experimentation, we ignore the direction of the edges.)

- DBLP, with 317,080 nodes and 1,049,866 edges
- Amazon, with 334,863 nodes and 925,872 edges
- LiveJournal, with 3,997,962 nodes and 34,681,189 edges
- Twitter, with 81,306 nodes and 1,768,149 edges
- YouTube, with 1,134,890 nodes and 2,987,624 edges

One of the most costly operations in all algorithms is computing the set $N^s(v)$ for various nodes v . To save time, whenever we compute this set, we store it in a hash table, to be reused again later on, if needed. For large data sets, there is insufficient memory to store all neighbors of distance s within the hash table. When memory begins to run low, we remove some entries from the hash table (using an LRI ordering) to make room for new neighbor results.

Comparing Bron-Kerbosch Adaptations. We start by comparing the baseline versions of our Bron-Kerbosch adaptations, i.e., CSCLIQUE1 and CSCLIQUE2, with the versions including the two optimizations considered. We append the letter ‘‘P’’ and ‘‘F’’ to CSCLIQUE2 to indicate that pivoting is used and that our feasibility check is performed.

Figure 9a shows the result of running our adaptations of the Bron-Kerbosch algorithm to find 100 connected 2-cliques, with and without various optimizations, for random ER graphs of varying numbers of nodes (between one thousand and one million), and average node degree 10. As was to be expected, CSCLIQUE1 is significantly superior to CSCLIQUE2. However, all three versions that do not use pivoting are much slower than the pivoting versions (the two overlapping lines at the bottom of the graph), running 30 to 60 times slower than the pivoting versions, for graphs of one million nodes. For SF graphs, the gap is even larger, with the non-pivoting versions running approximately 120 times slower on graphs with only one thousand nodes (and average node degree 10). For this reason, in the remainder of the experimentation, we only consider the algorithms CSCLIQUE2P and CSCLIQUE2PF, along with POLYDELAYENUM (which will be denoted PD in our graphs).

Varying Node Size. We continue in our study of how the size of the graph (as determined by the number of its nodes) affects runtime. As before, we generated random graphs with between

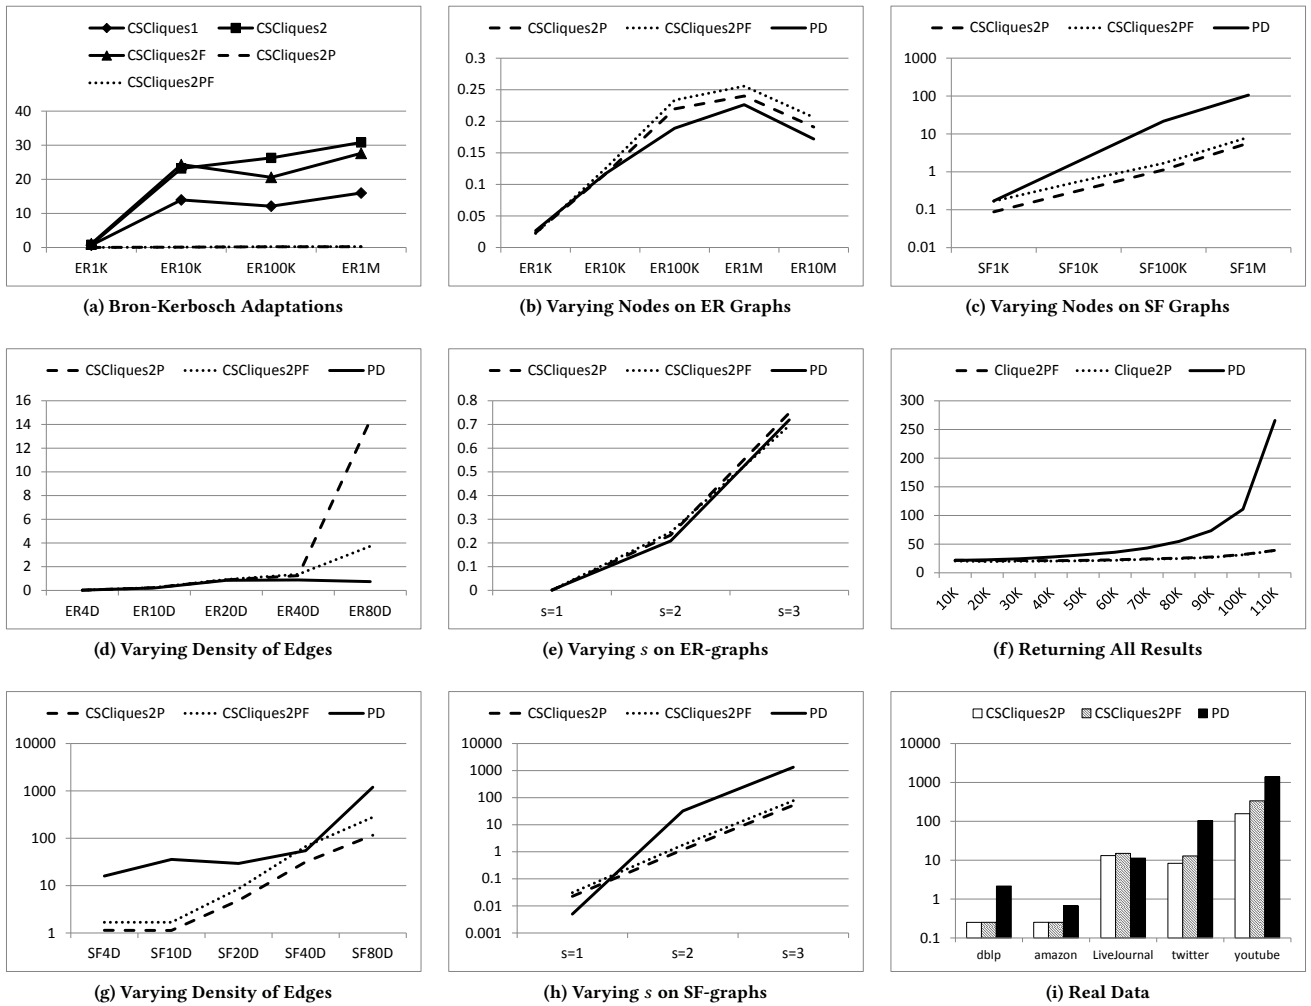

Figure 9: Execution times for varying parameters.

one thousand and one million nodes, and average node degree 10. We chose $s = 2$ and measured the time to return 100 connected s -cliques.

This experiment appears in Figures 9b and 9c. All times are in seconds, and that in Figure 9c the times are in log-scale. Algorithm POLYDELAYENUM (PD in the graphs) slightly outperforms CSCLIQUES2P and CSCLIQUES2PF on the ER graphs, but is significantly worse on the SF graphs. In addition, all algorithms perform worse on the latter, than on the former, probably due to the fact that average size of connected 2-cliques generated is much larger in a scale-free graph. For example, POLYDELAYENUM returned connected 2-cliques of average size 10.79 and 105.83, respectively, on the ER and SF graphs of size one million. The change in the trend of Figure 9b between 1M and 10M follows since the average size of connected 2-cliques is smaller over graphs with 10 million nodes, as the graph is sparser.

Varying Edge Density. We consider how the density of the edges affects the speed in which results can be returned. We generated random graphs with 100 thousand nodes, and an average degree of 4, 10, 20, 40 and 80. We chose $s = 2$, and measure the time to return 100 connected 2-cliques.

Figures 9d and 9g contain the result of this experiment for ER and SF graphs, respectively. As the density increases, algorithm POLYDELAYENUM once again outperforms CSCLIQUES2P and CSCLIQUES2PF on the ER graphs. CSCLIQUES2PF is superior to CSCLIQUES2P for degree density 80, as it avoids many recursive calls. (This is in contrast to the many other cases in which we observe that its time is inferior, as the overhead for testing feasibility is large.) On the SF graphs, on the other hand, POLYDELAYENUM is the slowest and CSCLIQUES2PF performs slightly worse than CSCLIQUES2P probably do to the high connectivity of scale-free graphs, which causes the feasibility check to always return true.

Varying s . We study how the choice of s affects the runtime. Once again, we generated a random graph with 100K nodes and average degree of 10. We measure the time to generate 100 connected s -cliques for values of s varying from 1 to 3. Recall that when $s = 1$, we actually return cliques.

The runtime appears in Figures 9e and 9h. Runtime increases as s increases, as it is increasingly more expensive to find neighbors of distance s . As before, runtime is significantly slower for SF graphs, as they have s -cliques that are much larger. The algorithm POLYDELAYENUM is slower than the others, but returns s -cliques that are larger, on average. (For example, for $s = 3$, on SF graphs,

Figure 10: Execution time for returning large results.

Figure 11: Average and max sizes.

POLYDELAYENUM returns 3-cliques of average size 1084, while the other algorithms return 3-cliques with average size 668.) Even for $s = 3$, the runtime remains reasonable, and in practice, larger values of s are usually not of interest.

Returning all Results. We consider the runtime when returning *all* connected s -cliques in a graph. For this experiment, we generated an ER graph with 100 thousand nodes and average degree of 10. This graph has 112,134 connected 2-cliques. We measure time elapsed between generating every 10 thousand results, until all results are generated.

Figure 9f contains the result of this experiment. Recall that POLYDELAYENUM runs in polynomial delay (Theorem 4.2), i.e., the delay between results is polynomial in $|V(G)|$. However, the CSCLIQUES s variations have no such guarantee. It is therefore somewhat surprising to see that, in practice, the delay between successive sets of 10 thousand results grows for POLYDELAYENUM while for CSCLIQUES2P and CSCLIQUES2PF remaining almost steady. Perhaps this can be explained by the high memory requirements of POLYDELAYENUM (e.g., as it must store all results created), which makes access to auxiliary data structures more expensive as more results are created.²

Non-synthetic Datasets. In Figure 9i we show the results of returning 100 connected 2-cliques over the real datasets presented in the beginning of this section. Once again, the algorithms CSCLIQUES2P and CSCLIQUES2PF outperform POLYDELAYENUM almost consistently. POLYDELAYENUM performs better only over the LiveJournal dataset, but the difference in runtime is small.

Returning Large Results. We consider the heuristics presented in Section 6 to find 100 connected 2-cliques that are larger than k ,

²Also, the reader may note that while the delay given by Theorem 4.2 is polynomial in the input, it is still quite large.

for some given size k . Once again, we generated random graphs with 100K nodes and average degree of 10 and used the real datasets as well. Our range of values for k for the random graphs was determined by the average size of answers returned by the algorithms when no size restriction was given. (With no size restriction, the average result size for the ER graph was approximately 10, and for the SF graph was between 35 and 60, depending on the algorithm used.) For the real graphs, we set $k = 10$.

In Figures 10a, 10b and 10c, the result of this experiment appears, comparing the optimized version of the algorithms (in black) against the regular algorithms (in red) until a hundred large results are found. Interestingly, the time for POLYDELAYENUM on SF graphs is steady, as this algorithm naturally creates large results in this setting. The Bron-Kerbosch adaptations timed out on SF graphs with large k and POLYDELAYENUM timed out on the youtube graph, running over an hour. Clearly, the optimizations for CSCLIQUES2P and CSCLIQUES2PF improve the runtime significantly in most cases, but the optimization for algorithm POLYDELAYENUM is not consistently superior.

We note that the optimizations discussed in Section 6 were very important in achieving the runtimes shown. The speedup with respect to the regular (non-optimized) versions were significant in most cases.

Comparing cliques and s -cliques size. To further motivate enumerating s -cliques for $s > 1$, we compare the sizes of s -cliques for $s = 1, 2, 3$ over the real datasets. For this experiment we randomly sampled 100 s -cliques, for each of the datasets and each of the values of s . We then calculated both average and maximum sizes. The result of this experiment appears in Figure 11. The datasets are organized by increasing edge density, and for each graph, we plot the average and maximum size of cliques, 2-cliques and 3-cliques. Unsurprisingly, the size of s -cliques is larger (for all choices of s) when the graph is more dense. In addition, observe that as s grows larger, the average and maximum size of the s -cliques increases. Note that the sizes are in log scale, and hence, differ significantly.

Depending on the application, finding highly cohesive sets of larger (or smaller) sizes may be more useful. For example, in many settings, communities that are very small, or very large, may be less useful. Smaller communities may not well-represent the actual facts on the ground, while huge communities may contain people who are not sufficiently related. The ability to choose a value for s , and then enumerate (as our algorithms do) gives the user maximum flexibility.

Summary of Results. As is apparent from the results above, all algorithms POLYDELAYENUM, CsCLIQUES2P and CsCLIQUES2PF have runtimes that are quite reasonable. Usually, the adaptations of Bron-Kerbosch have superior runtime to that of the algorithm POLYDELAYENUM, but the latter may be preferable for returning larger s -cliques, particularly on sparse graphs. When comparing CsCLIQUES2P and CsCLIQUES2PF, one can observe that usually the overhead of checking for feasibility (done in the latter algorithm) is larger than the gains derived by avoiding unnecessary recursive calls. (The only exception was for highly dense ER-graphs, in which feasibility checking clearly pays off.)

Another important difference between POLYDELAYENUM and the Bron-Kerbosch adaptations is in memory requirements. Running POLYDELAYENUM requires additional data structures (e.g., the queue Q and index I). Thus, its memory requirements are linear in the size of the output. This contrasts with the Bron-Kerbosch adaptations, which require memory that is linear in the input. In our implementation, we assumed that the structures for POLYDELAYENUM fit in main memory, but for larger inputs (or when desiring to run the algorithm until all results have been found), it would be necessary to use external memory structures.

8 CONCLUSION

This paper studied the problem of finding maximal connected s -cliques in a graph—a problem of high interest, due to the usefulness of clique relaxations. We have presented the first algorithms for this problem, by taking two completely different approaches for solving this problem. The correctness of our algorithms is proven and experimentation shows the efficiency of our approaches.

As future work, we intend to study applications in which connected s -cliques can be useful, such as community detection and link prediction. Optimizations of the algorithms, for special types of graphs (e.g., sparse graphs or bipartite graphs) are also an interesting direction for future work. Another important direction is adapting the algorithms to a distributed environment, as returning all s -cliques for large graphs can become infeasible for a single machine.

ABSTRACT

Record linkage has received significant attention in recent years due to the plethora of data sources that have to be integrated to facilitate data analyses. In several cases, such an integration involves disparate data sources containing huge volumes of records and must be performed in near real-time in order to support critical applications. In this paper, we propose the first summarization algorithms for speeding up *online* record linkage tasks. Our first method, called SkipBloom, summarizes efficiently the participating data sets, using their blocking keys, to allow for very fast comparisons among them. The second method, called BlockSketch, summarizes a block to achieve a constant number of comparisons for a submitted query record, during the matching phase. Additionally, we extend BlockSketch to adapt its functionality to streaming data, where the objective is to use a constant amount of main memory to handle potentially unbounded data sets. Through extensive experimental evaluation, using three real-world data sets, we demonstrate the superiority of our methods against two state-of-the-art algorithms for online record linkage.

1 INTRODUCTION

Massive amounts of data, stored in disparate data sources, have to be integrated and matched to support data analyses that can be highly beneficial to businesses, governments, and academia. Record linkage, also known as *entity resolution* or *data matching*, is the process of identifying records that *match*, i.e., refer to the same real-world entity. The lack of common unique identifiers for records that belong to different data sources, as well as the existence of variations, errors, misspellings, and typos in various data fields, constitute record linkage a challenging process. Traditionally, record linkage consists of two main steps: *blocking* and *matching*. In the blocking step, records that potentially match are grouped into the same block. Subsequently, in the matching step, records that have been blocked together are examined to identify those that match. Matching is implemented using either a *distance function*, which compares the respective field values of a record pair against specified distance thresholds, or a *rule-based approach*, e.g., “if the surnames and the zip codes match, then classify the record pair as matching”.

Several blocking approaches have been developed with the aim to scale the record linkage process to Big data sets without sacrificing accuracy [1, 6, 14, 32]. These methods perform the linkage process offline and provide the result set only when the entire linkage process has been completed. Given the size of modern data sets and the costly operations that have to be performed for record linkage, offline methods can take a significant amount of time to produce the matchings. There are many cases though, where *the linkage process has to return a fast response in order*

to allow for emergency actions to be triggered. Let us assume, for example, a central crime detection system that collects data from several sources, such as crime and immigration records, central citizens’ repositories, and airline transactions. Query data about a suspect could be submitted to this system in order to be matched with any possible similar records found therein. The results of this process have to be reported as fast as possible or, at least, within an acceptably low time period, in order to trigger police enforcement actions.

As another example, consider the recent series of bank and insurance company failures, which triggered a financial crisis of unprecedented severity. In order for these institutions to recover and return to normal business operation, they had to engage in merger talks. One of the driving forces of such mergers is the appreciation of the extent to which the customer databases of the constituent institutions are shared, so that the benefits of the merger can be proactively assessed in a timely manner. A very fast estimation of the extent of the overlap of the customer databases is thus a decisive factor in the merger process. To achieve this, the data custodians could use *summaries of their databases* in order to quickly estimate the overlap of their customers, instead of engaging in a tedious record linkage task. Although our motivation comes from the summarization of the blocking structure of a database, we believe that database summarization is an area of great interest with applications beyond record linkage.

To support real-world applications where record linkage has to be performed in near real-time, several online record linkage approaches have been proposed in the literature [5, 10, 24, 31]. These approaches require the availability of large amounts of main memory, which is necessary in order to store their corresponding data structures. For instance, [5] utilizes large inverted indexes, while [10, 24, 31] sort the records to form blocks by leveraging large matrices or huge graphs. Despite several efforts to utilize small amounts of memory, e.g., [24], the results in terms of performance clearly indicate the *inability of these algorithms to handle an increasingly large volume (or a continuous stream) of records in a real-time fashion*. Given that main memory is always *bounded* and the number of records may in several real-world applications be *unbounded*, the performance of these data structures quickly degrades significantly. Furthermore, in order to deal with this plethora of records and detect the matching pairs, the proposed methods usually resort to conducting *an excessive number of distance computations*. This strategy, however, is not efficient, since it incurs significant delays to the record linkage process.

In this paper, we introduce three methods for efficiently managing large volumes of records in the context of online record linkage. Our first method, called SkipBloom, performs a summarization (synopsis) of the blocking structure of a data set using a small footprint of main memory, whose size is logarithmic in the number of distinct processed blocking keys. This synopsis can be easily transferred to another site (or used remotely) to estimate the common number of blocking keys. Such a preliminary estimation may bring to surface important insights, which can

be further analyzed by the data custodians. The outcome of such analyses may encourage (or discourage) the data custodians to conduct a full-scale record linkage task.

Our second method, called BlockSketch, tackles the problem of blocks that are overwhelmed with records, which should be compared against a query record to detect matching pairs. BlockSketch instead of implementing the naïve linear approach, compares the query record with a *constant number of records in the target block*, which entails a bounded matching time. In order to achieve this optimization, BlockSketch compiles, for each block, a number of sub-blocks, which reflect the distances of the underlying blocked records from the blocking key. The algorithm places a query record to the sub-block whose records exhibit the smallest distances from the query record.

Our third method, called SBlockSketch, operates on data streams, where the entire data set is not known a-priori but, instead, there is an unbounded stream of incoming data records. SBlockSketch maintains a constant number of blocks in main memory at the cost of a time overhead during their replacement with blocks that reside in secondary storage. In this scheme, we propose a selection algorithm to effectively select the blocks that should be replaced, by taking into account their selectivity (by the incoming records) and age.

To the best of our knowledge, SkipBloom is the first algorithm for creating an appropriate synopsis of a blocking structure, while BlockSketch and SBlockSketch are the first methods for sufficiently summarizing a block for the needs of the matching phase of a record linkage task.

The rest of this paper is structured as follows: Section 2 presents the related work, while Section 3 outlines the building blocks utilized by our algorithms and provides the formal problem definition. Sections 4, 5, and 6 present our proposed algorithms from both a practical and a theoretical point of view. The results of our experimental evaluation, including a detailed comparison with baseline methods, are reported in Section 7, while Section 8 concludes this work.

2 RELATED WORK

A significant body of research work has been conducted in record linkage during the last four decades. This work has been nicely summarized in a number of survey articles [4, 9, 30]. However, only a very limited amount of work has targeted the area of near real-time record linkage, such as [5, 7, 8, 12, 15].

In [5], Christen et al. present an approach that involves a pre-processing phase, where the authors compute the similarities between commonly blocked values, using a set of inverted indexes. The authors use the double metaphone [3] method to encode the string values, which are then inserted into the inverted indexes. This scheme is extended in [27], where a heuristic method is presented to index the most frequent values of data fields. This method, though, requires a-priori knowledge of the values in certain fields and is not well-suited for settings where highly accurate results are needed. Ramadan and Christen in [26] utilize a tree structure where a sorting order is maintained according to a chosen field(s). A query record scans not only the node that is inserted, but also its neighboring nodes where similar records may also reside. Nevertheless, the distance computations that should be performed may degrade considerably the performance of this method in online settings.

Dey et al. in [7] develop a matching tree to speed up the decision about the matching status for a pair of records, so that

it can be made without the need to compare all field values. However, the performance of this method depends heavily on the training of the matching tree, which requires a large number of record pairs. Moreover, the authors do not draw any attention to the acute problem of reducing the record pairs comparisons. Ioannou et al. in [8] resolve queries under data uncertainty, using a probabilistic database. The effectiveness of their method heavily depends on the potential of the underlying blocking mechanism, which is used implicitly, to produce blocks of high-quality. In [12], Altwajry et al. propose a set of semantics to avoid resolving certain record pairs. Their scheme, however, focuses on how to resolve generic selection queries (e.g., range queries), rather than on minimizing the query time.

There is also another body of related literature that deals with *progressive* record linkage (e.g., [10, 24, 31]). These techniques report a large number of matching pairs *early* during the linkage process and are quite useful in the event of an early termination of the linkage process, or when there is limited time available for the generation of the complete result set.

The solutions proposed by Whang et al. in [31] and Papenbrock et al. in [24] are empirical and rely heavily on lexicographically sorting the input records to formulate clusters of similar records. Although the sorting technique is quite effective in finding similar values in certain cases, it cannot guarantee identification of matching record pairs. Consider, for example, the similar strings ‘Jones’ and ‘Kones’, where the first letter has been mistyped; using [24, 31], the corresponding records would definitely reside in different clusters (assuming a large number of records). Consequently, the corresponding pair of records would never be considered as matching.

More recently, Firmani et al. [10] introduced two progressive strategies that provide formal guarantees of maximizing recall, focusing though only on minimizing the number of queries to an oracle (which is an entity that replies correctly about the linkage status of a pair) and not on minimizing the running time. Both strategies implicitly assume an underlying blocking mechanism that has been applied on the data sets, and heavily rely on the effectiveness of that blocking mechanism. Their most serious shortcoming is the excessive amount of time-consuming similarity computations, which need to be performed between the formulated pairs in the blocks, *without achieving any increase in recall*. For example, in a data set of 3 million records (including the query set), more than 1.3 *billion* similarity computations should be performed without reporting any results!

There is also another body of work, termed as *meta-blocking* [22, 23], which investigates how to restructure the generated blocks with the aim of discarding redundant comparisons. Meta-blocking techniques, however, conduct a cumbersome transformation of a blocking structure into a graph, which renders these techniques not applicable to online settings.

In Section 7, we elaborate further on the approaches of Christen et al. and Firmani et al., which are the state-of-the-art methods with which we compare our proposed techniques.

3 BACKGROUND AND PROBLEM STATEMENT

In this section, we first introduce the necessary background and terminology for the understanding of our proposed schemes, and subsequently derive the problem statement.

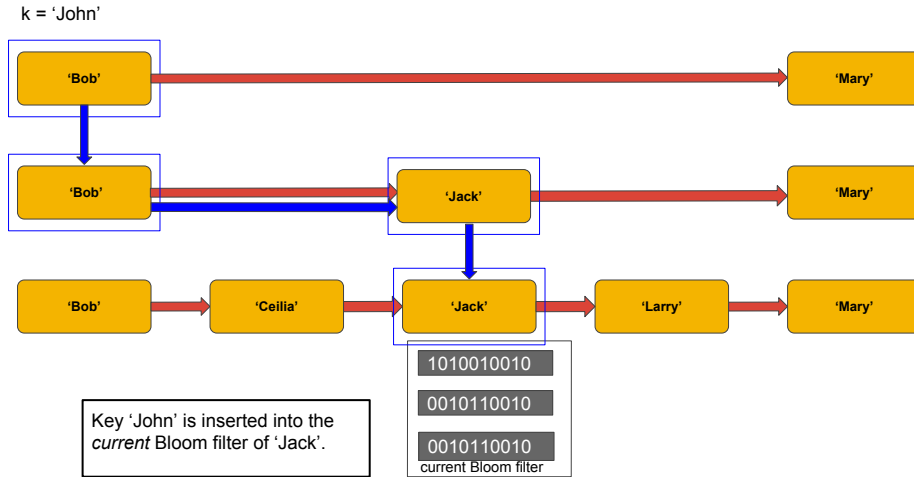

Figure 1: SkipBloom inserts and locates a key in logarithmic time using a small amount of main memory. The blue rectangles and arrows indicate the route to locate the nearest key to k .

3.1 Skip List

A skip list [25] is a probabilistic data structure that is designed to provide fast access to an ordered set of items. It is actually a sequence of lists, or *levels*, where the first list, termed as the *base level*, contains all the items inserted so far in sorted order. Each successive list is a copy of the previous with some elements skipped, until the empty list is reached. Its randomization lies in the number of levels an item will join, determined by tossing a fair coin¹. Each item of each list is linked to the same item in the previous list, as well as to the next item at the same level. The query operation for an item starts at the top-level, by horizontally scanning the items therein until it encounters either the target item or a larger item. In the case of a larger item, the same process is repeated at the lower level until the base level is reached. The running time to insert an item, as well as to report the existence of an item, is $O(\log(n))$, where n is the number of inserted items.

3.2 Bloom Filter

A Bloom filter [2] is a probabilistic data structure for representing a large number of items using a small number of bits, which are initialized to 0, to efficiently support membership queries. Each item is hashed by a set of universal hash functions that map it to certain positions, chosen randomly and uniformly, in the Bloom filter. Accordingly, these positions are set from 0 to 1. Upon querying for an item, the same process is followed, where:

- one can definitely infer that this item has not appeared, if all retrieved positions are set to 0.
- one can conjecture that this item has appeared with certain probability, if all retrieved positions are set to 1. The probabilistic nature of the reply is due to the fact that these positions may have been set to 1 by other items and not the query item.

3.3 Problem Formulation

Consider two data custodians who own data sets A and B , respectively. For each record r of A (or B), the data custodians use

¹As long as *tails* come up, we add the item to each successive list. We terminate this process when we encounter *heads*.

a function $k = \text{block}(r)$ that generates the blocking key k of r . This key is used to locate a *target block* in the blocking structure to either insert r into the target block (blocking), or iterate all the records already found therein and compare them with r (matching). We use D_A and D_B to denote the set of blocking keys of each of these data sets. Moreover, we refer to the fraction $\mathcal{D} = \frac{|D_A \cap D_B|}{|D_B|}$, as the *overlap coefficient* between A and B .

In this work we introduce three algorithms, namely SkipBloom, BlockSketch, and SBLOCKSketch, for addressing the following problems²:

Problem Statement 1. Calculate the overlap coefficient for A and B , by accurately summarizing D_A and D_B using **sublinear memory requirements and sublinear running time** in the number of inserted blocking keys.

Problem Statement 2. For each query record of A (or, equivalently, B), find the set of its matching records from B (or, equivalently, A) in **constant running time**.

Problem Statement 3. For each query record of A (or, equivalently, B), find the set of its matching records from B (or, equivalently, A) in **constant time**, using also a **constant amount of main memory**.

4 THE OPERATION OF SKIPBLOOM

SkipBloom is an efficient blocking data structure that reports membership queries of blocking keys (derived from a large data set) to the blocking structure, using only a small footprint of main memory. It implements the following generic operations:

- $\text{query}(k)$: Reports the membership (*true* or *false*) of key k to SkipBloom.
- $\text{insert}(k)$: Inserts key k into SkipBloom.

The operation of SkipBloom is based on a skip list that implements a mechanism to locate efficiently a blocking key, as well

²SkipBloom aims to address Problem 1, BlockSketch targets Problem 2, while SBLOCKSketch tackles Problem 3.

Figure 2: SkipBloom inserts a reference from the list of Bloom filters of ‘Johnson’ to the first Bloom filter of ‘Johns’, in order to maintain the consistency of the blocking mechanism.

as on a series of Bloom filters, which are used as fast memory-bounded buffers.

SkipBloom maintains, in expectation, \sqrt{n} blocks in main memory, stored in the base level of the skip list. Each such block, which is represented by its key³, includes a list of Bloom filters in order to store keys that have been driven by the mechanism of the skip list to this block. This actually means that the keys stored in the Bloom filters of a block are greater than the value of the corresponding key.

The operation of SkipBloom is illustrated in Figure 1. In this figure, a skip list is shown that contains five keys in the base level. Upon receiving a query record, which is first filtered by a blocking function to generate its key (e.g., $k = \text{‘John’}$), SkipBloom locates the block ‘Jack’ very fast, using the logarithmic runtime property of the underlying skip list. According to the operation of skip lists, this block is alphabetically the nearest key to k from the left. The next step is a simple insertion of k into a Bloom filter of ‘Jack’. Each block has an active Bloom filter, termed as *current*, and a number of inactive Bloom filters, which are used only during the query process, as we will shortly explain.

To answer a query on whether a certain key k exists or not, SkipBloom follows almost the same process as described above. Assume, for example, that SkipBloom receives the query $k = \text{‘Jonathan’}$. First, the skip list will be scanned to eventually locate ‘Larry’. Subsequently, each Bloom filter of this block will be iteratively queried until k is found, or the Bloom filters of ‘Larry’ are exhausted.

In what follows, we provide details that will justify certain design choices, such as the reason for maintaining a series of small (in length) Bloom filters in each block, instead of having a larger one. In order to populate the skip list with keys, we apply a simple Bernoulli random sampling algorithm that chooses each key with probability equal to $n^{-1/2}$. This sampling process ensures the uniform reflection of the distribution of keys from the data set to the skip list. This is an appealing feature, since SkipBloom easily tackles distribution anomalies, such as skews of certain ranges of keys, by choosing these keys and inserting them into the skip list to effectively reduce the bottleneck of certain keys and maintain uniformity (in expectation). Any uniform sampling method can be applied; we refer the interested readers to a comprehensive survey in [13].

If a large number of similar keys are generated, then the sampling routine will choose randomly similar keys to create the corresponding blocks. For example, consider the case of blocking a large number of surnames from the US census data. Then, possible blocks might be ‘Johns’, ‘Johnson’, and ‘Johnston’, which will

be created in this particular chronological order. Consequently, there will be keys other than ‘Johns’, e.g., ‘Jordan’ or ‘Jolly’, that will be inserted into the Bloom filters of ‘Johns’. These Bloom filters should be now transferred to (or referenced by) ‘Johnson’, and then to (by) ‘Johnston’. For this reason, we keep the number of keys that can be inserted into each Bloom filter small; this number will be accurately specified later. Moreover, we annotate each Bloom filter with its smallest and its greatest key, in terms of alphabetical order. By doing so, upon inserting ‘Johnson’, SkipBloom scans iteratively the Bloom filters of ‘Johns’ to locate Bloom filters that *might contain* ‘Johnson’, or any greater values. If such Bloom filters exist, a simple reference is established between the block of ‘Johnson’ and the corresponding Bloom filters. Figure 2 illustrates the reference of a block to a Bloom filter that belongs to the previous block.

Eventually, a record is stored into a key/value database system, maintaining its original blocking key, regardless of the block that was used in SkipBloom.

Algorithm 1 The query operation of SkipBloom.

Input: Skip list SL , query key k
Output: *true* if k is found, *false* otherwise
1: Key $p \leftarrow SL.query(k)$
2: **while** ($p.hasBloomfilters()$) **do**
3: $bf \leftarrow p.nextBloomfilter()$
4: **if** ($k \geq bf.min$ AND $k \leq bf.max$) **then**
5: **if** ($bf.member(k) == true$) **then**
6: **return true**
7: **end if**
8: **end if**
9: **end while**
10: **return false**

4.1 Algorithms

Algorithm 1 illustrates the query operation of SkipBloom. First, the skip list SL is queried to locate the nearest key p to the query k (line 1). Then, the Bloom filters that are both maintained and referenced by p ⁴ (line 2) are scanned iteratively to find k using the min and max values of each Bloom filter (line 4). If k is found, then the algorithm terminates (line 6). In case of composite keys, we perform a conjunction using the individual keys.

Algorithm 2 outlines the insertion of a key in SkipBloom. For each key k derived from each record, we determine with probability $\frac{1}{\sqrt{n}}$ whether k will be inserted into the skip list or not (line 1). In more detail, we generate a random value in $(0, 1)$ and then pick k if this value is less than $\frac{1}{\sqrt{n}}$. Since the generation of a random value is an expensive operation, we exploit the fact that the number of keys skipped between successive inclusions follow a geometric distribution [13]; accordingly, each time we pick a key, we generate the position of the next key, in the stream of records, that will be picked.

If a key k will be inserted into the skip list as a base level key, then a block is created after the nearest key to k (line 2). Then, SkipBloom has to locate each Bloom filter of p that may contain keys that should be now transferred to the newly created block of k (lines 4–8). In order to easily locate these Bloom filters, we annotate each Bloom filter used with the min and max keys it contains (line 5). The inclusion of a Bloom filter with a valid range of keys is achieved through a reference from p to k .

If a key will not be stored in the skip list, then the nearest key p to k is located in order to insert k in the current Bloom filter of

³Henceforth, *key* and *blocking key* will be used interchangeably.

⁴SkipBloom locates these Bloom filters performing a recursive process.

Algorithm 2 The insert operation of SkipBloom.

```

Input: Skip list  $SL$ , key  $k$ 
1: if ( $nextSample() == true$ ) then
2:    $Key\ p \leftarrow SL.insert(k)$   $\triangleright$  Key  $p$  is the nearest (previous) key to  $k$ 
3:    $List\ bfList \leftarrow k.createList()$   $\triangleright$  The list  $bfList$  that will
                                     host the Bloom filters of  $k$  is created
4:   for each  $bf$  in  $p$  do
5:     if ( $k \geq bf.min$  AND  $k \leq bf.max$ ) then
6:        $bfList.add(bf)$   $\triangleright$  A reference is added
                                     to each Bloom filter found in  $p$ 
                                     that might contain keys that belong to  $k$ 
7:     end if
8:   end for
9: else
10:   $Key\ p \leftarrow SL.query(q)$ 
11:   $bf \leftarrow p.getCurrentBloomFilter()$ 
12:   $bf.insert(k)$ 
13:  if ( $k \leq bf.min$ ) then
14:     $bf.min \leftarrow k$ 
15:  end if
16:  if ( $k \geq bf.max$ ) then
17:     $bf.max \leftarrow k$ 
18:  end if
19: end if
  
```

p (lines 10–12). Algorithm 2 eventually updates the min and max annotations of the current Bloom filter of p (lines 13–18).

4.2 Accuracy and Complexity Analysis

As we expect \sqrt{n} blocks in the base level of the skip list, where the sampling process ensures a uniform distribution of the corresponding blocking keys, the expected number c of keys in each block is:

$$E[c] = \frac{n}{\sqrt{n}} = \sqrt{n}. \quad (1)$$

By setting $u = \sqrt{n}/m$ to be the maximum number of keys that will be stored in each Bloom filter, where m is a constant value (e.g., $m = 10$), the number of Bloom filters in each block will be (in expectation) equal to m . Furthermore, the number m_{bt} of Bloom filters contained in block b at time t , specifies the upper and lower bound of the number n_{bt} of the distinct keys inserted, which is:

$$(m_{bt} - 1) \frac{\sqrt{n}}{m_{bt}} \leq n_{bt} \leq m_{bt} \frac{\sqrt{n}}{m_{bt}}. \quad (2)$$

The accuracy of SkipBloom to report the existence of a key depends on the false positive probability parameter fp of the Bloom filters. First, consider the event where a query key does not exist in any Bloom filter of the resulting block. The probability of reporting correctly this event, using one such Bloom filter, is $1 - fp$. Hence, the same probability by using collectively all the m Bloom filters is:

$$(1 - fp)^m, \quad (3)$$

since the content of a Bloom filter is independent from that of another Bloom filter.

In the case that a query key does exist in any⁵ Bloom filter of the resulting block, the probability of reporting this event is 1. Therefore, we bound from below the error probability of SkipBloom by $1 - (1 - fp)^m$.

Computational complexity: Based on Algorithm 1, the running time of querying SkipBloom is $O(\log(\sqrt{n}) + m + m\sqrt{n})$, where the first term denotes the time of scanning the skip list to locate the appropriate block, the second term denotes the time of scanning the Bloom filters found therein, and the last term is the time of scanning the Bloom filters referenced directly or indirectly by the chosen block.

⁵Since, we expect to have duplicate keys, it is quite natural that the same key may be stored into multiple Bloom filters of a block.

Algorithm 2 suggests that the running time of an insertion of a key into SkipBloom is $O(\log(\sqrt{n}) + m)$, where the two terms are the time of inserting a key into the skip list and the time of scanning the Bloom filters of the nearest key, respectively.

Memory complexity: The memory requirements of SkipBloom are $O(2\sqrt{n} + \sqrt{nm}) = O(\sqrt{n}(2 + m))$, because the skip list contains $O(2\sqrt{n})$ keys and each key in the base level of the skip list consists of $O(m)$ Bloom filters.

4.3 Using SkipBloom as a Synopsis of the Universe of Blocking Keys

SkipBloom can be used as a *synopsis*, termed also as *summarization*, of the universe of the blocking keys of a database, in order to facilitate an accurate pre-blocking process. During the execution of this process, the data custodians will resolve very fast the common blocks, which will be of great assistance in estimating the running time, in terms of the number of comparisons that will be needed (by exchanging the number of records in each common block). In turn, the data custodians will determine whether they will perform the linkage process or not, by considering several factors based on these preliminary results. For instance, if the number of common blocks is very small, then (a) the chances of identifying similar, or matching, record pairs are rather slim, and (b) the record linkage process itself may not be cost-effective.

Let us now consider the following scenario. Data custodian A generates a SkipBloom from database A , which is submitted to data custodian B . Subsequently, data custodian B iterates her blocking keys and queries the SkipBloom, which reports positive or negative answers for the existence of the query keys. This entails $O(n(\log(\sqrt{n}) + m + m\sqrt{n})) = O(n(\log(\sqrt{n}) + \sqrt{n}))$ running time,⁶ since each key of B is queried against the SkipBloom of A .

To further accelerate this process, data custodian B also generates a SkipBloom, to compile a uniform sample of keys and to use this SkipBloom to report membership queries. The keys found in the base level of the skip list are now queried against the SkipBloom of A , as illustrated in Figure 3.

Figure 3: The blocking keys of the databases are packed into their corresponding synopses, each of which is implemented as a SkipBloom (symbolized by SB). These synopses are used to draw inferences about the source databases.

Since, the keys of B constitute a randomly and uniformly chosen sample, they can be used as input to a Monte Carlo simulation [21], which will estimate the proportion (or the number) of identical blocking keys between the data sets of the two data custodians. Using only the synopses, the data custodians will acquire a clear picture about the overlapping keys with certain approximation guarantees. Monte Carlo simulation requires $(\epsilon^2 \vartheta)^{-1}$ (ignoring a small constant factor) keys from B in order to exhibit relative error ϵ with high probability. Since the proportion of identical keys is unknown, we bound it from below with a reasonable value, e.g., $\vartheta = 0.05$, to approach the number \sqrt{n} of the sampled keys that

⁶We assume that the number of distinct blocking keys is n in both A and B .

Figure 4: Illustration of a block with $\lambda = 2$ sub-blocks, whose key is $\langle \text{John}, \text{Jon} \rangle$. BlockSketch inserts records into the sub-blocks based on the distance of the key values of these records from the chosen representative(s). The sub-block for which one of its representatives exhibits the smallest distance from the key values of a record, is chosen as the target sub-block.

are contained in the SkipBloom of B . Even for a relatively small $n = 10^8$, the Monte Carlo simulation will provide its guarantees, since \sqrt{n} is greater than the required number of sampled keys for $\epsilon \geq 0.05$. The fraction of the overlapping keys found in the sample is used as an estimate for the overlap coefficient of the keys between the two databases. By comparing the synopses, we eventually achieve the much faster $O(\sqrt{n}(\log(\sqrt{n}) + \sqrt{n}))$ running time, compared to using only the synopsis of data custodian A .

5 THE OPERATION OF BLOCKSKETCH

The existence of blocks that contain a large number of records makes the *matching phase* (i.e., the comparison of query records against every record found in a target block) prohibitively expensive in highly demanding environments. The situation becomes even more challenging in environments where the matching record pairs have to be reported in near real-time.

To address this shortcoming, in this work we opt for a different strategy: we compare the query record with *a constant number of records of the target block*, which entails a bounded matching time. This optimization requires maintaining λ sub-blocks ($S_1, S_2, \dots, S_\lambda$) in each block, whose aim is to represent sufficiently the records inserted so far. In our proposed representation, a number of records play the key role of *representatives* for each sub-block. This allows to formulate groups of records inside each block that are more likely to match. We term our proposed algorithm as BlockSketch, because a small number of records comprise a sketch that represents sufficiently the records of an entire block. The concept of *sufficient representation* boils down to choosing representatives that exhibit certain distances from the corresponding blocking key. We note that BlockSketch can operate either autonomously or in conjunction with SkipBloom, where the latter will be used as a fast bounded memory to report whether a certain blocking key has appeared or not.

The fact that certain records are inserted into a block, using a blocking function, implies that all these records share some degree of similarity. Therefore, it is reasonable to assume that the distance between a key and a record⁷ will be upper bounded by $\lambda\theta$. Hence, BlockSketch formulates λ sub-blocks, each of which

⁷The distance either between a pair of records, or between a blocking key and a record, is determined by the distances of the certain field values, part of which usually make up the blocking key.

represents records with distances $\leq \theta, \leq 2\theta, \dots, \leq \lambda\theta$ from the key, where θ is the distance threshold of the keys of a pair of matching records. Upon receiving a key, BlockSketch aims to insert this record into the sub-block of the target block, where it is more likely to formulate matching record pairs. For this reason, each key is compared against all representatives found in a block, in order to locate the sub-block whose representative exhibits the smallest distance from the newly arrived key.

As an example, assume that we use edit distance as the similarity metric, $\theta = 2$ and $\lambda = 3$, and a blocking key is used that consists of the first three letters and the whole value of the *surname* and *given name* attributes, respectively. As Figure 4 shows, record $\langle \text{John}, \text{Jones}, 1970 \rangle$, whose key values exhibit a total distance of $2 \leq \theta$ from $\langle \text{John}, \text{Jon} \rangle$, is inserted into the 1-st sub-block, because of the representative $\langle \text{John}, \text{Jon} \rangle$. Similarly, $\langle \text{John}, \text{Jonker}, 1975 \rangle$, whose distance is $3 \leq 2\theta$ from $\langle \text{John}, \text{Jon} \rangle$, is inserted into the 2-nd sub-block, due to the comparison with the representative $\langle \text{John}, \text{Jonkers} \rangle$.

It is important to note that for threshold θ any metric that is used in record linkage processes can be supported, whether satisfying the triangle inequality or not. For example, a very commonly used metric in record linkage is the Jaro-Winkler similarity function [3], which takes on values in $[0, 1]$. Hence, one by setting the similarity threshold to θ' , and then by choosing $\theta = 1 - \theta'$, produces very reasonable sub-blocks.

The probability for a record to fall into a certain sub-block that holds its matching record, depends on the representatives of the target sub-block, as well as on the left and right neighboring sub-blocks. For instance, assume two neighboring sub-blocks with representatives *Jacks* and *Jackson*, respectively. The keys of these representatives comprise the values of the *surname* attribute. Key *Jackson* arrives, whose record is inserted into the identical sub-block of *Jackson*. At a later time, *Jacksn* arrives, that suffers from a typo, whose record is inserted into the sub-block of *Jacks*. We have thus missed the formulation of one matching record pair. BlockSketch tackles this deficiency by *using more than one representatives for each sub-block*⁸, so as to give more chances for grouping together matching record pairs. By doing so, if record a has been inserted into a sub-block, BlockSketch compares the key of its matching record b with more similar representatives to record a . To keep the number of representatives of a sub-block constant, whenever a key is chosen for inclusion in a sub-block, the algorithm tosses a coin to determine if this newly inserted key would be a representative as well. If it is chosen, a randomly picked old representative is evicted from the set of representatives.

As a last step, the query record is inserted into that sub-block which is maintained by a key/value database. The pairs formulated in this sub-block constitute the final result set.

5.1 Algorithm

Algorithm 3 outlines the basic operation of BlockSketch. For a query record q , the algorithm first retrieves an object S that contains the corresponding sub-blocks, either from a key/value database or from a cache structure in main memory (line 2). BlockSketch then iterates over the representatives of each sub-block and performs the distance computations between the key values of q and these representatives,⁹ whose results are stored in array u (line 5). The representative that exhibits the smallest

⁸The exact number of representatives will be specified later.

⁹A representative, being essentially a blocking key, has only key values.

distance from the key values of q specifies the sub-block (line 12) into which q is finally inserted (line 17). For ease of presentation, we omit from Algorithm 3 the details regarding the random choice and eviction of a representative from a sub-block.

Algorithm 3 The core operation of BlockSketch.

```

Input: Query record  $q$ 
1:  $k \leftarrow \text{block}(q)$ 
    ▶ Function  $\text{block}(\cdot)$  generates the blocking key, which will be used to look up the corresponding sub-blocks.
2:  $\text{SubBlocks } S \leftarrow \text{retrieve}(k)$ 
    ▶  $S$ , which is retrieved from secondary storage or from a cache structure, contains the sub-blocks of block  $k$ .
3: for  $i = 1$  to  $\lambda$  do
4:   for  $j = 1$  to  $\rho$  do
5:      $u[i][j] \leftarrow d(k, S[i][j])$ 
    ▶  $S[i][j]$  denotes the  $j$ -th representative of the  $i$ -th sub-block.
6:   end for
7: end for
8:  $\text{min} \leftarrow u[1][1]$ 
9: for  $i = 1$  to  $\lambda$  do
10:  for  $j = 1$  to  $\rho$  do
11:   if  $(\text{min} > u[i][j])$  then
12:     $\text{min} \leftarrow i$ 
    ▶ Find the  $i$ -th sub-block whose at least one of its representatives exhibits the smallest distance from  $k$ .
13:  end if
14: end for
15: end for
16:  $\text{represent}(k, \text{min})$ 
    ▶ Determine with a coin toss if  $k$  would be a representative for the chosen sub-block.
17:  $\text{insert}(q, k, \text{min})$ 
    ▶ Store  $q$  in a key/value database by setting the key as the concatenation of  $k$  and  $\text{min}$ .

```

5.2 Accuracy and Complexity Analysis

The probability of a record to fall into the correct sub-block is $1/\lambda$, since it completely relies on the distance from the corresponding representative. Hence, the inverse probability of a record not falling into the correct sub-block, and therefore not formulating a record pair, is $\leq 1 - 1/\lambda$. In order to amplify the probability of formulating a matching record pair, we give more chances for grouping together the two constituent records, by comparing each key with a number ρ of representatives, chosen randomly and uniformly from the underlying stream. We rigorously specify the required number of representatives that each sub-block should maintain, as the following lemma suggests.

LEMMA 5.1. *If a pair of records, which constitute a matching pair, has been brought in a certain block, then by maintaining $\rho = \lambda \ln(\frac{1}{\delta})$ representatives in each sub-block, this matching pair is detected with probability at least $1 - \delta$.*

PROOF. The probability of not detecting a matching pair that exists in a certain block is $(1 - \frac{1}{\lambda})^\rho$. We bound this probability above by δ and solve for ρ in the following:

$$(1 - \frac{1}{\lambda})^\rho < \delta \approx -\frac{\rho}{\lambda} < \ln(\delta) \iff \rho > \lambda \ln(\frac{1}{\delta}), \quad (4)$$

since $\ln(1 - \frac{1}{\lambda}) \leq -\frac{1}{\lambda}$. □

We subsequently apply the ceiling function on the value of ρ ($\lceil \cdot \rceil$), in order to select the smallest integer following ρ for the sake of optimality. ■

Computational complexity: The running time of BlockSketch is $O(\log n + \lambda\rho)$, which consists of the time

to retrieve a block from the database (which is logarithmic¹⁰), and the execution of the subsequent $\lambda \times \rho$ distance computations (ρ representatives for each of the λ sub-blocks).

Memory complexity: The storage requirements of BlockSketch are $O(\lambda n)$, where n is the number of blocking keys.

6 THE OPERATION OF SBLOCKSKETCH

Let us now suppose that the number of records, which are initiated from multiple sources, e.g., from different hospitals, is unbounded (or endless). This literally turns the record linkage scenario of a large number of records, into the record linkage of a stream of records. Therefore, BlockSketch will grow in both directions; it will not grow only in terms of sub-blocks, but also its number of blocks might unexpectedly grow considerably. Since our main memory is bounded, BlockSketch adapts its operation to record linkage tasks that involve streams of records.

In this version of BlockSketch, called SBBlockSketch, we bound the number of blocks, that are maintained in main memory, by an integer value μ which depends on the available main memory. Since the number of blocks is bounded, SBBlockSketch applies an eviction strategy, so as to insert a newly arrived blocking key from the stream, when there is not an empty slot to accommodate the corresponding block. We annotate each *live*¹¹ block with (a) the number of incoming records that generated its key, i.e., the number ξ of times this block has been chosen as the target block, and with (b) its age α , in terms of the number of times that this block has survived eviction, since its admission into main memory. We derive the eviction status of each block as follows:

$$es = e^{(w\xi - \alpha)}, \quad (5)$$

where factor w adjusts the weight of successes ξ of a block to its es . The intuition behind this scheme is that we promote (a) newer blocks against older ones, and (b) blocks that exhibit higher eligibility. The status of old blocks, that are additionally not chosen by the incoming records, will exponentially decay, which will result in their eviction from the main memory. SBBlockSketch is materialized by a hash table, which holds the live blocks, and the corresponding sub-blocks, and a priority queue, that is used to indicate which of these live blocks should be evicted in case of a newly arrived block (key).

Figure 5 illustrates the components of SBBlockSketch, namely the hash table T and the priority queue pq . T exists in main memory and contains a specified number μ of rows, each of which holds a block, as a function of the available main memory. Each row of T contains the sub-blocks of the corresponding block. The priority queue pq stores the eviction status of each live block in ascending order, so as to return the key of the block that holds the minimum eviction status. In the example shown in Figure 5, we observe that the block with key k_4 has survived $\alpha = 4$ evictions and has not been chosen as target block since its admission into T . These two events lead inevitably to its eviction, despite the existence of block k_2 , which has $\alpha = 10$ survivals, but it additionally exhibits $\xi = 6$ successes.

¹⁰For instance, LeveLDB (see <https://github.com/google/leveldb>) uses an in-memory highly efficient multi-level data structure, which enables logarithmic disk seeks in the number of stored blocking keys.

¹¹A *live* block is a block that is stored in main memory.

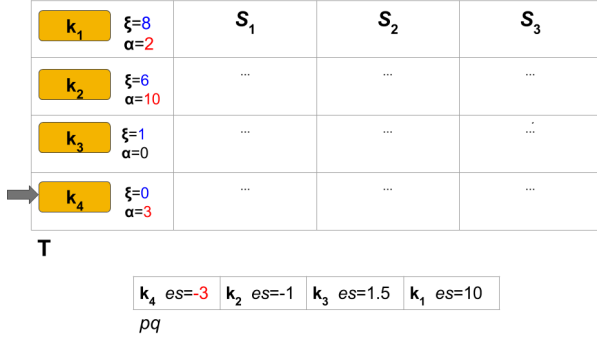

Figure 5: In this example, SBLOCKSKETCH uses a hash table T with $\mu = 4$ blocks, $\lambda = 3$ sub-blocks, and the weight of successes set to $w = 1.5$. On the arrival of an incoming new key, the block with key k_4 is evicted because of its low eviction status. The priority queue pq stores the eviction status (on a logarithmic scale) of each live block.

6.1 Algorithm

Algorithm 4 illustrates the operation of SBLOCKSKETCH, using a stream of data records. Upon receiving a record from the stream, the algorithm first derives its key, and then queries T (line 2). Only if this query is fruitless, SBLOCKSKETCH resorts to the structures of secondary storage (line 4). If the block that corresponds to the incoming record exists neither in T nor in secondary storage, then SBLOCKSKETCH initiates the eviction of the block from T that exhibits the minimum eviction status, as indicated by pq (line 7). Eventually, SBLOCKSKETCH computes the eviction status of each live block and rebuilds pq .

Algorithm 4 The eviction algorithm of SBLOCKSKETCH using a stream of records.

```

Input: Query record  $q$ 
1:  $k \leftarrow \text{block}(q)$ 
2:  $\text{SubBlocks } S \leftarrow T.\text{get}(k)$  ▷ Function  $\text{get}()$  retrieves an entry from hash table  $T$ .
3: if ( $S = \text{NULL}$ ) then
4:    $\text{SubBlocks } S \leftarrow \text{retrieve}(k)$ 
5: end if
6: if ( $S = \text{NULL}$ ) then
7:    $\text{SubBlocks } S \leftarrow pq.\text{poll}()$ ; ▷  $pq$  is a priority queue that holds the eviction status of each live block in ascending order.
▷ Function  $\text{evict}()$  transfers a certain block, which is essentially a structure of sub-blocks, from main memory into secondary storage.
8:    $S.\text{evict}()$ ; ▷ Function  $\text{calculateStatus}()$  computes the status of each live block and inserts it into  $pq$ .
9:    $\text{calculateStatus}()$ ;
10: end if

```

6.2 Accuracy and Complexity Analysis

The accuracy of SBLOCKSKETCH is not affected by the use of T , since the block in question might exist either in main memory or in secondary storage. However, T , whose operations are of $O(1)$ time, affects both running time and space.

Computational complexity: The running time depends on two mutually exclusive possibilities. The first one is when a block exists in T , where the running time is $O(\lambda)$ (see Section 5.2), while the other possibility is when a block should be evicted from T . The eviction requires accessing the priority queue, which is of $O(\sqrt{\mu})$ time, and then transferring the incoming block into T . The

Table 1: Technical characteristics of the data sets used. The blocking fields used, and their length (in characters) are shown in bold ($m = 5$).

	DBLP	NCVR	LAB
$ Q $	300K	500K	100K
$ A $	300M	500M	100M
fields	'author' [50%], 'venue' , 'year'	'given name' , 'surname' [50%], 'address' , 'town'	'assay' [6], 'result' 'year'
	$u = 3,465$	$u = 4,473$	$u = 2,000$

latter step consumes, as we discussed in Section 5.2, $O(\log(n))$ time in the number n of available blocks found in the secondary storage. Finally, we have to add the time to build the priority queue, which is $O(\mu \log(\sqrt{\mu}))$. Hence, the total running time for replacing a block is $O(\sqrt{\mu} + \log(n) + \mu \log(\sqrt{\mu}))$.

Memory complexity: The space occupied in main memory is exactly $O(\mu\lambda)$, where μ corresponds to the rows and λ to the cells of T (by assuming T as a two-dimensional array).

7 EXPERIMENTAL EVALUATION

For the experimental evaluation, we used three real-world data sets, namely (a) DBLP¹², which includes bibliographic data records, (b) NCVR¹³, which comprises a registry of voters, and (c) LAB¹⁴, which includes biological assays (e.g., albumin, hepatitis, or creatinine) and their corresponding results. The technical characteristics of these data sets are summarized in Table 1. For each record of each data set, denoted by Q , we generated 1,000 perturbed records, which were placed in a separate data set symbolized by A . We perturbed all the available fields using at most four edit, delete, insert, or transpose operations, chosen at random.

The blocking methods that were used for the needs of the evaluation were standard [4] and LSH blocking [18], which relies on the Locality-Sensitive-Hashing [11] technique. LSH blocking generates from a single record a certain number of blocking keys that are placed in multiple hash tables. This number of blocking keys is a function of several parameters [19] of LSH blocking, such as the distance threshold. The LSH technique is commonly used in the domain of record linkage [17, 18, 20, 29] because of its efficiency and accuracy guarantees. We used Hamming LSH blocking [18], in which records are embedded into the Hamming space using record-level Bloom filters [28]. LSH blocking implements redundant blocking, because a record is inserted into multiple independent blocks, which are accommodated into independent hash tables. In contrast, standard blocking inserts records that exhibit identical values, in an appropriately chosen blocking field(s), into the same block.

For performing the standard and the LSH blocking, we utilized LevelDB¹⁵ and LSHDB [16], respectively. The length of each Bloom filter, utilized by SkipBloom, was set to 32,000 bits for storing 5,000 keys, with false positive probability set to $fp = 0.05$.

We evaluated our schemes and their competitors according to the time needed, and the memory that was consumed to perform the record linkage process, as well as the recall and precision rates

¹²<http://dblp.uni-trier.de/xml>

¹³<http://dl.ncsbe.gov/index.html?prefix=data/>

¹⁴<https://dash-data.ucsd.edu/community/43>

¹⁵<https://github.com/google/leveldb>

that were achieved. We ran each experiment 20 times and plotted the average values in the figures. The software components were developed using the Java programming language (ver. 1.8) and the experiments were conducted in a virtual machine utilizing 4 cores of a Xeon CPU and 32GB of main memory.

7.1 Baseline Methods

We compared our schemes with two state-of-the-art methods for online record linkage. The first method, termed as INV [5], uses inverted indexes as its basic blocking structure. The main idea behind this method is the pre-computation of similarities between field values that have been inserted into the same block. An inverted index is used for this purpose, which stores the blocking keys encoded by the double metaphone method¹⁶. A weakness of this structure regards the storage of all field values of a record into the same set of indexes. As a result, one cannot be certain for a value encountered therein, to which field this value belongs. This ambiguity affects negatively the recall rates of INV.

The second method we compared against is the Edge Ordering strategy, termed as EO, which was introduced in [10]. EO utilizes an oracle, which is aware of the ground-truth, to resolve the matching status of a record pair. A graph is constructed by assuming each record pair, which materializes an edge connecting two vertices/records, formulated in each block. The algorithm performs all similarity computations in the target block in order to assign a probability estimate to each edge (pair) based on its similarity. In turn, EO selects those edges that are expected to maximize the recall, and submits them to the oracle that returns their matching status.

Both EO and INV utilize only key/value pairs, materialized by hash tables that map a key to list of record Id 's. These methods do not offer any component to report efficiently the membership of a certain key, or to adequately summarize the data set. Thus, in order to be fair in our comparison with these methods, we maintained the key/ Id 's mappings, as well as the entire records, in secondary storage.

Both the baseline methods and our proposed schemes used the Jaro-Winkler [3] function as the similarity measure, where the corresponding threshold was set to $\theta = 0.75$.

7.2 Experimental Results

In our first set of experiments, we evaluated the running time and memory performance, as well as the ability of the SkipBloom algorithm to provide accurate estimates in the pre-processing step of record linkage.

Figure 6a shows the total time needed to build the SkipBloom, by scaling the number of the streaming records using the NCVR data set. It is quite obvious that the time increases by a constant factor, depending on the number of records that are processed. The consumption of main memory is illustrated in Figure 6b, where SkipBloom exhibits almost linear performance. Specifically, although the number of records increases by 10 and 50 times, SkipBloom utilizes 0.6GB, 0.8GB, and 1.4GB of main memory, respectively. In contrast, a map data structure, symbolized by MAP, e.g., a HashMap in the Java programming language, exhibits a steep linear performance. In both scenarios, MAP throws fatal errors and terminates when it reaches the processing of 500M records.

¹⁶Using the double metaphone encoding method, 'SMITH' and 'SMYTH' are both encoded as 'SMO'.

Figure 6: Scaling the number of records to measure the time and space requirements of SkipBloom.

Table 2: Time (in seconds) consumed by SkipBloom for reporting the existence of a key.

	10M	100M	500M
Time	0.000277	0.000315	0.000365

Table 3: Evaluating the accuracy of SkipBloom in estimating the fraction of matching pairs.

ϵ	DBLP	NCVR	LAB
.10	0.94 \pm .023	0.95 \pm 0.021	0.94 \pm 0.022
.05	0.97 \pm .022	0.98 \pm 0.021	0.98 \pm 0.024

Table 2 illustrates the time consumed by SkipBloom to report the existence of a key. We remind to the reader the probabilistic nature of SkipBloom, whose performance depends on the number of comparisons that will take place until the target block is located (which is $O(\log(\sqrt{n}))$). For this reason, we observe that SkipBloom almost consumes the same amount of time when it has to process either 100M or 500M records.

The accuracy of SkipBloom is evaluated by the fraction of overlapping keys it estimates using the above-mentioned data sets. Table 3 clearly shows that SkipBloom approximates the overlap coefficient of A and Q for each data set, where in the worst case it exhibits an error nearly equal to 0.06 (which is within its approximation guarantees specified by ϵ).

In the next set of experiments, we compared our schemes against EO and INV. Figures 7a and 7b display the recall rates achieved by all methods using standard and LSH blocking, respectively. We observe in Figure 7a that EO exhibits slightly better recall rates than BlockSketch, by using all data sets, although the differences lie in the small range [0.01, 0.04]. Also, INV falls short in formulating those matching pairs that exhibit a high degree of perturbation, which is due to the weakness of the double metaphone scheme to group together such pairs into the same blocks. The recall rates of DBLP and NCVR are also higher than LAB, which is due to the longer (in characters) blocking keys, which render them more tolerant to the perturbation errors. BlockSketch achieves to maintain high recall rates, although we have to stress that the underlying blocking method drives the whole linkage process. As Figure 7b suggests, LSH blocking, which leverages redundancy, scores much better rates than standard blocking. Only BlockSketch and EO can use LSH blocking, because they essentially run on top of the blocking mechanism.

Figure 7: Measuring the recall and precision rates using standard blocking and LSH blocking.

On average, BlockSketch and EO achieve 10% and 8% higher recall rates, respectively, using LSH blocking.

Figures 7c and 7d show the precision rates using the two different blocking approaches described before. As one can observe, BlockSketch outperforms both EO and INV by a large margin, due to the effective categorization of records into the sub-blocks of each block. This minimizes significantly the required number of comparisons. Specifically, the precision rates of EO and INV fall by 18% and 21%, respectively, compared with the rates of BlockSketch. The reasons for this recession vary between the two methods. EO starts to produce meaningful recall rates after performing a large number of comparisons to derive the probability estimates for each pair. These comparisons, however, considerably reduce the precision rates. On the other hand, the double metaphone scheme of INV groups a large number of non-matching pairs into the same block, whose comparisons also result in low precision rates. The redundancy of LSH blocking accounts for the reduced precision rates of both BlockSketch and EO, as shown in Figure 7d, since both methods perform a larger number of comparisons for the pairs formulated in the blocks of each hash table. We observe though that BlockSketch retains its superiority over EO by scoring, on average, rates that are very close to 0.75. The time needed to perform the blocking step is illustrated in Figures 8a and 8b. EO and INV block each record a little faster than the combination of SkipBloom and BlockSketch, which for each insertion have to perform a constant number of comparisons with the representatives of the sub-blocks. Specifically, BlockSketch, through a single get operation, retrieves the representatives of a block from the database, as well as replaces them, through a single set operation, when needed. INV utilizes three hash tables to store the precomputed similarities, the encoded, and the original field values, which leads to certain delays.

Table 4: Average time (in seconds) for resolving a query record.

	DBLP	NCVR	LAB
standard	0.0051	0.0055	0.0045
LSH	0.0097	0.0098	0.0088

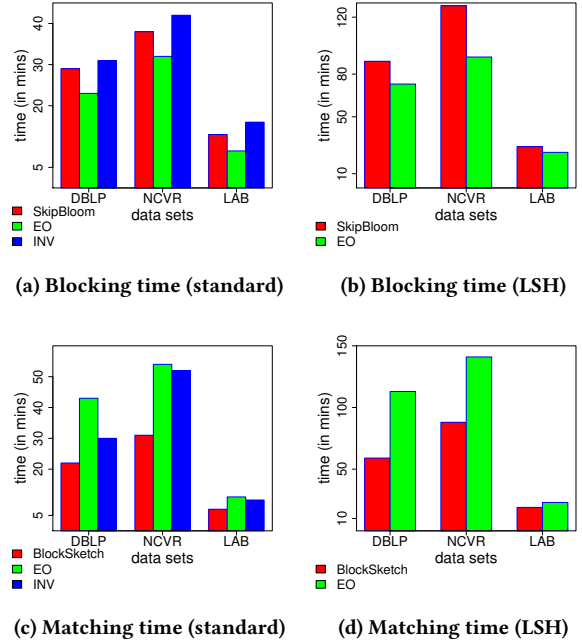

Figure 8: Measuring the time needed for blocking and matching for BlockSketch.

In Figures 8c and 8d, we present the time performance of BlockSketch and its competitors for resolving the query data sets, symbolized by Q (see Table 1), after having populated the blocking structures with the records of A . For each query record of Q , BlockSketch performs a constant number of comparisons in each target block, which results in superior performance. As Figure 8c suggests, BlockSketch is 2 \times and 1.5 \times faster than EO and INV, respectively, which both struggle to compare all records found in a block. Moreover, EO should build the graph to locate these record pairs that are expected to maximize the recall. Using LSH blocking, which is shown in Figure 8d, both BlockSketch and EO exhibit longer time rates, which are nearly 3 \times slower than before, due to the inherent redundancy of LSH. Since, a record pair might appear several times during the matching phase, for each record of Q , we utilize a map data structure¹⁷ to discard the comparisons of duplicate record pairs. Table 4 illustrates the time for resolving a single query record of Q during the matching phase. The constant number of distance computations for a single record accounts for the stable time performance of BlockSketch regardless of the size of the corresponding data set. In contrast, EO and INV consume running times which apart from the fact that in most cases they are almost the double of those of BlockSketch, they also depend on the number of records found in each block.

¹⁷The map structure is initialized for each record of Q .

(a) Running time (standard blocking) (b) Running time (LSH)

Figure 9: Measuring the time needed for blocking and matching for SBlockSketch.

(a) Running time (standard) (b) Running time (LSH)

Figure 10: Measuring the time needed for blocking and matching for SBlockSketch by varying μ using the NCVR data set.

In SBlockSketch, we initially set μ to a moderate size ($\mu = 1M^{18}$). In Figures 9a and 9b, we observe an average of 10% increase in time consumption than BlockSketch, only in NCVR and DBLP. The large number (over 60M) of distinct blocking keys that are generated in these data sets, resulted in relatively frequent evictions and disk seeks for the replacement of blocks in T . Nevertheless, the eviction status of highly selective (high ξ) but old (high α) blocks remained high during the blocking phase, which prevented their eviction from T . The running time of LAB remained almost intact due to the small number of blocking keys (about 10M) and the corresponding replacements. Since, SBlockSketch utilizes a single hash table T , LSH keys were formulated in a composite format *HashTableNo_Key* to accommodate all of them in T .

We next varied the values of μ and initiated the streaming of records of the NCVR data set. Figures 10a and 10b illustrate the time performance of SBlockSketch, where we observe that by doubling μ , we achieve significantly lower running time. For instance, by setting $\mu = 1M$, the corresponding time value is 43 minutes, which is almost 4 \times faster than the previous value (156 minutes) on the y-axis. In LSH blocking, the number of incoming records increases by a constant factor, which is the number of the LSH keys that are generated for each record. Since a large number of these keys are identical, the running time increases by 156% on average, as Figure 10b suggests, compared to the use of standard blocking.

¹⁸We had 32GB of main memory available.

Summary: Based on our conducted experiments, it becomes apparent that our proposed schemes are suitable for processing online queries for performing record linkage by using synopses of the blocking structures maintained in the persistent storage. They significantly outperform the state-of-the-art baselines, which rely their operation on memory-resident indexes regardless of the increasing volume of the underlying data sets.

8 CONCLUSIONS

In recent years, several applications have emerged which require access to consolidated information that has to be computed and presented in near real-time, through the linkage of records residing in voluminous disparate data sources. To address this need, we proposed the first summarization algorithms that operate in the blocking and matching steps of online record linkage to boost their performance. SkipBloom compiles a synopsis of the blocking structure of a data set using a small footprint of main memory, while BlockSketch compares each query record with a constant number of records in the target block, which results in a bounded matching time. Our experimental findings indicate that SkipBloom and BlockSketch outperform the state-of-the-art algorithms, in terms of the time needed, the memory used, and the recall and precision rates that are achieved during the linkage process. SBlockSketch utilizes a constant memory footprint to perform the linkage in settings that use streaming data.

ABSTRACT

We study the problem of *continuous object dissemination*—given a large number of users and continuously arriving new objects, deliver an object to all users who prefer the object. Many real world applications analyze users’ preferences for effective object dissemination. For continuously arriving objects, timely finding users who prefer a new object is challenging. In this paper, we consider an append-only table of objects with multiple attributes and users’ preferences on individual attributes are modeled as *strict partial orders*. An object is preferred by a user if it belongs to the *Pareto frontier* with respect to the user’s partial orders. Users’ preferences can be similar. Exploiting shared computation across similar preferences of different users, we design algorithms to find *target users* of a new object. In order to find users of similar preferences, we study the novel problem of clustering users’ preferences that are represented as partial orders. We also present an approximate solution of the problem of finding target users which is more efficient than the exact one while ensuring sufficient accuracy. Furthermore, we extend the algorithms to operate under the semantics of sliding window. We present the results from comprehensive experiments for evaluating the efficiency and effectiveness of the proposed techniques.

1 INTRODUCTION

Many applications serve users better by disseminating objects to the users according to their preferences. User preferences can be modeled via a variety of means including *collaborative filtering* [19], *top-k ranking* [7, 8], *skyline* [2], and *general preference queries* [5, 12]. In various scenarios, users’ preferences stand or only change occasionally, while the objects keep coming continuously. Such scenarios warrant the need for a capability of continuous monitoring of preferred objects. While previous studies have made notable contributions on continuous evaluation of skyline [14, 28] and top-k queries [29], we note that two important considerations are missing from prior works:

- *Many users*: There may be a large number of users and the users may have similar preferences. Prior studies focus on the query needs of one user and thus their algorithmic solutions can only be applied separately on individual users. A solution can potentially attain significant query performance gain by leveraging users’ *common preferences*.
- *Partially ordered attributes*: Prior works focus on top-k and skyline queries. In multi-objective optimization, a more general concept than skyline is *Pareto frontier*. Consider a table of objects with a set of attributes. An object is *Pareto-optimal* (i.e., it belongs to the Pareto frontier) if and only if it is not dominated by any other object [1, 13]. Object y dominates x if and only

if y is better than or equal to x on every attribute and is better on at least one attribute. In defining the *better-than* relations, most studies on skyline queries assume a total order on the ordinal or numeric values of an attribute, except for [17, 30] which consider strict partial orders. The psychological nature of human’s preferences determines that it is not always natural to enforce a total order. Oftentimes real-world preferences can only be modeled as strict partial orders [5, 12, 17].

Consider the following motivating applications which monitor Pareto frontiers on partially ordered attributes for many users.

- *Social network content and news delivery*: It is often impossible and unnecessary for a user to keep up with the plethora of updates (e.g., news feeds in Facebook) from their social circles. When a new item is posted, if the item is Pareto-optimal with respect to a user, it can be displayed above other updates in the user’s view. Similar ideas can be adopted by mass media to ensure their news reaches the right audience. User preferences can be modeled on content creator, topic, location, and so on. Enforcing total orders on such attributes is both cumbersome and unnatural.
- *Publication alerts*: Bibliography servers such as PubMed and Google Scholar can notify users about newly published articles matching their preferences on venues and keywords. Such attributes do not welcome total orders either.
- *Product recommendation*: When a new product becomes available, a retailer can notify customers who may be interested. It can distill customers’ preferences on product specifications (e.g., brand, display and memory for laptops) from profiles, past transactions and website browsing logs. Example 1.1 discusses this application more concretely.

Example 1.1. Consider an inventory of laptops in Table 1 and customers’ preferences on individual product attributes (display, brand and CPU) modeled as strict partial orders in Table 2. For an attribute, the corresponding strict partial order is depicted as a directed acyclic graph (DAG), more specifically a Hasse diagram. Given two values x and y in the attribute’s domain, the existence of a path from x to y in the DAG implies that x is preferred to y . With respect to customer c_1 and attribute brand, the path from *Lenovo* to *Toshiba* implies that c_1 prefers *Lenovo* to *Toshiba*. There is no path between *Toshiba* and *Samsung*, which indicates c_1 is indifferent between the two brands.

The strict partial orders on various attributes together represent a customer’s preferences on objects. For instance, c_1 prefers $o_2 = \langle 14, \textit{Apple}, \textit{dual} \rangle$ to $o_1 = \langle 12, \textit{Apple}, \textit{single} \rangle$, since they prefer 13–15.9 to 10–12.9 on display and *dual* to *single* on CPU. With regard to o_1 and $o_3 = \langle 15, \textit{Samsung}, \textit{dual} \rangle$, c_1 does not prefer one over the other because, though they prefer 13–15.9 to 10–12.9 and *dual* to *single*, they prefer *Apple* to *Samsung* on brand.

According to the data in Tables 1 and 2, if the existing products are o_1 to o_{14} (ignore o_{15} and o_{16} for now), the Pareto frontiers of c_1 and c_2 are $\{o_2\}$ and $\{o_2, o_3\}$, respectively. Suppose $o_{15} = \langle 16.5, \textit{Lenovo}, \textit{quad} \rangle$ just becomes available. For c_1 , o_{15} does not belong

to the Pareto frontier. It is dominated by o_2 , because c_1 prefers 14-inch display over 16.5-inch, *Apple* over *Lenovo*, and *dual*-core CPU over *quad*-core CPU. However, o_{15} is a Pareto-optimal object for c_2 since it is not dominated by any other object according to c_2 's preferences. It is thus recommended to c_2 , and the Pareto frontier of c_2 is updated to $\{o_2, o_3, o_{15}\}$. \triangle

This paper **formulates the problem of continuous monitoring of Pareto frontiers**: given a large number of users and continuously arriving new objects, for each newly arrived object, discover all users for whom the object is Pareto-optimal. Users' preferences are modeled as strict partial orders, one for each attribute domain of the objects.

It is key to devise an efficient approach to this problem. The value of a Pareto-optimal object diminishes quickly; the earlier it is found to be worth recommendation, the better. For instance, a status update in a social network keeps getting less relevant since the moment it is posted; a customer's need for a product may be fulfilled by a less preferred choice, if an even better option was not shown to the customer in time.

A simple, brute-force approach is to, given a newly arrived object, compute for every user if the object belongs to the Pareto

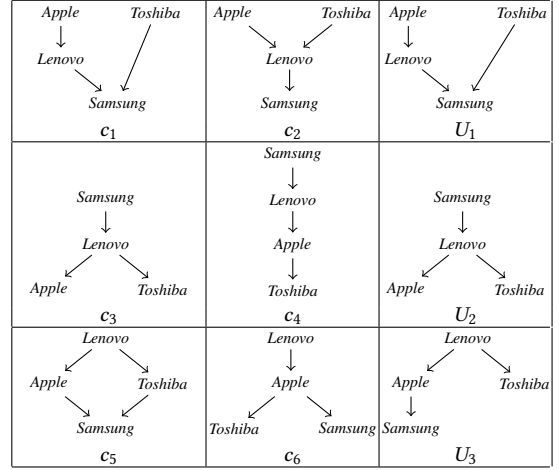

Table 3: User preferences with respect to brand. $U_1=\{c_1, c_2\}$, $U_2=\{c_3, c_4\}$, $U_3=\{c_5, c_6\}$.

frontier with respect to the user's preferences. This entails continuous maintenance of Pareto frontier for each and every user. The brute-force approach is subject to a clear drawback—repeated and wasteful maintenance of Pareto frontier for every user.

Sharing computation across users To tackle the aforementioned drawback, we partly resort to sharing computation across users. The challenge lies in the diversity of corresponding partial orders—a Pareto-optimal object with respect to one user may or may not be in the Pareto frontier for another user. Nonetheless, users have common preferences. In Table 2, both c_1 and c_2 prefer 13 – 15.9 inch display the most. Both prefer *Apple* and *Lenovo* to *Toshiba* and *Sony*, and they both prefer *single*-core CPU the least. In Table 2, U is a *virtual user* whose partial orders depict the common preferences of c_1 and c_2 . Intuitively, users having similar preferences can be clustered together.

We thus design algorithms to mitigate repetitive computation via sharing computation across similar preferences of users. To intuitively understand the idea, consider two example scenarios. i) If o is dominated by o' with respect to the common preferences of a set of users, then o is disqualified in Pareto-optimality for all users in the set. In Example 1.1, consider $o_{16}=(16, \textit{Toshiba}, \textit{single})$ as the new object. With respect to U , o_{16} is dominated by both $o_2=(14, \textit{Apple}, \textit{dual})$ and $o_{15}=(16.5, \textit{Lenovo}, \textit{quad})$. Therefore, o_{16} belongs to the Pareto frontier of neither c_1 nor c_2 . ii) Before the arrival of o_2 , obviously $o_1=(12, \textit{Apple}, \textit{single})$ is the only Pareto-optimal object for U , c_1 and c_2 . Now consider the entrance of o_2 . As o_1 is dominated by o_2 with respect to U , o_1 is replaced by o_2 in the Pareto frontier. This comparison is sufficient to decide that o_1 is dominated by o_2 for both c_1 and c_2 .

Clustering users To find users sharing similar preferences, we study the novel problem of clustering strict partial orders, which are used to model the preferences of both users and clusters. We measure the similarity between clusters and users by their common preferences. Such similarity measures factor in the different significance of preferences at various levels of the partial orders. Table 3 depicts six customers' preferences on brand, in which c_4 , c_5 , and c_6 prefer *Lenovo* to all other brands except that c_4 prefers *Samsung* over *Lenovo*. Consider the objects in Table 1. For both c_5 and c_6 , the Pareto frontiers contain $\{o_7, o_{10}, o_{15}\}$, while c_4 has $\{o_3, o_5, o_{12}\}$ as its Pareto frontier. We can say that c_5 and c_6 are more similar than c_4 and c_5 or c_4 and c_6 .

Approximation The clustering algorithm may produce clusters that comprise few users, due to diverse preferences. With

small clusters, the shared computation mentioned above may not pay off its overhead. Our response to this challenge is to use approximation. As in many data retrieval scenarios, insisting on exact answers is unnecessary and answers in close vicinity of the exact ones can be just good enough. Specifically, given a set of users, if a sizable subset of the users agree with a preference, the preference can be considered an approximate common preference. This relaxation eases the aforementioned concern regarding small clusters as more approximate common preferences lead to larger clusters. As an example, in Table 2, while c_2 does not share with c_1 the preference of *Apple* over *Samsung*, its preference does not oppose it either. We can consider “*Apple* over *Samsung*” as an *approximate common preference*. A possible set of approximate common preferences of c_1 and c_2 form the strict partial orders in the row for virtual user \hat{U} .

Alive objects Objects can have limited lifetime. The trends in social networks and news media change rapidly. Similarly, in any inventory, products become unavailable over time. In these scenarios users look for *alive* objects only. To meet this real-world requirement, we further extend our algorithms to operate under the semantics of a *sliding window* and thus to disseminate an object only during its lifespan.

In summary, the contributions of this paper are as follows:

- We study the problem of continuous object dissemination and formalize it as finding Pareto-optimal objects regarding partial orders. Given a large number of users and continuously arriving objects, our goal is to swiftly disseminate a newly arrived object to a user if the user’s preferences—modeled as strict partial orders on individual attributes—approve the object as Pareto-optimal.
- We devise efficient solutions exploiting shared computation across similar preferences of different users.
- We study the novel challenge of clustering user preferences represented as strict partial orders. Particularly we design similarity measures for such preferences.
- To address performance degradation due to small clusters, we present an approximate similarity measure that achieves high efficiency and accuracy of answers.
- We extend our proposed solutions to deal with Pareto frontier maintenance under sliding window.
- We conduct extensive experiments using simulations on two real datasets (a movie dataset and a publication dataset). The results demonstrate clear strengths of our solutions in comparison with baselines, in terms of execution time and efficacy.

2 RELATED WORK

Pareto-optimality is a subject of extensive investigation. Its study in the computing fields can be dated back to *admissible points* [1] and *maximal vectors* [13]. Börzsönyi et al. [2] introduced the concept of skyline—a special case of Pareto frontier—in which all attributes are numeric and amenable to total orders. Kießling [12] defined preferences as strict partial orders on which preference queries operate. After that, several studies specialized on skyline query evaluation over categorical attributes [3, 17, 18, 30], among which [17, 18, 30] particularly considered query answer maintenance and only [17, 30] allow partial orders on attribute values. Nevertheless, they all consider only one user and none utilizes shared computation across multiple users’ partial orders.

Given a set of objects, Wong et al. [25–27] identify the minimum set of preference relations that preclude an object from being in the Pareto frontier. This minimum set is the combination of each possible preference relation with regard to the values of all

unique objects in the set. In case of any update in the object set, the minimum disqualifying condition must be recomputed. Hence, it is not designed for continuously arriving objects.

Vlachou et al. [23, 24] and Yu et al. [29] aimed at finding all users who view a given object as one of their top- k favourites, i.e., the results of a reverse top- k query. Dellis et al. [6] studied reverse skyline query—selecting users to whom a given object is in the skyline. These works consider only numeric attributes. There is no clear way to extend them for categorical attributes or even partial orders.

All these studies, while about object dissemination, focused on different aspects of the problem than ours. Particularly, no previous studies on Pareto frontier maintenance have exploited shared computation across users’ preferences. Besides, as Sec. 5 shall explain, no prior work studied similarity measures for partial orders or how to cluster partial orders.

3 PROBLEM STATEMENT

Consider a set of users C and a table of objects O that are described by a set of attributes \mathcal{D} . For each user $c \in C$, their preference regarding O is represented by strict partial orders. For each attribute $d \in \mathcal{D}$, the strict partial order corresponding to c ’s preference on d is a binary relation over $dom(d)$ —the domain of d , as follows.

Definition 3.1 (Preference Relation and Tuple). Given a user $c \in C$ and an attribute $d \in \mathcal{D}$, the corresponding *preference relation* is denoted $>_c^d$. For two attribute values $x, y \in dom(d)$, if (x, y) belongs to $>_c^d$ (i.e., $(x, y) \in >_c^d$, also denoted $x >_c^d y$), it is called a *preference tuple*. It is interpreted as “user c prefers x to y on attribute d ”. A preference relation is irreflexive ($(x, x) \notin >_c^d$) and transitive ($(x, y) \in >_c^d \wedge (y, z) \in >_c^d \Rightarrow (x, z) \in >_c^d$), which together also imply asymmetry ($(x, y) \in >_c^d \Rightarrow (y, x) \notin >_c^d$). Δ

Definition 3.2 (Object Dominance). A user c ’s preferences regarding all attributes induce another strict partial order $>_c$ that represents c ’s preferences on objects. Given two objects $o, o' \in O$, c prefers o' to o if o' is identical or preferred to o on all attributes and o' is preferred to o on at least one attribute. More formally, $o' >_c o$ (called o' *dominates* o), if and only if $(\forall d \in \mathcal{D} : o.d = o'.d \vee o'.d >_c^d o.d) \wedge (\exists d \in \mathcal{D} : o'.d >_c^d o.d)$. If $(\forall d \in \mathcal{D} : o.d = o'.d)$, we say that o and o' are *identical*, denoted as $o = o'$. Δ

Definition 3.3 (Pareto Frontier). An object o is *Pareto-optimal* with respect to c , if no other object in O dominates it. The set of *Pareto-optimal objects* (i.e., the *Pareto frontier*) in O for c is denoted \mathcal{P}_c , i.e., $\mathcal{P}_c = \{o \in O \mid \nexists o' \in O \text{ s.t. } o' >_c o\}$. Note that the concept of skyline points [2] is a specialization of the more general Pareto frontier, in that the preference relations for skyline points are defined as total orders (with ties) instead of general strict partial orders. Δ

Definition 3.4 (Target Users). Given an object o , the set of all users for whom o belongs to their Pareto frontiers are called the *target users*. The target user set is denoted C_o , i.e., $C_o = \{c \in C \mid o \in \mathcal{P}_c\}$. Δ

Example 3.5. Consider Table 1 and Table 2. $O = \{o_1, o_2, \dots, o_{15}\}$ (ignore o_{16} for now), $C = \{c_1, c_2\}$, and $\mathcal{D} = \{\text{display, brand, CPU}\}$. With respect to c_1 , (10–12.9, 16–18.9), (*Apple, Samsung*) and (*dual, triple*) are some of the preference tuples on attributes display, brand and CPU, respectively. Similarly, for c_2 , (16–18.9, 19–up), (*Toshiba, Sony*) and (*triple, dual*) are some sample preference tuples.

$\mathcal{P}_{c_1} = \{o_2\}$, since all other objects are dominated by o_2 with respect to c_1 . $\mathcal{P}_{c_2} = \{o_2, o_3, o_{15}\}$, as o_2, o_3 and o_{15} dominate $\{o_1,$

$o_4, o_6, o_8, o_9, o_{13}$, $\{o_4, o_6, o_8, o_{13}\}$ and $\{o_4, o_5, o_7, o_{10}, o_{11}, o_{12}, o_{14}\}$, respectively. Therefore, $C_{o_2} = \{c_1, c_2\}$ and $C_{o_3} = C_{o_{15}} = \{c_2\}$. Objects other than o_2, o_3, o_{15} do not have target users in C , i.e., $C_o = \emptyset, \forall o \in O - \{o_2, o_3, o_{15}\}$. Δ

Problem Statement The problem of *continuous monitoring of Pareto frontiers* is, given a set of users C , their preference relations on attributes \mathcal{D} , and a set of continuously growing objects O with the latest object o , find C_o —the target users of o .

In this problem setting, we assume a sizable preference relation is available for each user. In reality, we have insufficient information about the preferences of a less active user, i.e., the corresponding partial orders may contain very few preference tuples. In the extreme case, a new user, for whom we have no information regarding their preferences, admits all objects as Pareto-optimal. Such less active users and new users are the subject of the well-known *cold-start* problem in recommendation systems, which is outside of the scope of this work.

4 SHARING COMPUTATION ACROSS USERS

Algorithm Baseline A simple method to our problem will check, for every user, whether a new object belongs to the corresponding Pareto frontier. The pseudo code of this approach, named Baseline, is shown in Alg. 1. Upon the arrival of a new object o , for every user c , it sequentially compares o with the current Pareto-optimal objects in \mathcal{P}_c . 1) If o is dominated by any o' or o is identical to o' , further comparison with the remaining objects in \mathcal{P}_c is skipped. In the case of o being dominated by o' , o is disqualified from being a Pareto-optimal object; if o is identical to o' , then o is Pareto-optimal, i.e., it is inserted into \mathcal{P}_c . 2) If o dominates any o' , o' is discarded from \mathcal{P}_c . It can be concluded already that o belongs to \mathcal{P}_c , but the comparisons should continue since o may dominate other existing objects in \mathcal{P}_c . 3) If o is not dominated by any object in \mathcal{P}_c , it becomes an element of \mathcal{P}_c . Readers familiar with the literature on skyline queries may have realized that the gist of the algorithm is essentially the basic skyline query algorithm [2]. The crux of its operation is based on an important property, that it suffices to compare new objects with only the Pareto-optimal objects, since any new object dominated by a non Pareto-optimal object must be dominated by some Pareto-optimal objects too.

Algorithm 1: Baseline

Input: C : all users; O : existing objects; o : a new object

Output: C_o : target users of o

```

1  $C_o \leftarrow \emptyset$ ;

```

With regard to a user c , the complexity of finding the Pareto frontier among n objects is $O(n^2)$. Alg. 1 needs $O(n^2 \cdot |C|)$ time to compute the Pareto frontiers for all users in C . The drawback of Baseline is it repeatedly applies the same procedure for every user. In terms of computation efficiency, the approach may become particularly unappealing when there are a large number of users and new objects constantly arrive. To counter this drawback, our idea is to share computations across the users that exhibit similar preferences. To this end, our method is simple and intuitive. If several users share a set of preference tuples, it is only necessary to compare two objects once, if they attain the attribute values in the preference tuples. If an object is dominated by another object according to these common preference tuples, it is dominated with respect to all users sharing the same preferences. This idea guarantees to filter out only “true negatives” for these users, and it only needs to further discern “false positives” for each individual user.

Definition 4.1 (Common Preference Tuple and Relation). Given a set of users $U \subseteq C$, an attribute $d \in \mathcal{D}$, and two values $x, y \in \text{dom}(d)$, if (x, y) belongs to preference relation $>_c^d$ for all $c \in U$, then it is called a *common preference tuple*. The set of common preference tuples of U on attribute d is denoted $>_U^d$, i.e., $>_U^d = \bigcap_{c \in U} >_c^d$. By definition, $>_U^d$ also represents a strict partial order (Theorem 4.2, proof omitted). We call it a *common preference relation*. It can be viewed as the preference of a virtual user that is denoted U . Δ

THEOREM 4.2. $>_U^d$ is a strict partial order. Δ

Since, for each $d, >_U^d$ is a strict partial order, the set of users’ preferences (i.e., the virtual user U ’s preferences) regarding all attributes in \mathcal{D} induce another strict partial order $>_U$ on objects.

Definition 4.3 (Pareto Frontier for U). An object o is *Pareto-optimal* with respect to U if no other object dominates it according to $>_U$. The Pareto frontier of O for U is denoted \mathcal{P}_U , i.e., $\mathcal{P}_U = \{o \in O \mid \nexists o' \in O \text{ s.t. } o' >_U o\}$. Δ

Example 4.4. From Table 2, $>_{c_1}^{\text{CPU}} = \{(dual, single), (dual, quad), (dual, triple), (triple, single), (quad, single)\}$ and $>_{c_2}^{\text{CPU}} = \{(dual, single), (triple, single), (quad, single), (triple, dual), (quad, dual), (quad, triple)\}$. According to Def. 4.1, the common preference relation of c_1 and c_2 is $>_{\{c_1, c_2\}}^{\text{CPU}} = \{(dual, single), (triple, single), (quad, single)\}$. Similarly we can derive $>_{\{c_1, c_2\}}^{\text{display}}$ and $>_{\{c_1, c_2\}}^{\text{brand}}$. In Table 2, the three partial orders are depicted in a row labeled as a virtual user U . The Pareto frontier of U is $\mathcal{P}_U = \{o_2, o_3, o_{10}, o_{15}\}$. Δ

THEOREM 4.5. Given any set of users U , for all $c \in U$, $\mathcal{P}_U \supseteq \mathcal{P}_c$ and $\overline{\mathcal{P}}_U \subseteq \bigcap_{c \in U} \overline{\mathcal{P}}_c$. Δ

Proof: We prove by contradiction. Suppose that there exists $c \in U$ such that $\mathcal{P}_U \not\supseteq \mathcal{P}_c$, which would mean there exists $o \in O$ such that $o \in \mathcal{P}_c$ and $o \notin \mathcal{P}_U$. That implies the existence of an $o' \in O$ such that $o' >_U o$ and $o' \not>_c o$. However, by Def. 4.1, $o' >_U o$ implies $o' >_c o$. Therefore, the existence of o' is impossible. This contradiction eventually leads to that $\mathcal{P}_U \supseteq \mathcal{P}_c$. Hence, $\mathcal{P}_U \supseteq \bigcup_{c \in U} \mathcal{P}_c$, which implies $\overline{\mathcal{P}}_U \subseteq \bigcap_{c \in U} \overline{\mathcal{P}}_c$ according to De Morgan’s laws.

LEMMA 4.6. Given any set of users U , for all $c \in U$, $\mathcal{P}_c = \{o \in \mathcal{P}_U \mid \nexists o' \in \mathcal{P}_U \text{ s.t. } o' >_c o\}$. Δ

Example 4.7. In Table 2, $\mathcal{P}_U = \{o_2, o_3, o_{10}, o_{15}\}$ and $\mathcal{P}_{c_1} \cup \mathcal{P}_{c_2} = \{o_2, o_3, o_{15}\}$. $\mathcal{P}_U \supseteq \mathcal{P}_{c_1} \cup \mathcal{P}_{c_2}$. Moreover, $\overline{\mathcal{P}}_U = \{o_1, o_4, o_5, o_6, o_7, o_8, o_9, o_{11}, o_{12}, o_{13}, o_{14}\}$ and $\overline{\mathcal{P}}_{c_1} \cap \overline{\mathcal{P}}_{c_2} = \{o_1, o_4, o_5, o_6, o_7, o_8, o_9, o_{10}, o_{11}, o_{12}, o_{13}, o_{14}, o_{15}\}$. $\overline{\mathcal{P}}_U \subseteq \overline{\mathcal{P}}_{c_1} \cap \overline{\mathcal{P}}_{c_2}$. Δ

Theorem 4.5 suggests an appealing quality of the common preference relations of U . By $\mathcal{P}_U \supseteq \mathcal{P}_c$, the Pareto frontier of U subsumes the Pareto frontier of every user member in U . What it means is that, if we simply compute the Pareto frontier of U , we get to retain all the objects that we eventually look for. Consider \mathcal{P}_c as the ground truth and \mathcal{P}_U as the predictions. The objects that are filtered out ($\overline{\mathcal{P}}_U$) are all “true negatives” and there are no “false negatives”. The set \mathcal{P}_U may contain “false positives”, which we just need to throw out after further verification, as Lemma 4.6 suggests.

This approach’s merit is the potential saving on object comparisons. For a cluster of users, many non Pareto-optimal objects may be filtered out altogether for all the users, without incurring the same comparisons repeatedly for each user.

To capitalize on the above ideas, our method must answer three questions. (1) How to find users sharing similar preferences? (2) For a set of similar users U , how to maintain the corresponding Pareto frontier \mathcal{P}_U based on their common preference relations $>_U^d$ for different attributes d ? (3) For each user c in U , how to discern the “false positives” in \mathcal{P}_U and thus find \mathcal{P}_c . Note that the second and the last challenges need to be addressed for constantly arriving new objects.

For (1), our method is to cluster users based on the similarity between their preference relations. While many clustering methods have been developed for various types of data, none is specialized in clustering partial orders. Our clustering method is discussed in Sec. 5. For (2) and (3), our algorithm takes a *filter-then-verify* approach and is thus named FilterThenVerify, of which the pseudo code is displayed in Alg 2.

Alg. FilterThenVerify Upon the arrival of a new object o , for every cluster U , FilterThenVerify compares o with the current members of \mathcal{P}_U based on the preference relations of the virtual user U . Various actions are taken, depending on the comparison outcomes, as follows:

I) If o dominates any o' in \mathcal{P}_U according to $>_U^d$ of all relevant d , o' is removed from \mathcal{P}_U (Line 7 of Procedure updateParetoFrontierU in Alg. 2). For every $c \in C$ such that $o' \in \mathcal{P}_c$, o' is also discarded from \mathcal{P}_c (Line 6 of Procedure updateParetoFrontierU).

II) If o is dominated by any o' in \mathcal{P}_U , then o does not occupy the Pareto frontier of any user in U (Theorem 4.5). Further operations involving o are unnecessary (Line 8 of Procedure updateParetoFrontierU).

III) After comparing o with all current objects in \mathcal{P}_U , if it is realized that o is not dominated by any o' , then o becomes a member of \mathcal{P}_U (Line 9 of updateParetoFrontierU). Furthermore, for each $c \in U$, o is further compared with the members of \mathcal{P}_c based on the preference relations of c , by using Procedure updateParetoFrontier of Alg.1 (Line 6 of Alg.2).

Example 4.8. In this example we explain the execution of FilterThenVerify on Table 1 and Table 2. Suppose users c_1 and c_2 form a cluster U , of which the preference relations are depicted in Table 2. The existing objects are o_1 to o_{14} , and $o_{15} = \langle 16.5'', \text{Lenovo, quad} \rangle$ is the object that just becomes available. Before o_{15} arrives, the Pareto frontier of U is $\mathcal{P}_U = \{o_2, o_3, o_7, o_{10}\}$. The algorithm starts by comparing o_{15} with each element in \mathcal{P}_U . As o_{15} dominates $o_7 = \langle 9.5'', \text{Lenovo, quad} \rangle$ according to U ’s

Algorithm 2: FilterThenVerify

Input: U_1, U_2, \dots, U_n : clusters of users; O : existing objects; o : a new object
Output: C_o : target users of o

```

1  $C_o \leftarrow \emptyset$ ;
2 foreach  $U \in \{U_1, U_2, \dots, U_n\}$  do
3    $isPareto \leftarrow \text{updateParetoFrontierU}(U, o)$ ;
4   if  $isPareto$  then
5     foreach  $c \in U$  do
6        $\text{updateParetoFrontier}(c, o)$ ; //Algorithm 1
7 return  $C_o$ ;

Procedure: updateParetoFrontierU ( $U, o$ )
1  $isPareto \leftarrow \text{true}$ ;
2 foreach  $o' \in \mathcal{P}_U$  do
3   if  $o >_U o'$  then
4     foreach  $c \in U$  do
5       if  $o' \in \mathcal{P}_c$  then
6          $\mathcal{P}_c \leftarrow \mathcal{P}_c - \{o'\}$ ;  $C_{o'} \leftarrow C_{o'} - \{c\}$ ;
7          $\mathcal{P}_U \leftarrow \mathcal{P}_U - \{o'\}$ ;
8       else if  $o' >_U o$  then  $isPareto \leftarrow \text{false}$ ; break ;
9 if  $isPareto$  then  $\mathcal{P}_U \leftarrow \mathcal{P}_U \cup \{o\}$  ;
10 return  $isPareto$ ;

```

preference relations, o_7 is discarded from \mathcal{P}_U . Before o_{15} arrives, o_7 belongs to \mathcal{P}_{c_2} and $C_{o_7} = \{c_2\}$. Hence, o_7 is removed from \mathcal{P}_{c_2} and C_{o_7} becomes empty. o_{15} does not dominate any other object in \mathcal{P}_U . It is not dominated by any either. Therefore, it is inserted into \mathcal{P}_U .

o_{15} is further compared with the existing members of \mathcal{P}_{c_1} and \mathcal{P}_{c_2} . It is dominated by $o_2 = \langle 14'', \text{Apple, dual} \rangle$ according to c_1 ’s preference relations. Thus it is not part of \mathcal{P}_{c_1} . According to c_2 ’s preferences, o_{15} does not dominate any existing Pareto optional object (except the aforementioned o_7 which by now is already discarded). Therefore \mathcal{P}_{c_2} is not further changed and o_{15} becomes part of \mathcal{P}_{c_2} . Overall, $C_{o_{15}} = \{c_2\}$.

Moreover, consider the arrival of $o_{16} = \langle 16'', \text{Toshiba, single} \rangle$ after o_{15} . In the process of comparing o_{16} with $\mathcal{P}_U = \{o_2, o_3, o_{10}, o_{15}\}$, it is realized that o_{16} is dominated by o_2 according to U ’s preference relations. Therefore, it does not belong to \mathcal{P}_U . It is thus unnecessary to further compare o_{16} with \mathcal{P}_{c_1} or \mathcal{P}_{c_2} . $C_{o_{16}} = \emptyset$. Thereby, updateParetoFrontierU acts as a sieve to filter out non Pareto-optimal objects such as o_{16} . In this way FilterThenVerify reduces computation cost by avoiding repeated comparisons with such objects. Δ

Complexity Analysis of Alg. 2 As we discussed earlier, given a user c , the complexity of finding Pareto frontier among the n objects is $O(n^2)$. Assume k is the number of clusters. With regard to the virtual user for each cluster U , the complexity of finding Pareto frontier \mathcal{P}_U among the n objects is $O(n^2 \cdot k)$ (calling Procedure updateParetoFrontierU in Line 3 of Alg. 2). Assume each \mathcal{P}_U on average has m objects. In Lines 4-6, Alg. 2 finds \mathcal{P}_c from \mathcal{P}_U for each user c in U (recall that $\mathcal{P}_U \supseteq \mathcal{P}_c$). As Lines 4-6 iterate for each cluster (Line 2), the algorithm eventually computes \mathcal{P}_c for each $c \in C$. Therefore, the complexity of finding Pareto frontier \mathcal{P}_c among the m objects is $O(m^2 \cdot |C|)$. Overall, FilterThenVerify needs $O(n^2 \cdot k + m^2 \cdot |C|)$ time to find the target users for all objects. We compare FilterThenVerify and Baseline in terms of time complexity. Apparently $k < |C|$ and $m < n$. Thus, $n^2 \cdot k < n^2 \cdot |C|$ and $m^2 \cdot |C| < n^2 \cdot |C|$.

5 SIMILARITY MEASURES FOR CLUSTERING USER PREFERENCES

This section discusses how to cluster users based on their preference relations. Our focus is on the similarity measures rather than the clustering method. The method we adopt is the conventional hierarchical agglomerative clustering algorithm [9]. At every iteration, the method merges the two most similar clusters. The common preference relation of the merged cluster U on each attribute d , i.e., \succ_U^d , is computed. It then calculates the similarity between U and each remaining cluster. Given two clusters U_1 and U_2 , their similarity $sim(U_1, U_2)$ is defined as the summation of the similarities between their preference relations on individual attributes, as follows. This resembles the high-level idea of using L_1 norm distance between centroids for measuring inter-cluster similarity in conventional hierarchical clustering.

$$sim(U_1, U_2) = \sum_{d \in \mathcal{D}} sim^d(U_1, U_2) \quad (1)$$

Individual users' and clusters' preference relations on attributes are strict partial orders. No prior work studied clustering approaches or similarity measures for partial orders. Similarity measures commonly used in clustering algorithms assume numeric or categorical attributes. Kamishima et al. [10, 11] and Ukkonen et al. [22] cluster total orders but not partial orders. Given two totally ordered attributes, these works use the comparative ranks of the corresponding values to measure similarity. Clearly, such similarity measures are not applicable for partially ordered attributes.

In this section we propose four different similarity functions for defining $sim^d(U_1, U_2)$.

1) Intersection size This is simply the size of the intersection of $\succ_{U_1}^d$ and $\succ_{U_2}^d$, i.e., the number of common preference tuples of all users in the two clusters U_1 and U_2 . It is defined as

$$sim_i^d(U_1, U_2) = |\succ_{U_1}^d \cap \succ_{U_2}^d| \quad (2)$$

Example 5.1. Table 3 shows three clusters U_1 ($\{c_1, c_2\}$), U_2 ($\{c_3, c_4\}$), and U_3 ($\{c_5, c_6\}$) and the common preference relation associated with each cluster on attribute *brand*. U_1 and U_2 do not share any preference tuple and thus $sim_i^{\text{brand}}(U_1, U_2) = 0$. U_1 and U_3 have (*Apple, Samsung*) and (*Lenovo, Samsung*) as common preference tuples, i.e., $sim_i^{\text{brand}}(U_1, U_3) = 2$. Similarly, U_2 and U_3 share (*Lenovo, Apple*) and (*Lenovo, Toshiba*), i.e., $sim_i^{\text{brand}}(U_2, U_3) = 2$. \triangle

2) Jaccard similarity The measure sim_i captures the absolute size of the intersection of two preference relations. It does not take into account their differences. Consider three clusters U_1, U_2 and U_3 such that $sim_i^d(U_1, U_2) = sim_i^d(U_1, U_3)$ (i.e., $|\succ_{U_1}^d \cap \succ_{U_2}^d| = |\succ_{U_1}^d \cap \succ_{U_3}^d|$) and $|\succ_{U_1}^d \cup \succ_{U_2}^d| < |\succ_{U_1}^d \cup \succ_{U_3}^d|$. We can argue that the similarity between U_1 and U_2 should be higher than (instead of equal to) that between U_1 and U_3 , because U_1 and U_2 have a larger percentage of common preference tuples than U_1 and U_3 . To address this limitation of sim_i , we define the *Jaccard similarity* between two preference relations as their intersection size over their union size, i.e., the ratio of common preference tuples to all preference tuples in the two preference relations. Formally,

$$sim_j^d(U_1, U_2) = \frac{|\succ_{U_1}^d \cap \succ_{U_2}^d|}{|\succ_{U_1}^d \cup \succ_{U_2}^d|} = \frac{sim_i^d(U_1, U_2)}{|\succ_{U_1}^d \cup \succ_{U_2}^d|} \quad (3)$$

Example 5.2. Continue Example 5.1. $\succ_{U_1}^{\text{brand}}$ and $\succ_{U_3}^{\text{brand}}$ have 6 preference tuples in total while $\succ_{U_2}^{\text{brand}}$ and $\succ_{U_3}^{\text{brand}}$ have 7. Thus, $sim_j^{\text{brand}}(U_1, U_3) = 2/6$ and $sim_j^{\text{brand}}(U_2, U_3) = 2/7$. \triangle

3) Weighted intersection size Intersection size and Jaccard similarity are based on the cardinalities of intersection and union sets of preference relations. In counting the cardinalities, they both treat all preference tuples equal. We argue that this is counter-intuitive. Values at the top of a partial order matter more than those at the bottom, in terms of their impact on which objects belong to the Pareto frontier. Accordingly we introduce *weighted intersection size*, a modified version of intersection size sim_i . In counting the common preference tuples of two preference relations, it assigns a weight to each preference tuple. Formally,

$$sim_{wi}^d(U_1, U_2) = \sum_{(v, v') \in \succ_{U_1}^d \cap \succ_{U_2}^d} \frac{1}{2} \times \left(\frac{1}{\min D(s, v) + 1} + \frac{1}{\min D(s, v') + 1} \right) \quad (4)$$

In the above equation, with regard to an attribute d , the similarity between two clusters' preference relations is a summation over their common preference tuples. For each common preference tuple (v, v') , it computes the average weight of the better value v with respect to U_1 and U_2 , respectively. Given a cluster U , S_U^d is the set of *maximal values* in the partial order \succ_U^d and $D(s, v)$ for each $s \in S_U^d$ is the shortest distance from s to v in \succ_U^d . The weight of v in U is the inverse of the minimal distance from any maximal value to v (plus 1, to avoid division by zero). The concept of maximal value is defined as follows.

Definition 5.3 (Maximal Value). With regard to \succ_U^d , value $x \in \text{dom}(d)$ is a *maximal value* if no other value in $\text{dom}(d)$ is preferred over x . The set of maximal values for \succ_U^d is denoted S_U^d . Formally, $S_U^d = \{x \in \text{dom}(d) \mid \nexists y \in \text{dom}(d) \text{ s.t. } (y, x) \in \succ_U^d\}$. \triangle

Example 5.4. Continue Example 5.1. The maximal values in $\succ_{U_1}^{\text{brand}}$, $\succ_{U_2}^{\text{brand}}$ and $\succ_{U_3}^{\text{brand}}$ are $S_{U_1}^{\text{brand}} = \{\text{Apple, Toshiba}\}$, $S_{U_2}^{\text{brand}} = \{\text{Samsung}\}$ and $S_{U_3}^{\text{brand}} = \{\text{Lenovo}\}$, respectively. In the partial order corresponding to $\succ_{U_1}^{\text{brand}}$, the minimal shortest distances to *Apple*, *Lenovo*, *Samsung*, and *Toshiba* from the maximal values $\{\text{Apple, Toshiba}\}$ are 0, 1, 1 and 0, respectively. The corresponding weights are 1, 1/2, 1/2 and 1. Similarly, in $\succ_{U_2}^{\text{brand}}$, the weights of *Apple*, *Lenovo*, *Samsung* and *Toshiba* are 1/3, 1/2, 1 and 1/3, respectively. In $\succ_{U_3}^{\text{brand}}$, the corresponding weights are 1/2, 1, 1/3 and 1/2, respectively.

U_1 and U_3 have (*Apple, Samsung*) and (*Lenovo, Samsung*) as common preference tuples. For the two better-values in these preference tuples—*Apple* and *Lenovo*, the average weights are both 3/4. The similarity $sim_{wi}^{\text{brand}}(U_1, U_3) = \frac{1+\frac{1}{2}}{2} + \frac{\frac{1}{2}+1}{2} = \frac{3}{2}$. Similarly, U_2 and U_3 have (*Lenovo, Apple*) and (*Lenovo, Toshiba*) as common preference tuples. In U_2 and U_3 , the average weight of *Lenovo*—the better-value in both common preference tuples—is 3/4. The similarity $sim_{wi}^{\text{brand}}(U_2, U_3) = \frac{\frac{1}{2}+1}{2} + \frac{\frac{1}{2}+1}{2} = \frac{3}{2}$. \triangle

4) Weighted Jaccard similarity This measure is a combination of the last two ideas—Jaccard similarity and weighted intersection size. As in Jaccard similarity, *weighted Jaccard similarity* computes the ratio of intersection size to union size. Similar to weighted intersection size, the values in a preference relation are assigned weights corresponding to their minimal shortest distances to the preference relation's maximal values. The measure's definition is as follows.

$$\begin{aligned}
& \text{sim}_{w_j}^d(U_1, U_2) \geq \sum_{(v, v') \in >_{U_1}^d \cap >_{U_2}^d} \frac{1}{2} \times \left(\frac{1}{\min_{s \in S_{U_1}^d} D(s, v) + 1} + \frac{1}{\min_{s \in S_{U_2}^d} D(s, v) + 1} \right) \\
& \quad \left| \sum_{(v, v') \in >_{U_1}^d \cup >_{U_2}^d} \frac{1}{2} \times \left(\frac{1}{\min_{s \in S_{U_1}^d} D(s, v) + 1} + \frac{1}{\min_{s \in S_{U_2}^d} D(s, v) + 1} \right) \right. \\
& = \text{sim}_{w_i}^d(U_1, U_2) \left| \left[\text{sim}_{w_i}^d(U_1, U_2) + \sum_{(v, v') \in >_{U_1}^d - >_{U_2}^d} \frac{1}{\min_{s \in S_{U_1}^d} D(s, v) + 1} \right. \right. \\
& \quad \left. \left. + \sum_{(v, v') \in >_{U_2}^d - >_{U_1}^d} \frac{1}{\min_{s \in S_{U_2}^d} D(s, v) + 1} \right] \right. \quad (5)
\end{aligned}$$

Example 5.5. Continue Example 5.4. Now $\text{sim}_{w_j}^{\text{brand}}(U_1, U_3) = \frac{\frac{3}{2}}{(1+1)+(1+1)+\frac{3}{2}} = \frac{3}{11}$, since $>_{U_1}^d - >_{U_3}^d = \{(Apple, Lenovo), (Toshiba, Samsung)\}$ and $>_{U_3}^d - >_{U_1}^d = \{(Lenovo, Apple), (Lenovo, Toshiba)\}$. Similarly, $\text{sim}_{w_j}^{\text{brand}}(U_2, U_3) = \frac{\frac{3}{2}}{(1+1+1)+(1+\frac{1}{2})+\frac{3}{2}} = \frac{3}{12}$, as $>_{U_2}^d - >_{U_3}^d = \{(Samsung, Lenovo), (Samsung, Apple), (Samsung, Toshiba)\}$ and $>_{U_3}^d - >_{U_2}^d = \{(Lenovo, Samsung), (Apple, Samsung)\}$. Note that $\text{sim}_{w_j}^{\text{brand}}(U_1, U_3) > \text{sim}_{w_j}^{\text{brand}}(U_2, U_3)$ although $\text{sim}_{w_i}^{\text{brand}}(U_1, U_3) = \text{sim}_{w_i}^{\text{brand}}(U_2, U_3)$. \triangle

6 APPROXIMATE USER PREFERENCES

Two conflicting factors have crucial impacts on the effectiveness of FilterThenVerify. One is the size of the common preference relations. The other is the size of the clusters. Specifically, the more preference tuples a cluster's users share, the more objects can be filtered out and thus the less verifications need to be done for individual users. On the contrary, the more users a cluster contains, the more repeated comparisons are avoided for these individual users. There is a clear tradeoff between these two factors, since larger clusters (i.e., more users in each cluster) naturally leads to smaller common preference relations.

Our approach to this challenge is *approximation*. As discussed in Sec. 1, it suffices for many applications to approximately identify target users. In this section, we show that we can find such approximation through a relaxed notion of common preference tuple, namely *approximate common preference tuple*. For a set of users, it allows a preference tuple to be absent from a tolerably small subset. If a sizable subset of the users agree with the preference tuple, it is considered an approximate common preference tuple. This relaxation addresses the aforementioned concern, since more approximate common preferences lead to larger clusters.

6.1 Approximate Common Preference Tuples and Relations

Based on the aforementioned objective, we procedurally construct approximate common preference relations. Before we provide its formal definition, we explain the intuition, as follows. Given a cluster of users, the resulting approximate common preference relation always includes the common preference tuples. The remaining possible preference tuples are considered in descending order of their frequencies, since preference tuples with higher frequencies are shared by more users. A preference tuple is included into the approximate common preference relation only if its reverse tuple is not included. This guarantees asymmetry. Furthermore, when a preference tuple is included, the transitive closure of the updated approximate common preference relation is also included.

This guarantees transitivity. Irreflexivity is guaranteed too since this procedure never considers preference tuples in the form of (x, x) . These altogether assure the constructed preference relation is a strict partial order. Given an append-only database of objects, a strict partial order ensures that preference query results are independent of the order by which objects are appended to the database. We denote the approximate common preference relation by $\widehat{\succ}_U^d$. It can be viewed as the preference of a virtual user (denoted \widehat{U}) on attribute d . Moreover, we denote the Pareto frontier of \widehat{O} for \widehat{U} as $\widehat{\mathcal{P}}_U$.

Definition 6.1 (Approximate Common Preference Tuple and Relation). Given a set of users $U \subseteq \mathcal{C}$, an attribute $d \in \mathcal{D}$ of which $|\text{dom}(d)| = m$, consider $A_1 \dots A_{P_2^m}$ which is an ordered permutation of all possible preference tuples $\{(x, y) \in \text{dom}(d) \times \text{dom}(d) \mid x \neq y\}$ such that $\text{freq}(A_i) \geq \text{freq}(A_{i+1})$ for $i \in [1, P_2^m - 1]$, in which $\text{freq}(A_i)$ denotes the percentage of users in U whose preference relations contain preference tuple A_i . The *approximate common preference relation* $\widehat{\succ}_U^d$ is defined as R_j in which j is the largest index $i \in [1, P_2^m]$ that satisfies the condition $(|R_i| < \theta_1 \wedge \text{freq}(A_i) > \theta_2) \vee \text{freq}(A_i) = 1$ where R_i is defined as

$$R_i = \begin{cases} \{A_i\} & \text{if } i = 1 \\ (R_{i-1} \cup \{A_i\})^+ & \text{if } R_{i-1} \cup \{A_i\} \text{ is a strict partial order} \\ R_{i-1} & \text{otherwise} \end{cases}$$

and θ_1 and θ_2 are two given thresholds. θ_1 limits the size of the resulting $\widehat{\succ}_U^d$ while θ_2 excludes infrequent preference tuples from $\widehat{\succ}_U^d$. \triangle

θ_1 and θ_2 regulate the size of $\widehat{\succ}_U^d$. A pair of large θ_1 and small θ_2 allows $\widehat{\succ}_U^d$ to include infrequent preference tuples. In such a case the approximate common preference relation becomes ineffective, since Procedure updateParetoFrontierU in Alg.2 may retain a large number of candidates that must be verified for each $c \in U$. On the other hand, a pair of small θ_1 and large θ_2 may limit $\widehat{\succ}_U^d$ to contain only $>_{U'}^d$, in which case the concern regarding small common preference relation remains.

As Def. 6.1 itself is procedural, it naturally corresponds to a greedy algorithm for constructing approximate preference relation $\widehat{\succ}_U^d$. The pseudo code GetApproxPreferenceTuples is in Alg. 3. First, all the common preference tuples are included (Lines 2-3). After that, preference tuples are considered in the order of frequency, as long as the two thresholds are satisfied (Line 4). For each preference tuple in consideration, if it together with all chosen tuples hitherto do not violate the properties of a strict partial order, their transitive closure is included into the approximate preference relation (Lines 6-7).

Example 6.2. We use Figure 1 to explain the execution of GetApproxPreferenceTuples. Figure 1a depicts three users' preference relations on brand. Suppose together these three users form a cluster. Assume $\theta_1 = 7$ and $\theta_2 = 60\%$.

Table 4 shows the frequencies of all possible preference tuples after sorting. For instance, since all users prefer *Apple* to *Toshiba*, the corresponding frequency is $3/3$; the frequency of *(Apple, Samsung)* is $2/3$ as two of these three users prefer *Apple* to *Samsung*. At first GetApproxPreferenceTuples includes the common preference tuple *(Apple, Toshiba)* into $\widehat{\succ}_U^d$. It then includes *(Apple, Samsung)*, *(Lenovo, Toshiba)*, and *(Toshiba, Samsung)* as approximate preference tuples too. Furthermore, upon the addition of *(Toshiba, Samsung)*, GetApproxPreferenceTuples includes *(Lenovo, Samsung)* as well since *(Lenovo, Toshiba)* and

Algorithm 3: GetApproxPreferenceTuples

Input: A_i : ordered permutation of all possible preference tuples, defined on $dom(d)$, in descending order of their frequencies among users U , θ_1 and θ_2 : thresholds

Output: $\widehat{\succ}_U^d$: approximate common preference relation of U on attribute d

```

1 for  $i = 1$  to  $P_2^{dom(d)}$  do
2   if  $freq(A_i) = 1$  then
3      $\widehat{\succ}_U^d \leftarrow \widehat{\succ}_U^d \cup \{A_i\}$ ; continue;
4   if  $|\widehat{\succ}_U^d| \geq \theta_1$  or  $freq(A_i) \leq \theta_2$  then
5     break;
6   if  $(\widehat{\succ}_U^d \cup \{A_i\})$  is a strict partial order then
7      $\widehat{\succ}_U^d \leftarrow (\widehat{\succ}_U^d \cup \{A_i\})^+$ ;
8 return  $\widehat{\succ}_U^d$ ;

```

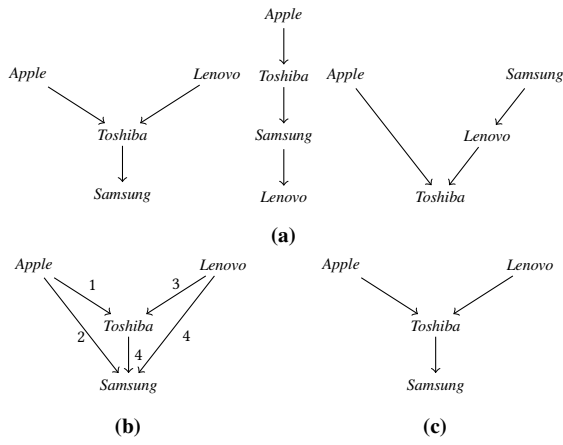

Figure 1: Execution of GetApproxPreferenceTuples. a) Input: the preferences of 3 users w.r.t. brand. b) The sequence of included approximate preference tuples. c) Output: the final Hasse diagram representation of the partial order.

(A, T)	(A, S)	(L, T)	(T, S)	(S, L)	(A, L)	(L, S)	(T, L)	(S, T)	(L, A)	(T, A)	(S, A)
3/3	2/3	2/3	2/3	2/3	1/3	1/3	1/3	1/3	0/3	0/3	0/3

Table 4: All possible preference tuples in order of frequency. (A, L, S and T stand for Apple, Lenovo, Samsung and Toshiba.)

(Toshiba, Samsung) transitively induce it. The algorithm then considers (Samsung, Lenovo), which is disqualified since its reverse tuple (Lenovo, Samsung) is already included. Otherwise the tuples will not form a strict partial order. The algorithm stops at (Apple, Lenovo) because its frequency is below the threshold 60%. Fig. 1b illustrates the sequence of the included tuples and Fig. 1c depicts the output approximate preference relation in the form of a Hasse diagram. Δ

6.2 False Positives and False Negatives due to Approximation

FilterThenVerify (Alg.2) is extended to use approximate preference tuples and thus we rename it FilterThenVerifyApprox. The algorithm itself remains the same. Procedure updateParetoFrontierU maintains $\widehat{\mathcal{P}}_U$ as the candidate Pareto frontier. The algorithm eventually returns $\widehat{\mathcal{P}}_c$ for each user $c \in U$, in which $\widehat{\mathcal{P}}_c = \{o \in \widehat{\mathcal{P}}_U \mid \nexists o' \in \widehat{\mathcal{P}}_U \text{ s.t. } o' \succ_c o\}$, i.e., $\widehat{\mathcal{P}}_U \supseteq \widehat{\mathcal{P}}_c$. Thus, $\widehat{C}_o = \{c \in C \mid o \in \widehat{\mathcal{P}}_c\}$. We use the example below to explain its execution over approximate preference relations.

Set	Area Covered
\mathcal{O}	I,II,III,IV,V,VI
\mathcal{P}_U	II,III,IV,V,VI
$\widehat{\mathcal{P}}_U$	IV,V,VI
\mathcal{P}_c	III,IV
$\widehat{\mathcal{P}}_c$	IV,V

Figure 2: Venn diagram depicting \mathcal{O} , \mathcal{P}_U , $\widehat{\mathcal{P}}_U$, \mathcal{P}_c and $\widehat{\mathcal{P}}_c$. **Table 5: Areas covered by \mathcal{O} , \mathcal{P}_U , $\widehat{\mathcal{P}}_U$, \mathcal{P}_c and $\widehat{\mathcal{P}}_c$ in Fig.2.**

Approx.	Exact		
	Pareto frontier	Pareto frontier	Non Pareto frontier
	IV	IV	V
	Non Pareto frontier	III	I,II,VI

Table 6: Confusion matrix w.r.t. c.

Example 6.3. Reconsider Example 4.8, but use the approximate preference relations associated with virtual user \widehat{U} in Table 2. Upon the arrival of o_{15} , it is compared with the elements in $\widehat{\mathcal{P}}_U = \{o_2, o_7\}$. $\widehat{\mathcal{P}}_U$ becomes $\{o_2, o_{15}\}$ since o_{15} dominates o_7 . o_7 is then also removed from $\widehat{\mathcal{P}}_{c_2}$. o_{15} is further compared with $\widehat{\mathcal{P}}_{c_1} = \{o_2\}$ and $\widehat{\mathcal{P}}_{c_2} = \{o_2\}$, which does not lead to any further change. Overall, $\widehat{C}_{o_{15}} = \{c_2\}$. The target users using approximate preference relations remain identical to the exact ones, i.e., no loss of accuracy in this case. Δ

The rest of this section focuses on the accuracy of FilterThenVerifyApprox. It produces *false positives* if there exists such an o that $o \in \widehat{\mathcal{P}}_c$ but $o \notin \mathcal{P}_c$. It produces *false negatives* if there exists such an o that $o \notin \widehat{\mathcal{P}}_c$ but $o \in \mathcal{P}_c$. Below we present Theorems 6.5 and 6.7 to analyze how $\widehat{\mathcal{P}}_U$ and $\widehat{\mathcal{P}}_c$ relate to \mathcal{P}_U and \mathcal{P}_c .

LEMMA 6.4. Given a set of users U and an attribute d , the common preference relation \succ_U^d and an approximate common preference relation $\widehat{\succ}_U^d$ satisfy the following properties:

- 1) The approximate preference tuples are a superset of the common preference tuples, i.e., $\widehat{\succ}_U^d \supseteq \succ_U^d$.
- 2) If any preference tuple along with its reverse tuple do not belong to the approximate common preference relation, neither of them belongs to the common preference relation either, i.e., $(x, y) \notin \widehat{\succ}_U^d \wedge (y, x) \notin \widehat{\succ}_U^d \Rightarrow (x, y) \notin \succ_U^d \wedge (y, x) \notin \succ_U^d$. Δ

THEOREM 6.5. Given objects \mathcal{O} and users U , the Pareto frontier with regard to approximate common preference relations is a subset of the Pareto frontier with regard to common preference relations, i.e., $\widehat{\mathcal{P}}_U \subseteq \mathcal{P}_U$. Δ

Proof: We prove by contradiction. Suppose $\widehat{\mathcal{P}}_U \not\subseteq \mathcal{P}_U$, which would mean there exists $o \in \mathcal{O}$ such that $o \in \widehat{\mathcal{P}}_U$ and $o \notin \mathcal{P}_U$. That leads to the existence of an o' such that $o' \succ_U o$ and $o' \not\succeq_{\widehat{U}} o$. However, $o' \succ_U o$ implies $o' \succ_{\widehat{U}} o$ because $\widehat{\succ}_U^d \supseteq \succ_U^d$ for every d (Lemma 6.4). Therefore, the existence of o' is impossible. This contradiction proves that $\widehat{\mathcal{P}}_U \subseteq \mathcal{P}_U$. \blacksquare

LEMMA 6.6. Given any set of users U , for all user $c \in U$, $\widehat{\mathcal{P}}_U \supseteq \widehat{\mathcal{P}}_c$. Δ

THEOREM 6.7. Given any set of users U , for all user $c \in U$, $\widehat{\mathcal{P}}_U \cap \mathcal{P}_c \subseteq \widehat{\mathcal{P}}_c$. Δ

Proof: We prove by contradiction. Suppose $\widehat{\mathcal{P}}_U \cap \mathcal{P}_c \not\subseteq \widehat{\mathcal{P}}_c$, which would mean there exists $o \in \mathcal{O}$ such that $o \in \widehat{\mathcal{P}}_U \cap \mathcal{P}_c$ and $o \notin \widehat{\mathcal{P}}_c$. $o \notin \widehat{\mathcal{P}}_c$ implies the existence of an $o' \in \mathcal{O}$ such that $o' \in \widehat{\mathcal{P}}_c$ and $o' \succ_c o$ (since $o \in \widehat{\mathcal{P}}_U \cap \mathcal{P}_c$ and thus $o \in \widehat{\mathcal{P}}_U$ which

means $o' \not\prec_{\widehat{U}} o$. Since $o' \succ_c o$, $o \notin \mathcal{P}_c$ (Def. 3.3) and thus $o \notin \widehat{\mathcal{P}}_U \cap \mathcal{P}_c$. In other words, the existence of o' is impossible. This contradiction proves that $\widehat{\mathcal{P}}_U \cap \mathcal{P}_c \subseteq \widehat{\mathcal{P}}_c$. ■

Consider a cluster U and a user $c \in U$. The Venn diagram in Fig. 2 shows the effect of approximation through depicting \mathcal{O} (rectangle), \mathcal{P}_U (outer blue circle), $\widehat{\mathcal{P}}_U$ (outer red ellipse), \mathcal{P}_c (inner blue circle), and $\widehat{\mathcal{P}}_c$ (inner red ellipse). Besides, Table 5 elaborates the area covered by these sets while Table 6 shows the confusion matrix for c . Note that using approximate common preference relations results in false negatives (III). Mistakenly declaring III as not Pareto-optimal further allows false positives (V) to sneak in.

With these notations in place, we are ready to quantify the accuracy of FilterThenVerifyApprox using standard evaluation measures in information retrieval. Specifically, *precision* is the fraction of objects found by FilterThenVerifyApprox that are truly Pareto-optimal, i.e., $\frac{\sum_{c \in C} \widehat{\mathcal{P}}_c \cap \mathcal{P}_c}{\sum_{c \in C} \widehat{\mathcal{P}}_c}$. *Recall* is the fraction of Pareto-optimal objects that are correctly found by FilterThenVerifyApprox, i.e., $\frac{\sum_{c \in C} \widehat{\mathcal{P}}_c \cap \mathcal{P}_c}{\sum_{c \in C} \mathcal{P}_c}$. With regard to a specific user c , the algorithm's precision, recall and accuracy can be represented using the areas in Fig. 2, as follows.

$$precision = \frac{|IV|}{|IV \cup V|} \quad (6)$$

$$recall = \frac{|IV|}{|III \cup IV|} \quad (7)$$

$$accuracy = \frac{|I \cup II \cup IV \cup VI|}{|I \cup II \cup III \cup IV \cup V \cup VI|} \quad (8)$$

6.3 Similarity Functions

To make the clustering solution in Sec. 5 compatible with approximate preference relations, we extend the similarity measures, using ideas inspired by the Jaccard similarity for non-negative multidimensional real vectors [4].

1) Jaccard Similarity Consider an attribute d with $|dom(d)| = m$. For each cluster U , construct a vector $\mathbf{U} = (\mathbf{U}(1), \mathbf{U}(2), \dots, \mathbf{U}(P_2^m))$. For $i \in [1, P_2^m]$, $\mathbf{U}(i)$ represents the frequency of A_i (Definition 6.1) in U . Given two clusters U and V , their *Jaccard similarity* on attribute d is

$$sim_{ij}^d(U, V) = \frac{\sum_i \min(\mathbf{U}(i), \mathbf{V}(i))}{\sum_i \max(\mathbf{U}(i), \mathbf{V}(i))} \quad (9)$$

Example 6.8. Consider U_1 and U_3 in Table 3. Suppose $A(i)$ for $i \in [1, P_2^m]$ are ((Apple, Lenovo), (Apple, Samsung), (Apple, Toshiba), (Lenovo, Apple), (Lenovo, Samsung), (Lenovo, Toshiba), (Toshiba, Apple), (Toshiba, Lenovo), (Toshiba, Samsung), (Samsung, Apple), (Samsung, Lenovo), (Samsung, Toshiba)). The two vectors are $\mathbf{U}_1 = (2/2, 2/2, 0/2, 0/2, 2/2, 0/2, 0/2, 1/2, 2/2, 0/2, 0/2, 0/2)$ and $\mathbf{U}_3 = (0/2, 2/2, 1/2, 2/2, 2/2, 2/2, 0/2, 0/2, 1/2, 0/2, 0/2, 0/2)$. For instance, \mathbf{U}_1 has $1/2$ on the 8^{th} -dimension since only one of the two users' preference relations contains (Toshiba, Lenovo). Hence, $sim_{ij}^{\text{brand}}(U_1, U_3) = 0.36$. △

2) Weighted Jaccard Similarity This measure, denoted as sim_{wj}^d , extends the namesake measure in Sec. 5 with the idea above. Its definition is the same as Eq. 9 except that a value $\mathbf{U}(i)$ in a vector represents the frequency of A_i in U that takes into consideration the weights explained in Sec. 5. Consider A_i as the preference tuple $(A_i(x), A_i(y))$. This similarity measure is defined as follows.

$$sim_{wj}^d(U, V) = \sum_i \left(\min \left(\frac{1}{|U|} \times \sum_{c \in U} \frac{1}{\min D(s, A_i(x))+1}, \frac{1}{|V|} \times \sum_{c \in V} \frac{1}{\min D(s, A_i(x))+1} \right) \right. \\ \left. / \sum_i \left(\max \left(\frac{1}{|U|} \times \sum_{c \in U} \frac{1}{\min D(s, A_i(x))+1}, \frac{1}{|V|} \times \sum_{c \in V} \frac{1}{\min D(s, A_i(x))+1} \right) \right) \right) \quad (10)$$

Example 6.9. In Table 3, in the partial order depicting $\succ_{c_6}^{\text{brand}}$, the distance to *Apple* from the maximal value *Lenovo* is 1, i.e., the weight of *Apple* is $1/2$. Since only one of the two users in U_3 has (Apple, Toshiba) in their preference relation, \mathbf{U}_3 has $\frac{1}{2} + 0 = \frac{1}{4}$ on the 3^{rd} -dimension. In this way, we get $\mathbf{U}_1 = (2/2, 2/2, 0/2, 0/2, 1/2, 0/2, 0/2, 1/2, 2/2, 0/2, 0/2, 0/2)$ and $\mathbf{U}_3 = (0/2, 1/4, 2/2, 2/2, 2/2, 0/2, 0/2, 1/4, 0/2, 0/2, 0/2)$. Therefore, $sim_{wj}^{\text{brand}}(U_1, U_3) = 0.19$. △

7 ALIVE OBJECT DISSEMINATION

In Sec. 1, we discussed motivating applications such as social network content dissemination, news delivery and product recommendation. The significance of a particular social network content (e.g. a post in Facebook) or a piece of news diminishes eventually. Similarly, in any inventory, products are consumed and perishable products expire over time. In other words, objects can have limited lifetime. Thus, upon the arrival of a new object, it needs to compete only with the alive objects. To meet this requirement, we extend our problem as continuous monitoring of Pareto frontiers over *alive objects* for many users and formalize it as finding Pareto frontiers over *sliding window*.

Suppose $\mathcal{O} = \{o_1, o_2, \dots, o_N\}$ is a stream of objects, in which the subscript of each object is its timestamp. We consider a sliding window as a sequence of W recent objects. Upon the arrival of an incoming object o_{in} , an object o_{out} expires if $in - out = W$. Specifically, the sliding window contains objects whose timestamps are in $(out, in]$, i.e., an object $o_i \in \mathcal{O}$ is alive during $(out, in]$ if $i \in (out, in]$. Given the concept of sliding window, we extend the definition of Pareto frontier in Def. 3.3 and the problem statement in Sec. 3.

Definition 7.1 (Pareto Frontier). An alive object o is Pareto-optimal with respect to c , if no other alive object dominates it. $\mathcal{P}_c = \{o_i \in \mathcal{O} \mid \nexists o_j \in \mathcal{O} \text{ s.t. } o_j \succ_c o_i \wedge i, j \in (out, in]\}$. The target users of o_{in} is $C_{o_{in}} = \{c \in C \mid o_{in} \in \mathcal{P}_c\}$ (Def. 3.4). △

Problem Statement The problem of continuous monitoring of Pareto frontiers over sliding window is, given a set of users C , their preference relations on attributes \mathcal{D} , and a stream of objects \mathcal{O} with the incoming object o_{in} as well as the outgoing object o_{out} , find $C_{o_{in}}$ —the target users of o_{in} .

Algorithms BaselineSW and FilterThenVerifySW We extend Baseline and FilterThenVerify to BaselineSW and FilterThenVerifySW, respectively, to accommodate sliding window. We note that no prior work studied Pareto frontier maintenance with regard to strict partial orders over sliding window. [15, 16, 21] studied skyline maintenance over sliding window, assuming numeric attributes. [18] considered total orders (with ties) on categorical

attributes instead of general partial orders. There is no clear way to extend these works for partially ordered attributes.

Due to space limitations, we leave the detailed pseudo codes and descriptions of BaselineSW and FilterThenVerifySW to the extended version of this paper [20]. Below we highlight the key concepts that dictate the design of these algorithms.

Under the constraint of having a sliding window, an object can be excluded from Pareto frontier forever if it is dominated by any succeeding object. This observation is formalized as Theorem 7.2.

THEOREM 7.2. *Consider a user $c \in C$ and two objects $o_i, o_j \in O$ such that $o_i \prec_c o_j$ and $i < j$. After the arrival of o_j , o_i can never be part of \mathcal{P}_c in its remaining lifetime.* \triangle

Proof: Since $i < j$, o_i expires before o_j and the sliding window always includes o_j if it includes o . Since o_j dominates o_i , o_i will never get into \mathcal{P}_c after the arrival of o_j . \blacksquare

By Theorem 7.2, we extend our algorithms to maintain a *Pareto frontier buffer* which stores at most W recent objects that are not dominated by any succeeding object. Clearly, o_{in} is part of the Pareto frontier buffer.

Definition 7.3 (Pareto Frontier Buffer). With regard to user c and the sliding window $(out, in]$, an alive object o belongs to the Pareto frontier buffer if it is not dominated by any succeeding object. The Pareto frontier buffer is $\mathcal{P}\mathcal{B}_c = \{o_i \in O \mid \nexists o_j \in O \text{ s.t. } o_j \succ_c o_i \wedge i, j \in (out, in] \wedge i < j\}$. By definition, $\mathcal{P}\mathcal{B}_c \supseteq \mathcal{P}_c$ (Def. 7.1). \triangle

THEOREM 7.4. *Given a set of users U , for all $c \in U$, i) $\mathcal{P}\mathcal{B}_U \supseteq \mathcal{P}_U$ and ii) $\mathcal{P}\mathcal{B}_U \supseteq \mathcal{P}\mathcal{B}_c$.* \triangle

Proof: i) Together Def. 7.1 and 7.3 imply that $\mathcal{P}\mathcal{B}_U \supseteq \mathcal{P}_U$.

ii) We prove by contradiction. Suppose that there exists $c \in U$ such that $\mathcal{P}\mathcal{B}_U \not\supseteq \mathcal{P}\mathcal{B}_c$, which would mean there exists $o \in O$ such that $o \in \mathcal{P}\mathcal{B}_c$ and $o \notin \mathcal{P}\mathcal{B}_U$. That implies the existence of an $o' \in O$ such that $o' \succ_U o$ and $o' \not\succeq_c o$. However, by Def. 4.1, $o' \succ_U o$ implies $o' \succ_c o$. Therefore, the existence of o' is impossible. In conclusion, $\mathcal{P}\mathcal{B}_U \supseteq \mathcal{P}\mathcal{B}_c$. \blacksquare

Note that, BaselineSW needs to maintain an exclusive Pareto frontier buffer for each user ($\mathcal{P}\mathcal{B}_c$) while a Pareto frontier buffer per cluster ($\mathcal{P}\mathcal{B}_U$) is sufficient for FilterThenVerifySW.

8 EXPERIMENTS

8.1 Experiment Setup

The algorithms were implemented in Java. The maximal heap size of Java Virtual Machine (JVM) was set to 16 GB. The experiments were conducted on a computer with 2.0 GHz Quad Core 2 Duo Xeon CPU running Ubuntu 8.10.

Datasets Currently there exists no publicly available dataset that captures real users' preferences in partial orders. We thus simulated such partial orders using two real datasets of users' preferences.

Movie Dataset We joined the Netflix dataset (netflixprize.com) with data from IMDB (imdb.com). The Netflix dataset contains the ratings (ranging from 0 to 5) given by users to movies. From IMDB we fetched the movies' attribute values, including actors, directors, genres, and writers. In this way, we found the attributes of 12,749 Netflix movies. The goal is to, for each particular movie, identify users who may like it according to their preferences on those attributes. The mapping from our problem formulation to this dataset is the following: (i) O is the set of 12,749 movies. (ii) C is the set of users. It includes the 1,000 most active users based on how many movies they have rated. (iii) $\mathcal{D} = \{\text{actor,}$

director, genre, writer}. (iv) Given the lack of user preference data, for each attribute, the partial order corresponding to a user's preferences is simulated as follows. For two attribute values, the user's preference is based on the *average rating* and the *count* of movies satisfying these attribute values. More specifically, consider a user c who has rated m movies featuring actor a . Suppose the ratings of these movies are r_1, r_2, \dots, r_m . Given c and a , the average rating is $R_a = \frac{\sum_i r_i}{m}$ and the count is $M_a = m$. Consider another actor b . If $(R_a > R_b \wedge M_a \geq M_b) \vee (R_a \geq R_b \wedge M_a > M_b)$, then $(a, b) \in \succ_c^{\text{actor}}$. Intuitively, if user c watches more movies featuring a than b and gives them higher ratings, our simulation assumes the user prefers a to b .

Publication Dataset We collected from the ACM Digital Library (dl.acm.org) 17,598 publications and their attributes, including affiliations, authors, conferences and topic keywords. The users are the authors themselves. The goal is to notify them about newly published articles. The recommendations are based on the users' preference relations on the attributes. The mapping from our problem formulation to this dataset is the following: (i) O is the set of papers. (ii) C is the set of authors. It includes the 1,000 most prolific authors based on how many publications they have, similar to the 1,000 most active users in the movie dataset. (iii) $\mathcal{D} = \{\text{affiliation, author, conference, keyword}\}$. The domain of attribute author is the same 1,000 authors in C . (iv) Given a user, the partial order on each attribute is simulated based on their preferences on the attribute values. The preference between two values on affiliation (and similarly author) is based on the *number of collaborations* between the user and the affiliation/author and the *number of citations*. For conference and keyword, the preference between two values is based on *number of publications* and *number of citations*. More specifically, consider a user c and an affiliation (or similarly another author) a . Suppose c has p_a collaborations with a and has cited articles from a q_a times. If $(p_a > p_b \wedge q_a \geq q_b) \vee (p_a \geq p_b \wedge q_a > q_b)$, then $(a, b) \in \succ_c^{\text{affiliation}}$ (or $(a, b) \in \succ_c^{\text{author}}$). With regard to a conference (keyword) x , suppose c has r_x publications associated with x and has cited publications associated with x s_x times. If $(r_x > r_y \wedge s_x \geq s_y) \vee (r_x \geq r_y \wedge s_x > s_y)$, then $(x, y) \in \succ_c^{\text{conference}}$ (or $(x, y) \in \succ_c^{\text{keyword}}$).

8.2 Baseline, FilterThenVerify, and FilterThenVerifyApprox

We conducted experiments to compare the performance of Baseline, FilterThenVerify and FilterThenVerifyApprox. For FilterThenVerify (resp. FilterThenVerifyApprox), users are clustered by the conventional hierarchical agglomerative clustering algorithm [9] using the similarity functions in Sec. 5 (resp. Sec. 6.3) and, for each cluster, it extracts the common preference relation (resp. approximate common preference relation). The experiments use three parameters which are number of objects ($|O|$), number of attributes (d), and branch cut (h). In hierarchical clustering, the *branch cut* h is a threshold that controls the number of clusters by governing the minimum pairwise similarity that two clusters must satisfy in order to be merged into one cluster. The sequential order of merging clusters is depicted as a tree called *dendrogram*. The branch cut thus controls where to cut the dendrogram. In Example 5.5, the set of clusters are $\{\{c_1, c_2, c_5, c_6\}, \{c_3, c_4\}\}$ for $h \in (0, \frac{3}{11}]$. This is because $\text{sim}(U_4, U_2) = 0$ where $U_2 = \{c_3, c_4\}$ and U_4 is the cluster composed of c_1, c_2, c_5 , and c_6 .

Table 7: The precision, recall and F-measure (in percentage) of FilterThenVerifyApprox. Varying h , $d=4$.

Fig.3a shows, for each of the three methods on the movie dataset, how its cumulative execution time (by milliseconds, in logarithmic scale) increases while the objects (i.e., movies) are sequentially processed. Fig.4a depicts similar behaviours of these methods on the publication dataset. Fig.3b and Fig.4b, for the two datasets separately, further present the amount of work done by these methods, in terms of number of pairwise object comparisons (in logarithmic scale) for maintaining Pareto frontiers. The figures show that FilterThenVerify and FilterThenVerifyApprox beat Baseline by 1 to 2 orders of magnitude. The reason is as follows. With regard to a user c , Baseline considers all objects as candidate Pareto-optimal objects and compares all pairs. On the contrary, FilterThenVerify eliminates an object o if the corresponding common preference tuples disqualify o . FilterThenVerifyApprox incurs even less comparisons by benefiting from shared computations for clusters of users.

Fig.5a (Fig.6a) shows that the execution time of all these methods increased super-linearly by number of attributes (d). Fig.5b (Fig.6b) further reveals that the number of object comparisons also increases similarly. This is not surprising because more attributes result in larger Pareto frontiers, which makes it necessary for objects to be compared with more existing Pareto-optimal objects.

Table 7 reports the precision, recall and F-measure of FilterThenVerifyApprox on varying h . We can observe that, when h got smaller, the recall slowly decreased. This is expected because smaller h results in larger clusters and potentially more approximate common preference tuples for each cluster. Those approximate common preference tuples cause false negatives—the domination and elimination of objects that are instead in the Pareto frontier under the true common preference tuples, which

Figure 7: Effect of window size. Varying W , $|O| = 1M$, $h = 0.55$, $d = 4$.

are a subset of the approximate common preference tuples. What can be more surprising is the almost perfect precision under the various h values in Table 7, i.e., almost no false positives were introduced into the results. For a user c , an object o becomes a false positive if every single Pareto optimal object that dominates o becomes a false negative. As long as one of its dominating objects is not mistakenly filtered out, o will not be mistakenly introduced into the Pareto frontier. Therefore, an object is much less likely to become a false positive than a false negative. Overall, under the h values in Table 7, both precision and recall remain high. This may suggest that the thresholds θ_1 and θ_2 (Sec. 6.1) effectively ensure that the approximate common preference relation only includes frequent preference tuples and does not overgrow in size.

8.3 BaselineSW, FilterThenVerifySW, and FilterThenVerifyApproxSW

We further compare the performance of FilterThenVerifySW and FilterThenVerifyApproxSW with BaselineSW. In this regard, we simulated two data streams—movie and publication where O is

Data stream	W	$h = 0.70$			$h = 0.65$			$h = 0.60$			$h = 0.55$		
		Precision	Recall	F-measure	Precision	Recall	F-measure	Precision	Recall	F-measure	Precision	Recall	F-measure
Movie	400	100	89.36	94.38	100	87.33	93.24	100	85.94	92.44	100	81.95	90.08
	800	100	87.87	93.54	100	85.78	92.34	100	84.04	91.33	100	80.10	88.95
	1600	100	88.65	93.98	100	86.58	92.81	100	85.01	91.90	100	81.10	89.56
	3200	99.99	94.80	97.33	100	93.08	96.41	100	92.29	95.99	100	88.99	94.17
Publication	400	100	94.58	97.21	100	93.57	96.68	100	92.98	96.36	100	92.06	95.87
	800	100	94.79	97.32	100	93.60	96.70	100	93.01	96.38	100	91.98	95.82
	1600	100	94.62	97.24	100	93.44	96.61	100	92.85	96.29	100	91.81	95.73
	3200	100	96.71	98.33	100	95.98	97.95	100	95.67	97.79	100	95.27	97.58

Table 8: The precision, recall and F-measure (in percentage) of FilterThenVerifyApproxSW. Varying W and h , $|O|=1M$, $d=4$.

composed of duplicated sequence of the corresponding dataset such that $|O|=1$ million. Following [21], we experimented with windows of size 400, 800, 1,600, and 3,200. Fig.7a shows the cumulative execution times (by milliseconds, in logarithmic scale) of the aforementioned methods on the movie stream. Fig.7a reveals that the cumulative execution times increase super-linearly by W as wider window broadens the size of Pareto frontiers. These figures illustrate that both FilterThenVerifySW and FilterThenVerifyApproxSW outperformed BaselineSW by 1 to 2 orders of magnitude, which concurs with the comparative behaviours of FilterThenVerify, FilterThenVerifyApprox and Baseline. This concurrence is also applicable for the publication stream (Fig.7b). The reason behind the comparative behaviour of Baseline, FilterThenVerify and FilterThenVerifyApprox is also applicable in this case. Moreover, BaselineSW maintains exclusive Pareto buffer for each user (\mathcal{PB}_C) while FilterThenVerifySW shares a Pareto buffer across users in a cluster (\mathcal{PB}_U). Therefore, in sliding window protocol, the filter-then-verify approach attains the benefit of clustering in a greater extent.

Table 8 demonstrates the precision, recall and F-measure of FilterThenVerifyApproxSW on varying W and h . We can observe that the recall declines slowly by h . Yet h does not have significant impact on the efficacy of FilterThenVerifyApproxSW. Besides, the loss of accuracy is due to false negatives rather than false positives. These behaviors concur with FilterThenVerifyApprox and the reasons behind are same as before. In addition, Table 8 reveals that W does not have noticeable impact on efficacy and FilterThenVerifyApprox remains effective on varying W .

9 CONCLUSION

We studied the problem of continuous object dissemination, which is formalized as finding the users who approve a new object in Pareto-optimality. We designed algorithm for efficient finding of target users based on sharing computation across similar preferences. To recognize users of similar preferences, we studied the novel problem of clustering users where each user's preferences are described as strict partial orders. We also presented an approximate solution of the problem of finding target users, further improving efficiency with tolerable loss of accuracy. Experimental evaluation validated the efficiency and effectiveness of our proposed solutions.

ABSTRACT

Data confidentiality is concerned in database-as-a-service (DBaaS) model. The cloud server should not have access to user's plain data. Data is encrypted before they are stored in cloud database. Query computation over encrypted data by the server is not straight-forward. Many research works have been done on this problem. A common goal is to let the server obtain the selection result without leaking information about plain data. In existing solutions, the selection result is simply dumped by the server after the query answer is returned. Our idea is to make use of such *past results* of selections to improve processing speed for new queries. We developed an indexing mechanism called *past result knowledge base* (PRKB) to improve processing speed of selection with comparison predicate(s) in EDBMS. All operations related to PRKB are done by the server only. In our empirical studies, PRKB can reduce processing cost by orders of magnitudes compared to the case PRKB is not used.

1 INTRODUCTION

In database-as-a-service (DBaaS) model, a data owner (DO) uploads its data to a database managed by a third party service provider (SP) who is responsible to answer DO's queries and provides administrative services, e.g., backup recovery and access control. Data confidentiality is concerned when SP is compromised, e.g., by a malicious DBA administrating the database server. For instance, a rogue DBA has stolen 2.3 millions customer records of a Fortune 500 company¹, including bank account and credit card information. Encrypted database management systems (EDBMSs), such as Cipherbase [2–4] and SDB [19, 35], are recently developed to address data confidentiality concerns in case SP is compromised. The idea in EDBMS is to use *application level encryption* where data is encrypted and decrypted by DO and the private keys are only known to DO. Even if an attacker somehow gets access to the database at SP, the attacker can only obtain encrypted information without the keys to decrypt the data.

A challenge in EDBMS is to allow SP to compute selection over encrypted data, without knowing any other information about plain data (so that minimal number of encrypted tuples are processed in the next operations, e.g., join and/or aggregation). Many solutions were proposed, e.g., [12, 25] for range query and [13] for keyword search. In this paper, we address optimization of computing selection with comparison predicate(s) in EDBMS.

Fig. 1 shows an overview of our method, *past result knowledge base* (PKRB). The results of past selections are consolidated and stored in PRKB at SP. SP can use PRKB to reduce processing cost

Figure 1: Overview of PRKB for query processing

Encrypted tuples	Selection		
	σ_1	σ_2	σ_3
\bar{t}_1	✓	X	✓
\bar{t}_2	X	✓	✓
\bar{t}_3	✓	✓	?
\bar{t}_4	✓	✓	?

Table 1: Example scenario. If an encrypted tuple satisfies (or does not satisfies resp.) a selection, a '✓' (or 'X' resp.) is shown. '?' denotes that the result for the encrypted tuple is not known yet.

of a new selection. We use the following example to illustrate the cost reduction idea.

Suppose there are 4 encrypted tuples \bar{t}_i for $i = 1$ to 4. Each tuple has one attribute X only. There are 3 selections σ_1 , σ_2 , and σ_3 , each with a simple comparison predicate in the form of ' $X < c$ ' or ' $X > c$ ' where c is a user-defined parameter unknown to SP. σ_1 and σ_2 are computed already. σ_3 is partially computed. The scenario is shown in Table 1.

SP can reason as following to determine the values of '?' in Table 1. The result of σ_1 partitions the encrypted tuples into two groups, $P_1 = \{\bar{t}_1, \bar{t}_3, \bar{t}_4\}$ and $P_2 = \{\bar{t}_2\}$. We use $P_i > P_j$ to denote that all tuples in P_i have a larger plain value than all tuples in P_j . Since σ_1 is a simple comparison predicate, there are only two possible scenarios: either (i) $P_1 > P_2$ or (ii) $P_2 > P_1$. We assume it is the case of scenario (i), i.e., \bar{t}_2 has the smallest plain value. Similarly, from the result of σ_2 , SP obtains two partitions $P_3 = \{\bar{t}_1\}$ and $P_4 = \{\bar{t}_2, \bar{t}_3, \bar{t}_4\}$. It must be either $P_3 > P_4$ or $P_4 > P_3$. Since $\bar{t}_2 \in P_4$ and \bar{t}_2 has the the smallest value, it must be the case $P_3 > P_4$. As a result, SP obtains the order of (plain values of) all encrypted tuples in this scenario as ' $\bar{t}_2 < \bar{t}_3, \bar{t}_4 < \bar{t}_1$ '. This order information is *partial* only as SP cannot determine which encrypted tuple is larger for \bar{t}_3 and \bar{t}_4 . For σ_3 , \bar{t}_1 and \bar{t}_2 are found to satisfy the selection condition. \bar{t}_3 and \bar{t}_4 are ordered between \bar{t}_1 and \bar{t}_2 , so \bar{t}_3 and \bar{t}_4 must also satisfy the selection condition, i.e., both '?' must be '✓' in Table 1. SP can perform the same analysis for scenario (ii) and obtains the same conclusion.

In the above example, SP can determine whether \bar{t}_3 and \bar{t}_4 satisfy a new selection σ_3 without accessing them and thus saves the processing cost on these two encrypted tuples. Such saving is significant because the process to check whether an encrypted

¹<http://www.computerworld.com/article/2542360/security0/database-admin-steals-2-3m-consumer-records-at-fidelity-national-subsiary.html>

tuple satisfies a comparison predicate is usually expensive. For example, in Cipherbase [2], the encrypted tuple is decrypted (within a trusted hardware) before the predicate is tested. The additional decryption cost is significant compared to the cost of a simple comparison. As demonstrated in our empirical evaluation, only a small portion of encrypted tuples cannot be determined using PRKB and only this group of tuples require to be processed by SP using the usual cryptographic way. The overall processing cost is greatly reduced.

We highlight the distinguished features of PRKB as follows:

- *DO is not involved* in any part (e.g., building or using) of PRKB. No information is required to be sent from DO to SP for PRKB. All information in PRKB is solely based on what SP has observed in past query computation. It can be realized easily that PRKB does not leak more information than the underlying EDBMS.
- *PRKB is compatible to any encryption scheme* that tells SP which encrypted tuples satisfy the selection. As long as the encryption scheme provides such trapdoor, PRKB can be used on top of it. This allows PRKB to be deployed on top of many existing systems, e.g., Cipherbase and SDB.
- *Information in PRKB is in plain*. Unlike encrypted index, PRKB consists of information about past selection results. All operations related to PRKB are efficient and the size of PRKB is compact.

The rest of this paper is organized as follows. We discuss related work in Sec. 2. In Sec. 3, we define the models used in our problem. We describe what PRKB is and how SP builds PRKB in Sec. 4. In Sec. 5 and Sec. 6, we describe our algorithms for processing a single comparison predicate and multi-dimensional range query respectively. We describe how to handle database update in Sec. 7. We empirically evaluate PRKB and related algorithms in Sec. 8. We conclude this paper in Sec. 9.

2 RELATED WORK

Different solutions were developed for computing individual database operations over encrypted data, e.g., range query [6, 12, 25, 28], keyword search [7, 13] and join [26]. A potential problem of these solutions is that integration of the above solutions is not trivial. Encrypted database management system (EDBMS) [2, 4, 5, 19, 29, 33, 35] offers an integrated solution that supports a wide range of SQL operations. We aim to deploy our optimization technique for selection with comparison predicate(s) in EDBMS. We first review existing EDBMSs in Sec. 2.1. Then, we review indexing options for EDBMS in Sec. 2.2. Lastly, we review techniques that hide selection results from SP in Sec. 2.3.

2.1 EDBMS

There are several approaches to implementing EDBMS.

The first approach, e.g., TrustedDB [5] and Cipherbase [2, 4], makes use of a trusted hardware. There is a trusted machine (TM) at SP. For instance, TrustedDB uses Cryptographic Coprocessor and Cipherbase uses FPGA. Such hardware devices are (physically) tamper-resistant. An attacker is assumed not to be able to see the data or process inside TM. TM is given the decryption key of DO. Any computation related to encrypted data can be handled by TM. For instance, to process a comparison predicate, the encrypted value of each tuple and the instructions (with encrypted user parameters) are passed to TM. TM decrypts the data, makes the comparison, and returns the comparison result to SP.

The second approach uses secret sharing methods, e.g., SDB [19, 35]. Secret sharing splits each data item into shares. Some shares are stored at DO² while some are stored at SP. Without collecting all the shares of a data item, SP cannot recover its plain value. Multi-party computation (MPC) operators are developed to execute database operations by DO and SP communicating with each other in multiple rounds. An advantage of MPC approach is that any computation can be computed [15]. However, it incurs a high communication cost in query processing.

Another approach is to use multiple encryption schemes, each to support a different set of operations. Example system is CryptDB [29] / MONOMI [33]. (MONOMI is an extension of CryptDB to further support aggregation.) Specifically, CryptDB uses order preserving encryption (OPE), e.g., [1, 28], to process comparison predicates. OPE preserves the numerical order of plain data under encryption, i.e., if $x > y$, $E(x) > E(y)$ for any x, y where E denotes the encryption function. Comparison predicates can be computed efficiently and indexing over OPE-encrypted data is just like indexing over plain data. A downside of this approach is that it leaks the total order of plain data to SP. Recent studies show that inference attack [22, 27] can recover accurately the plain data of OPE-encrypted data using the total order information.

2.2 Indexing on encrypted data

Our method, PRKB, is similar to indexing, because SP uses additional space to remember past results in order to boost the performance in query computation. PRKB has a significant difference to mainstream indexing methods for encrypted data: *PRKB is solely done by SP*, while existing indexing mechanisms for encrypted data require DO's involvement, e.g., to build the encrypted index, or requires DO to encrypt data using specific algorithms. In the following, we briefly discuss existing indexing methods for encrypted data.

In [11, 14, 31], an encrypted index tree is built by DO and stored at SP. SP simply serves as a storage without processing capabilities. DO retrieves parts of the index from SP iteratively to traverse the index. Data confidentially can be proven as SP never see any data in plain. Access pattern of the index can also be protected from SP, e.g., in [14], at the cost of increased processing and communication cost. DO has a significant amount of workload. We do not prefer this approach in DBaaS where DO may not be as powerful as SP.

[12, 23, 25] developed new encryption methods for computing comparison predicate or range query with indexing support. In [23], data is encrypted using a special vector encryption method [34]. An index can be built over these encrypted values. A problem is there is information leaked in the encryption scheme, as shown in [17], and plain data can be recovered in some scenarios. In [25], a security notion of index indistinguishable is introduced and an index is developed that achieves the proposed security notion. However, such security notion is proven to be weak [10]. In [12], it transforms the problem of range query into keyword search and uses existing searchable symmetric encryption (SSE) [7, 8] to compute the result. A series of schemes with different indexing options, each offers different security strength, is developed. In all methods above, SP see the selection results as this is the objective of the problem. Our method PRKB can also be implemented on top of these encryption methods. In our empirical studies, we will compare our method to [12].

²In SDB, the shares at DO can be generated using an RSA-like share-generating function. This reduces storage cost at DO.

Some EDBMSs we discussed in Sec. 2.1 also use indexing. Cipherbase uses an encrypted B+-tree. The index reveals the total order of plain data to SP and is thus also vulnerable to inference attack. SDB uses domain-partitioning index [18, 21]. The data domain is divided into partitions by DO. SP is informed by DO the partition each data item falls into. Due to additional information leak, we do not consider these methods suitable for our problem.

2.3 Hiding selection result from SP

Our problem assumes the selection result is known by SP. The selection result can potentially be hidden by access pattern hiding technique, e.g., oblivious RAM (ORAM) [16, 32] and/or private information retrieval [9]. For instance, [4] discussed an option to integrate ORAM in Cipherbase. The trade-off is that each data access has a polylog cost. Due to high overhead, ORAM was not implemented in Cipherbase. Similar to Cipherbase, other EDBMSs we reviewed in Sec. 2.1 do not use any access pattern hiding technique. Our method can be deployed on existing EDBMSs, including TrustedDB, CipherBase and SDB.

3 MODELS

3.1 Preliminary: EDBMS

Our problem is based on an underlying encrypted database management system (EDBMS). In this section, we describe the EDBMS model, that is compatible to EDBMSs that we discussed in Sec. 2.1.

Parties. There are two parties: data owner (DO) and service provider (SP). DO has a set of relational tables in the database. Each table T is a set of tuples, i.e., $T = \{t_i\}$ where t_i denotes the i -th tuple. DO encrypts T to be \bar{T} such that $\bar{T} = \{\bar{t}_i \mid \bar{t}_i = E(t_i)\}$ for every $t_i \in T$ where E denotes the encryption function. (We use \bar{X} to represent the encrypted version of X in the rest of the paper.) \bar{T} is sent to SP for storage and DO does not store T . The private keys are only known by DO.

Selection processing. EDBMS allows selection to be computed over encrypted data by SP. The selection contains one or more comparison predicates, e.g., ' $X > 10$ '. SQL supports a wide range of comparison predicates, e.g., comparison operators ($>$, $<$, \geq , and \leq), and BETWEEN operator etc. In general, for existing EDBMSs that employ attributed-based encryption, SP can tell (i) which type of operator is used because the algorithms to process them are different³; and (ii) which encrypted attribute is concerned so that other encrypted values of other attributes are not accessed during selection processing. In our problem, we focus on comparison predicate in the form of ' $X \text{ op } c$ ' where op is a comparison operator. In Appendix A, we briefly discuss how BETWEEN operator can be handled. As we discussed in Sec. 2.1, there are different ways to implement EDBMS to support selection processing. An ideal method allows SP to observe the selection result without seeing any information about plain data. We use the following model (based on the model in [24]) to capture the selection processing mechanism of EDBMS.

QPF model. Let p_i, \bar{p}_i be the plain and encrypted version of a comparison predicate. There is a query processing function (QPF) Θ such that

$$\Theta(\bar{p}_i, \bar{t}_j) = \begin{cases} 1, & \text{if } t_j \text{ satisfies } p_i \\ 0, & \text{otherwise} \end{cases}$$

³Comparison operators ($>$, $<$, \geq , and \leq) are handled by the same algorithm and hence SP cannot distinguish them.

\bar{p}_i is generated by DO and acts as a trapdoor that allows SP to observe the selection result of p_i . SP cannot observe the selection result of any predicate without such trapdoor, i.e., SP's knowledge of selection results is limited by *number of comparison predicates* issued by DO.

Applications. The above QPF model is generic [24] such that the selection processing mechanisms of majority of related work can be captured. For instance, among the EDBMSs that we have studied in Sec. 2.1, TrustedDB [5], Cipherbase [2, 4], and SDB [19, 35] satisfy this model, i.e., our method can be implemented on top of these systems. CryptDB [29] and MONOMI [33] also satisfy our EDBMS model, but they also reveal the total order of plain data (in addition to selection results) to SP. With total order known, there are simpler options to optimize query processing and security strength is significantly lowered. CryptDB and MONOMI are not our target applications and our underlying EDBMS should not reveal the total order information.

Our method can also be integrated to many other standalone methods for selection processing on encrypted database, e.g., [12, 20, 25, 30]. As long as these methods reveal the selection results to SP, our method can be applied. Methods that do not reveal the selection results to SP (see Sec. 2.3) are not our target applications. In our empirical studies, we will compare our method to the indexing method in [12], the state-of-the-art method for range query processing on encrypted data.

3.2 Problem in this paper: optimizing selection with comparison predicate

Our objective is to reduce the processing cost of selection at SP. A baseline method for SP is to test all encrypted tuples using the QPF one by one. The bottleneck of performance is QPF evaluation. Note that a comparison can be done extremely fast, e.g., in one cycle. QPF evaluation is relatively more expensive in general. For example, in Cipherbase, the encrypted tuple is decrypted within a trusted machine before the comparison is done. The decryption cost is significant compared to the simple comparison. Our goal is to *reduce number of QPF uses*.

Our problem is similar to an indexing problem, which trades (SP's) storage for speed. However, unlike traditional indexing problem for encrypted data, our method (i) does not rely on specific encryption method; and (ii) does not require DO's involvement⁴ in building and using "our index".

Our indexing mechanism, namely past result knowledge base (PRKB), composes of the following 4 algorithms.

$I \leftarrow \text{initPRKB}(\bar{T})$: is run by SP to initialize the index I .

$I \leftarrow \text{updatePRKB}(I, \bar{p}_i)$: is run by SP to update the index I with an encrypted predicate \bar{p}_i .

$(\bar{T}_W, \bar{T}_{NS}) \leftarrow \text{QFilter}(\bar{T}, I, \bar{p}_i)$: is run by SP to find two exclusive subsets of \bar{T} using the index: (i) \bar{T}_W represents the 'Winner' group. All encrypted tuples in this group must satisfy the plain predicate p_i ; and (ii) \bar{T}_{NS} represents the 'Not sure' group. Encrypted tuples in this group may satisfy p_i but some may be false positives. This group of encrypted tuples requires further processing by SP to confirm the exact selection result.

⁴DO may still be involved in QPF evaluation, e.g., in SDB [19, 35], and our method does invoke QPF. We do not count this as DO's involvement for the index because such involvement exists in EDBMS without our index.

$\overline{T_{WNS}} \leftarrow \text{QScan}(\overline{T_{NS}}, \mathcal{I}, \overline{p_i})$: is run by SP to confirm the exact selection result by examining each encrypted tuple one by one. QScan is similar to a linear scan but with optimization using information from PRKB.

SP can initiate PRKB (for an attribute) by *initPRKB* to create an ‘empty’ knowledge base as there is no past result observed by SP yet. As SP receives queries from DO, SP observes new selection results and can use them to extend PRKB using *updatePRKB*.

After executing *QFilter* and *QScan*, the selection result is then $\overline{T_W} \cup \overline{T_{WNS}}$. Fig.2b shows the procedure and messages in communication of EDBMS using PRKB. In contrast, Fig.2a shows the same procedure of EDBMS without using PRKB. As we will show in the paper, *QFilter* is cheap and $\overline{T_{NS}}$ is significantly smaller than \overline{T} . Only $\overline{T_{NS}}$ is processed by QScan. The overall cost can be thus reduced.

3.3 Security discussions

In the security model of EDBMS, an attacker has compromised SP and is able to observe anything SP can see. Or in simpler interpretation, SP is the attacker. An ideal situation is that SP observes no information about plain data. Unfortunately, there is some inherit information leak that we cannot avoid. The selection results and any information derived from them can be seen by SP because it is the objective of selection processing over encrypted data. The security goal of EDBMS is then to minimize leakage of any other information about plain data.

In our problem, we use the same attack model as EDBMS that the attacker has compromised SP. The security goal is to minimize additional leakage to SP caused by our method. As we will show in the paper, *our indexing method PRKB is built and used solely by SP using existing selection results*. No (encrypted or plain) information is ever sent from DO to SP for our index. For instance, readers can compare Fig.2b and Fig.2a which show the communication between DO and SP in EDBMS with or without using PRKB. The messages in the two cases are identical. Any information that can be derived by SP from PRKB can also be obtained by SP in EDBMS without PRKB. There is no additional leakage caused by PRKB.

Another important issue is that selection results are assumed to be observed by SP. We remark that this assumption is held in many existing methods. As discussed in [24] that selection results allow SP to eventually recover a total order of encrypted data on their plain values. The total order information can then be used in inference attack [22, 27] to recover accurate plain values. Data confidentiality is completely lost. The technique in [24] requires SP to observe $O(D^4)$ queries, where D is the domain size of an attribute, so as to let SP recover the total order information. Experiments in [24] showed that the total order can be recovered in a short time for a small data domain (e.g., $D \leq 365$). On the other hand, when the domain size D is large, it becomes impractical for SP to collect $O(D^4)$ queries for the attack. Yet, SP is able to observe certain number of queries. This allows SP to observe *partial* ordering information. We thus performed empirical evaluation to see how much ordering information SP can recover when SP observes limited number of queries. The details are presented in Sec. 8.1.

4 BUILDING PAST RESULT KNOWLEDGE BASE (PRKB)

In this section, we present what information SP can observe in query processing of EDBMS and how SP can use the observed

information to build a past result knowledge base (PRKB). PRKB can then be used by SP to reduce query processing cost for new range queries.

Consider a comparison predicate p_C in the form of ‘ $C \text{ op } x$ ’ where x is a user-defined query parameter and op is one of the following: $>$, $<$, \geq , and \leq . $\overline{p_C}$ is a trapdoor generated by DO that allows SP to observe, using QPF Θ , whether an encrypted tuple satisfies the predicate without seeing the plain data and plain predicate. Note that SP does not know which comparison operator op is used in p_C . SP can divide the encrypted tuples in \overline{T} into two partitions: (i) P_T : the partition of encrypted tuples where QPF outputs 1, i.e.,

$$P_T = \{\overline{t_i} \mid \overline{t_i} \in \overline{T} \text{ and } \Theta(\overline{p_C}, \overline{t_i}) = 1\}$$

and (ii) P_F : the partition of encrypted tuples P_F where QPF outputs 0, i.e.,

$$P_F = \{\overline{t_i} \mid \overline{t_i} \in \overline{T} \text{ and } \Theta(\overline{p_C}, \overline{t_i}) = 0\}$$

We can easily prove that either all encrypted tuples in P_T have a larger plain value on C than all encrypted tuples in P_F or it is the reverse case. For example, consider a comparison predicate ‘ $C < 9$ ’. P_T contains all encrypted tuples with plain values on C less than 9. P_F contains all encrypted tuples with plain values on C greater than or equal to 9. All encrypted tuples in P_F have a larger plain value on C than any encrypted tuple in P_T . Note that if the comparison predicate is ‘ $C > 9$ ’, all encrypted tuples in P_T have a larger plain value on C . SP cannot distinguish which set of encrypted tuples, P_T or P_F , is having larger plain values than the other. To capture the above special ordering relationship between two sets of encrypted tuples, we define two symbols below.

Definition 4.1. (Relationship between partitions.) Let $P_1 = \{\overline{t_i}\}$ and $P_2 = \{\overline{t_j}\}$ be two sets of encrypted tuples, $t_i[C]$ be the plain value of t_i on attribute C . We write $P_1 \overset{C}{<} P_2$ if $\forall \overline{t_i} \in P_1, \forall \overline{t_j} \in P_2, t_i[C] < t_j[C]$. We write $P_1 \overset{C}{\mapsto} P_2 \overset{C}{\mapsto} \dots \overset{C}{\mapsto} P_n$ if either (i) $P_1 \overset{C}{<} P_2 \overset{C}{<} \dots \overset{C}{<} P_n$ or (ii) $P_1 \overset{C}{>} P_2 \overset{C}{>} \dots \overset{C}{>} P_n$.

If the comparison predicate is ‘ $C < 9$ ’, $P_T \overset{C}{<} P_F$. However, SP does not observe the plain comparison predicate. SP can only conclude that $P_T \overset{C}{\mapsto} P_F$. The ordering information SP can learn from $\overline{p_C}$ is *partial* only because (i) SP does not know the ordering relationship between individual tuples in a partition; and (ii) SP cannot conclude which partition of P_T and P_F is actually larger.

Definition 4.2. (Partial order partitions of a relational table.) Let \overline{T} be a set of encrypted tuples. We define partial order partitions of \overline{T} , denoted as POP_k^C , as a set of k partitions $P_i \subset \overline{T}$ s.t. (i) $P_i \cap P_j = \emptyset$ for $i \neq j$; (ii) $\bigcup_{i=1}^k P_i = \overline{T}$; and (iii) $P_1 \overset{C}{\mapsto} P_2 \overset{C}{\mapsto} \dots \overset{C}{\mapsto} P_k$.

From a single encrypted predicate $\overline{p_C}$ in the above example, SP finds $\text{POP}_2^C : P_T \overset{C}{\mapsto} P_F$. With more encrypted predicates observed, SP can enhance its past result knowledge by extending POP_2^C . Before we discuss how SP extends its knowledge, we define two concepts related to a new encrypted predicate on existing partition order partitions POP_k^C for $k \geq 2$.

Definition 4.3. (Trapdoor equivalence.) Let $\overline{p_1}$ and $\overline{p_2}$ be two encrypted comparison predicates on the same attribute C of an encrypted table \overline{T} . Let $P_{ab} = \{\overline{t_i} \mid \overline{t_i} \in \overline{T} \text{ and } \Theta(\overline{p_a}, \overline{t_i}) = b\}$ for

Figure 2: Communication protocol of EDBMS between DO and SP

$a = 1$ or 2 , $b = 0$ or 1 . \bar{p}_1 is said to be *equivalent* to \bar{p}_2 if either (i) $P_{10} = P_{20}$ and $P_{11} = P_{21}$; or (ii) $P_{10} = P_{21}$ and $P_{11} = P_{20}$.

Definition 4.4. (Homogeneous partition & output-isomorphic partitions.) Given $POP_k^C : P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots \xrightarrow{C} P_k$ and an encrypted predicate \bar{p} on attribute C . A partition P_a is said to be *homogeneous* w.r.t. \bar{p} if $\forall \bar{t}_i, \bar{t}_j \in P_a, \Theta(\bar{p}, \bar{t}_i) = \Theta(\bar{p}, \bar{t}_j)$. P_a is said to be *T-homogeneous* (resp. *F-homogeneous*) w.r.t. \bar{p} if $\forall \bar{t}_i \in P_a, \Theta(\bar{p}, \bar{t}_i) = 1$ (0 resp.). Two partitions P_a, P_b are said to be *output-isomorphic* w.r.t. \bar{p} if either (i) both partitions are T-homogeneous or (ii) both partitions are F-homogeneous.

We explain the intuition of the above two definitions below. Two equivalent encrypted predicates divide the encrypted table \bar{T} into the same two partitions. All encrypted tuples in a homogeneous partition have the same QPF output. A homogeneous partition is further labeled T-homogeneous (or F-homogeneous) if the QPF output is 1 (or 0) for all encrypted tuples in the partition. A non-homogeneous partition contains tuples with mixed QPF outputs, i.e., some gives 1 and some gives 0. Two output-isomorphic partitions means that all encrypted tuples in the partitions have the same QPF output. Two encrypted predicates are equivalent if they divide the encrypted tuples into the same two partitions. Note that two equivalent encrypted predicates do not necessarily mean their plain comparison predicates are the same. For example, if two comparison predicates are ' $C < 9$ ' and ' $C > 8$ ' and there is no tuple with value 8-9, the two corresponding encrypted predicates give the same two partitions, i.e., they are equivalent. Since equivalent encrypted predicates give the same partitions, only inequivalent encrypted predicates provide different partitioning information which can enhance SP's knowledge.

Now, we consider what SP observes when there is a new encrypted predicate with an existing POP_k^C . We summarize the scenario in the following lemma.

LEMMA 4.5. Given $POP_k^C : P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots \xrightarrow{C} P_k$. Let \mathbb{P} be the set of encrypted predicates for deriving POP_k^C . Let \bar{p} be a new encrypted predicate on attribute C . The following two cases must hold.

Case 1: \bar{p} is equivalent to some encrypted predicate in \mathbb{P} if and only if there is a separating point s s.t. (i) all partitions P_i for $i = 1$ to s are output-isomorphic, (ii) all partitions P_j for $j = s + 1$ to k are output-isomorphic; and (iii) P_i and P_j are not output-isomorphic for $i = 1$ to s and $j = s + 1$ to k .

Case 2: \bar{p} is inequivalent to all encrypted predicates in \mathbb{P} if and only if there is a separating point s s.t. (i) all partitions P_i for $i = 1$ to $s - 1$ are output-isomorphic, (ii) all partitions P_j for $j = s + 1$ to

Figure 3: Example instance of Case 1 in Lemma 4.5.

Figure 4: Example instance of Case 2 in Lemma 4.5.

k are output-isomorphic; (iii) P_i and P_j are not output-isomorphic for $i = 1$ to $s - 1$ and $j = s + 1$ to k ; and (iv) P_s is non-homogeneous.

Fig. 3 and Fig. 4 show the examples of Case 1 and Case 2.

Now, SP obtain $POP_k^C : P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots \xrightarrow{C} P_k$, generated based on a set of encrypted predicates \mathbb{P} . Note that when SP is given a new encrypted predicate \bar{p}' , SP does not know whether \bar{p}' is equivalent to some encrypted predicate in \mathbb{P} . According to Lemma 4.5, SP observes a non-homogeneous partition only in case 2. Reversely, if SP observes a non-homogeneous partition, SP can conclude that \bar{p}' is inequivalent, i.e., \bar{p}' allows SP to extend POP_k^C .

Assume now SP receives a new inequivalent encrypted predicate \bar{p}' . Let P_s be the non-homogeneous partition in POP_k^C . Since P_s is non-homogeneous, SP can divide P_s into two smaller partitions based on the outputs of Θ :

$$P_{sT} = \{\bar{t}_i \mid \bar{t}_i \in P_s \mid \Theta(\bar{p}', \bar{t}_i) = 1\} \text{ and}$$

$$P_{sF} = \{\bar{t}_i \mid \bar{t}_i \in P_s \mid \Theta(\bar{p}', \bar{t}_i) = 0\}$$

For example, in Fig. 4, the encrypted predicate divides P_s into P_{sT} on the right and P_{sF} on the left. P_{sT} and P_{sF} are now homogeneous. Either one of them must be output-isomorphic to P_{s-1} and the other partition must be output-isomorphic to P_{s+1} . Without loss of generality, assume P_{sF} is output-isomorphic to P_{s-1} and P_{sT} is output-isomorphic to P_{s+1} (like the scenario in Fig. 4). SP can conclude that $P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots \xrightarrow{C} P_{s-1} \xrightarrow{C} P_{sF} \xrightarrow{C} P_{sT} \xrightarrow{C} P_{s+1} \xrightarrow{C} P_k$. As a result, SP extends POP_k^C to POP_{k+1}^C with one more inequivalent encrypted predicate. By mathematical induction, SP can compute POP_k^C with $k - 1$ inequivalent encrypted predicates.

The above discussion only shows that SP can observe POP_k^C with $k - 1$ inequivalent encrypted predicates. We will describe how SP can efficiently update POP_k^C to POP_{k+1}^C with an additional encrypted predicate in Sec. 5.3 after we discuss how we

make use of POP_k^C to optimize selection processing of comparison predicates. POP_k^C represents the knowledge extracted from past queries. Technically, PRKB contains only one item: POP_k^C . When SP decides to build PRKB on attribute C , the algorithm $initPRKB(\bar{T})$ initiates PRKB as POP_1^C where all encrypted tuples in \bar{T} reside in one big partition. As SP receives an inequivalent encrypted predicate, SP extends its PRKB from POP_k^C to POP_{k+1}^C .

5 SINGLE COMPARISON PREDICATE PROCESSING

In this section, we describe our method of SP processing comparison predicate using PRKB. As discussed in Sec. 4, PRKB contains one single item POP_k^C , which is a set of k partitions of encrypted tuples. Let P_i be a partition in POP_k^C for $i = 1$ to k s.t. $P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots \xrightarrow{C} P_k$. Let \bar{p} be an encrypted predicate SP receives from DO. From lemma 4.5, there is a *separating point* s such that it divides the partitions (except the non-homogeneous partition in Case 2) into two groups where all partitions in the same group are output-isomorphic to each other w.r.t. \bar{p} , i.e., Θ outputs the same for all encrypted tuples in all partitions within the same group. If SP knows the value of s , SP can determine the QPF outputs of all encrypted tuples in the above two groups with 2 QPF uses only. This can significantly save the computational cost at SP. However, SP does not know s in the beginning. So, the first task of SP in processing a comparison predicate is to find out the separating point s . This is done by the algorithm $QFilter$. $QFilter$ can narrow the possible candidates of s down to just two candidates, i.e., only two out of k partitions could be non-homogeneous. Since there are always two candidates of partitions, we call them *Not-sure pair (NS-pair)*. The QPF outputs of encrypted tuples in all the other $k - 2$ partitions can be determined right away. Then, the algorithm $QScan$ will scan every encrypted tuple in NS-Pair to confirm the value of s , with early stop strategy applied.

In the following, we first present how $QFilter$ helps SP find out the separating point efficiently in Sec. 5.1. Then, we present $QScan$ in Sec. 5.2. Finally, we discuss how SP updates PRKB from POP_k^C to POP_{k+1}^C efficiently in Sec. 5.3.

5.1 QFilter: searching for NS-Pair

Before we talk about the algorithm $QFilter$, we present the following lemma about searching for separating point s .

LEMMA 5.1. *Given partial order partitions POP_k^C of an encrypted table \bar{t} and an encrypted predicate \bar{p} on C . Let P_i be a partition in POP_k^C for $i = 1$ to k s.t. $P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots \xrightarrow{C} P_k$. Let s be the separating point mentioned in lemma 4.5. Let \bar{t}_x, \bar{t}_y be 2 encrypted tuples in P_a, P_b respectively s.t. $a < b$. We have if $\Theta(\bar{p}, \bar{t}_x) = \Theta(\bar{p}, \bar{t}_y)$, then $s \leq a$ or $s \geq b$.*

In the beginning, the separating point s may be any value from 1 to k . Lemma 5.1 helps to prune the candidates of s . There are two important observations from Lemma 5.1: (i) SP just needs to test on one sample encrypted tuple in P_a and P_b ; and (ii) Lemma 5.1 does not prune the case of $s = a$ and $s = b$.

Following observation (i), SP adopts a sampling strategy to make use of the pruning shown in lemma 5.1. In the rest of the paper, we use ' $P_i.sample$ ' to denote the random encrypted tuple drawn from a partition P_i . Then, in observation (ii), since the pruning always leave at least two candidates, SP cannot confirm

the actual separating point using only sampled encrypted tuples. The sampling technique will always reduce the number of candidates to exactly 2. Thus, we call the two partitions corresponding to these 2 candidates *Not-sure pair (NS-pair)*. After SP finds NS-Pair using the sampling technique, SP scans the two partitions and confirm the separating point using $QScan$.

Algorithm 1 shows the pseudo code of $QFilter$.

Algorithm 1: QFilter

```

Input : Encrypted table  $\bar{T}$ 
Input : PRKB  $\mathcal{I} = POP_k^C : P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots \xrightarrow{C} P_k$ 
Input : Encrypted predicate  $\bar{p}_i$ 
Output :  $\langle \bar{T}_W, \bar{T}_{NS} \rangle$ 
1  $label_1 = \Theta(\bar{p}_i, P_1.sample)$ ;
2  $label_k = \Theta(\bar{p}_i, P_k.sample)$ ;
3 if  $label_1 = label_k$  then
4   // boundary case
5   if  $label_1 = 1$  then
6      $\bar{T}_W = \bigcup_{j=2}^{k-1} P_j$ ;
7   else
8      $\bar{T}_W = \phi$ ; //  $\bar{T}_W$  is empty
9   end
10   $\bar{T}_{NS} = \langle P_1, P_k \rangle$ ;
11 else
12  // use binary search to locate NS-Pair
13   $a = 1$ ; // first partition (head)
14   $b = k$ ; // last partition (tail)
15  do
16     $m = \lfloor \frac{a+b}{2} \rfloor$ ;
17     $label_m = \Theta(\bar{p}_i, P_m.sample)$ ;
18    if  $label_a = label_m$  then
19       $a = m$ ;
20    else
21       $b = m$ ;
22    end
23  while  $b - a > 1$ ;
24   $\bar{T}_{NS} = \langle P_a, P_b \rangle$ ;
25  if  $label_1 = 1$  then
26     $\bar{T}_W = \bigcup_{j=1}^{a-1} P_j$ ;
27  else
28     $\bar{T}_W = \bigcup_{j=b+1}^k P_j$ ;
29  end
30 end
31 return  $\langle \bar{T}_W, \bar{T}_{NS} \rangle$ ;

```

SP starts the search by applying Θ on $P_1.sample$ and $P_k.sample$ (line 1-2). There are two possible scenarios.

Scenario (i): if $\Theta(\bar{p}_i, P_1.sample) = \Theta(\bar{p}_i, P_k.sample)$, we call this the boundary case (line 5-10). Following Lemma 5.1, $s \leq 1$ or $s \geq k$, i.e., $s = 1$ or $s = k$. In this scenario, $\langle P_1, P_k \rangle$ is the NS-Pair returned by this phase (line 10). Any two partitions P_u and P_v for $u, v = 2$ to $k - 1$ must be output-isomorphic and have the same QPF output as the samples of P_1 and P_k . The Winner group \bar{T}_W can be found accordingly (line 5-8).

Scenario (ii): if $\Theta(\bar{p}_i, P_1.sample) \neq \Theta(\bar{p}_i, P_k.sample)$, we call this the recursive case (line 13-28). SP uses binary search to locate NS-Pair. SP applies Θ to the sample in the middle partition

$P_m.sample$ where $m = \lfloor \frac{1+k}{2} \rfloor$. If $\Theta(\overline{p}_i, P_1.sample) = \Theta(\overline{p}_i, P_m.sample)$, following lemma 5.1, $s \leq 1$ or $s \geq m$. If $s = 1$, all partitions P_i for $i > 1$ should be output-isomorphic to each other. Since $\Theta(\overline{p}_i, P_m.sample) \neq \sigma(P_k.sample)$, s cannot be 1. Thus, s must lie in $[m, k]$. SP recursively repeats the above procedure to find the separating point s in $[m, k]$. The search ends when there are two candidates left, x and $x + 1$. $\langle P_x, P_{x+1} \rangle$ is the NS-Pair returned. The rest of the partitions can be divided into two groups: the first group is P_1 to P_{x-1} and the second group is P_{x+1} to P_k . Any two partitions in the same group must be output-isomorphic and partitions in either one of the groups must be T-homogeneous. By looking at the QPF output of a sample encrypted tuple from the two groups, the Winner group \overline{T}_W can be set (line 25-28).

5.2 QScan: finding exact selection result

Let $\langle P_a, P_b \rangle$ be the NS-Pair SP obtained from *QFilter*. Encrypted tuples in these two partitions are tested using QPF Θ to see which one is actual answer in the selection result. Note that there are two cases in lemma 4.5. Case 1: \overline{p}_i is equivalent to an encrypted predicate in \mathbb{P} ; or Case 2: \overline{p}_i is inequivalent to all encrypted predicates in \mathbb{P} . The difference between the two cases is that the separating partition in Case 2 is non-homogeneous while all partitions are homogeneous in Case 1. SP can make use of the above difference and adopts an early stop strategy: SP first applies Θ on every encrypted tuples in P_a . If P_a is found to be non-homogeneous, it must be Case 2 and $s = a$. SP does not need to apply Θ on any encrypted tuples in P_b . In the other case where P_a is found to be homogeneous, SP continues to apply Θ on every encrypted tuples in P_b . If P_b is non-homogeneous, it is Case 2 and $s = b$. Otherwise, it is Case 1. In either case, *QScan* finds the set of encrypted tuples $\overline{T}_{WNS} \subseteq P_a \cup P_b$ that satisfy the predicate, i.e.,

$$\overline{T}_{WNS} = \{\overline{t}_j \mid \overline{t}_j \in P_a \cup P_b \text{ and } \Theta(\overline{p}_i, \overline{t}_j) = 1\}$$

Algorithm 2 shows the pseudo code of *QScan*.

Algorithm 2: QScan

Input : $\overline{T}_{NS} = \langle P_a, P_b \rangle$ where $a < b$
Input : PRKB $\mathcal{I} = POP_k^C : P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots \xrightarrow{C} P_k$
Input : Encrypted predicate \overline{p}_i
Output: $\overline{T}_{WNS} = \{\overline{t}_j \mid \overline{t}_j \in P_a \cup P_b \text{ and } \Theta(\overline{p}_i, \overline{t}_j) = 1\}$

- 1 // First scan P_a
- 2 $P_{a_T} = \{\overline{t}_j \mid \overline{t}_j \in P_a \text{ and } \Theta(\overline{p}_i, \overline{t}_j) = 1\}$; $P_{a_F} = P_a - P_{a_T}$;
- 3 $\overline{T}_{WNS} = P_{a_T}$;
- 4 **if** $P_{a_T} = \emptyset$ **or** $P_{a_F} = \emptyset$ **then**
- 5 // P_a is homogeneous, SP scans P_b as well
- 6 $P_{b_T} = \{\overline{t}_j \mid \overline{t}_j \in P_b \text{ and } \Theta(\overline{p}_i, \overline{t}_j) = 1\}$; $P_{b_F} = P_b - P_{b_T}$;
- 7 $\overline{T}_{WNS} = \overline{T}_{WNS} \cup P_{b_T}$;
- 8 **else**
- 9 // P_a is non-homogeneous, early stop is applied
- 10 **if** $label_b = 1$; // $label_b$ is found in *QFilter*
- 11 **then**
- 12 | $\overline{T}_{WNS} = \overline{T}_{WNS} \cup P_b$; // P_b is T-homogeneous
- 13 **end**
- 14 **end**
- 15 **return** \overline{T}_{WNS}

The complexity of the entire selection processing is $O(\frac{n}{k} + \lg n)$ where n is number of encrypted tuples in \overline{T} and k is number of partitions in PRKB.

5.3 updatePRKB: update procedure of PRKB

Recall that only inequivalent encrypted predicate can help SP to extend PRKB (see Sec. 4). During the execution of *QScan*, SP already knows whether the new encrypted predicate \overline{p}_i is equivalent to some encrypted predicate in \mathbb{P} , which generates SP's current PRKB, POP_k^C . Only when either P_a or P_b is non-homogeneous (found in *QScan*), \overline{p}_i is inequivalent (see Lemma 4.5). In such case, *QScan* (line 2 or line 6) has divided an existing partition P_s into two smaller partitions P_{s_T} and P_{s_F} where $s = a$ (line 2) or b (line 6). Without further QPF uses, SP can easily update POP_k^C to POP_{k+1}^C by replacing P_s with P_{s_T} and P_{s_F} in POP_k^C . The order of P_{s_T} and P_{s_F} in POP_{k+1}^C is determined by whether P_{s-1} is T-homogeneous or F-homogeneous. Like Fig. 4, if P_{s-1} is F-homogeneous, we have $POP_{k+1}^C : P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots P_{s-1} \xrightarrow{C} P_{s_F} \xrightarrow{C} P_{s_T} \xrightarrow{C} P_{s+1} \xrightarrow{C} \dots \xrightarrow{C} P_k$.

updatePRKB is efficient since it does not require additional QPF uses.

6 MULTI-DIMENSIONAL RANGE QUERY

In this section, we will introduce the method to optimize processing of a d -dimensional range query for $d \geq 2$. We address the most common form of d -dimensional range: the query is to retrieve all encrypted tuples with plain values falling into a d -dimensional hyper-rectangle defined by DO. The query can be described in SQL in the following form: SELECT * FROM R WHERE $c_{1a} < C_1 < c_{1b}$ AND $c_{2a} < C_2 < c_{2b}$ AND ... AND $c_{da} < C_d < c_{db}$, where C_i is an attribute in the relational table R and $c_{ia} < c_{ib}$ are query parameters defined by DO for $i = 1$ to d .

Recall that SP is not able to see the plain query parameters and the plain values of encrypted tuples. In EDBMS, the d -dimensional range query is processed as $2d$ comparison predicates (two comparisons for each dimension: $c_{ia} < C_i$ and $C_i < c_{ib}$). DO generates and gives $2d$ encrypted predicates to SP for processing the query. In existing EDBMS, SP has to apply up to $2d$ encrypted predicates on all tuples⁵, i.e., the total number of QPF uses can be $2dn$ where n is number of encrypted tuples in \overline{T} . A better alternative now is to use the single comparison predicate processing technique in Sec. 5. SP finds out the satisfying tuples of each comparison predicate. Then, SP intersects the set of satisfying tuples to find out the final selection result. Number of QPF uses can be greatly reduced compared to existing processing mechanism of EDBMS. This is our baseline method for processing multi-dimensional range query. In this section, we will describe our solution for multi-dimensional range query that is more efficient than the baseline method. In our discussion below, we will focus on 2D case for easier illustration.

6.1 Visualization of partitions on a grid

For a 2D range query, two attributes, say X and Y , are concerned. SP has maintained two partial order partitions, say $POP_{k_x}^X$ and $POP_{k_y}^Y$ of the encrypted table \overline{T} . $POP_{k_x}^X$ and $POP_{k_y}^Y$ are two partitioning ways of \overline{T} , i.e., every encrypted tuple \overline{t} in \overline{T} will be located in one and only one partition of $POP_{k_x}^X$ and one and

⁵EDBMS can stop processing for a tuple when one of the predicates is not satisfied. Actual number of QPF uses varies.

Figure 5: Visualization of the grid in 2D space

Figure 6: Illustration of partitions scanned in processing 2D range query by different methods. Encrypted tuples in the central T-region must be part of answer set.

only one partition in $POP_{k_y}^Y$. Let P_i^X be a partition in $POP_{k_x}^X$ for $i = 1$ to k_x and P_j^Y be a partition in $POP_{k_y}^Y$ for $j = 1$ to k_y . Let $G_{i,j} = P_i^X \cap P_j^Y$. We prepare a $k_x \times k_y$ grid. $G_{i,j}$ is represented as a cell at location (i, j) in the grid. Each encrypted tuple falls into one and only one grid cell $G_{i,j}$ for some i, j . The grid then represents the visualization of partitions of encrypted tuples in the 2D space. Fig. 5 shows the generated 2D grid. We remark that SP does not know the plain values of boundaries of partitions or the plain values of encrypted tuples in $G_{i,j}$, and the complete grid is not actually computed in query processing.

Now, we use the grid to visualize the processing mechanism of existing methods and identify redundancy in them. A linear scan on all encrypted tuples is equivalent to scanning all the grid cells. A better baseline solution using our single comparison predicate processing method can narrow the search on each dimension to just NS-Pairs. Only the partitions of NS-Pairs require full scan on all encrypted tuples, thus saving a significant amount of QPF uses by SP. For a 2-dimensional range query, there are two comparison predicates on each dimension. Thus, we have 4 NS-Pairs, two on each dimension to be scanned. Fig. 6a shows the illustration of scanning only the NS-Pairs in the grid. Scanning for each NS-Pair is done independently and thus a full column or row in the grid is scanned. In multi-dimensional range query, an encrypted tuple has to satisfy the comparison predicates in all dimensions. In the process of finding NS-Pairs, some of the partitions are also known to be F-homogeneous. For example, in Fig. 6a, there are 2 NS-Pairs on X. Let (P_a^X, P_{a+1}^X) and (P_b^X, P_{b+1}^X) be these two NS-Pairs, where $a < b$. Partitions from P_1^X to P_{a-1}^X must be F-homogeneous. Thus, $G_{i,j}$ for $i = 1$ to $a-1$ are not necessary to be scanned and SP can safely conclude that all encrypted tuples in these cells will not be part of the result set. Similarly, SP can apply the same pruning in other dimensions. The remaining partitions to be scanned is shown in Fig. 6b. Number of QPF uses of SP is thus reduced.

Figure 7: SP tests different encrypted predicates on encrypted tuples in different regions. NS-Pair X1, X2, Y1 and Y2 are generated according to encrypted predicates $\overline{p_{X1}}$, $\overline{p_{X2}}$, $\overline{p_{Y1}}$ and $\overline{p_{Y2}}$ respectively

6.2 Systematic scanning procedure for multi-dimensional range query

In this section, we present how SP can systematically and efficiently perform the scan. There are two major issues we need to address to achieve efficiency.

First, note that SP does not test all the encrypted predicates on the encrypted tuples in the area shown in Fig. 6b. Recall that there are $2d$ encrypted predicates where d is the number of dimension of the query. Each encrypted predicate gives an NS-Pair. Let \overline{p} be the encrypted predicate giving the NS-Pair (P_a, P_b) . Only grid cells that are computed by intersecting P_a or P_b with other partitions require testing by \overline{p} . For example, Fig. 7 shows the encrypted predicates needed for different cells in Fig. 6b.

Second, as we presented in Sec. 5.2, an early stop strategy can be used to further reduce the number of QPF uses by SP in comparison predicate processing. SP can use the same strategy in processing multi-dimensional range query as well. Each dimension has two comparison predicates resulting in two NS-Pairs. Let (P_a, P_{a+1}) and (P_b, P_{b+1}) be the two NS-Pairs, where $a < b$. We call P_{a+1} and P_b the *inner NS-partition*; and P_a and P_{b+1} the *outer NS-partition*. If SP first scans the outer NS-partition and finds that it is non-homogeneous, SP can further conclude that the inner NS-partition is T-homogeneous. On the other hand, if SP scans the inner NS-partition first and finds out that it is non-homogeneous, SP can conclude that the outer NS-partition of the same NS-Pair is F-homogeneous. Besides, once an encrypted tuple is found to have QPF output 0 for an encrypted predicate, it can never be in the selection result. SP does not need to test other encrypted predicates on this encrypted tuple.

In summary, the procedure to process multi-dimensional range query is done by the following steps:

- (1) Use *QFilter* to find the NS-Pair for each encrypted predicate.
- (2) Compute the required grid cells, e.g., in Fig. 6b, by intersecting the partitions in different $POP_{k_i}^{C_i}$ for different attributes C_i .
- (3) Test encrypted predicates using QPF on encrypted tuples in different regions of the grid, e.g., according to Fig. 7, and apply early stop strategy when possible. (Details are described above in this section.)
- (4) Return as selection result those encrypted tuples with QPF output 1 for all encrypted predicates in step (3) and the encrypted tuples in the central T-region, e.g., in Fig. 6b.

The entire process takes $O(d(\frac{n\alpha^{d-1}}{k} + \lg k))$ where n is number of encrypted tuples in \overline{T} , k is number of partitions in PRKB, d is

number of dimensions of the query and α is the selectivity on each dimension. Assume α remains the same, the query cost decreases as d increases. Our selection processing technique for multi-dimensional range query is scalable to number of dimensions.

7 DATABASE UPDATE HANDLING

The selection processing techniques we presented in Sec. 5 and Sec. 6 are designed for a static database where the contents of encrypted tuples do not change. In this section, we discuss how we can support update operations in a database.

There are 3 kinds of update operations in SQL: (1) INSERT statements; (2) DELETE statements; and (3) UPDATE statements. UPDATE statements can be considered as insertion of a new tuple after deletion of an existing tuple. We just need to cater for insertion and deletion.

7.1 Insertion Handling

When there is a new encrypted tuple to be inserted to EDBMS, SP needs to update PRKB, POP_k^C , to assign the new encrypted tuple to the correct partition. To facilitate the update, SP needs to remember the set of past $k - 1$ encrypted predicates \mathbb{P} that generates POP_k^C . SP can order the encrypted predicates in \mathbb{P} according to $POP_k^C: P_1 \xrightarrow{C} P_2 \xrightarrow{C} \dots \xrightarrow{C} P_k$ because the encrypted predicates are the separators that form the partitions. Let \bar{p}_x be the encrypted predicate s.t. partitions P_i for $i = 1$ to x are output-isomorphic and partitions P_j for $j = x + 1$ to k are output-isomorphic but P_i and P_j are not output-isomorphic, e.g., the encrypted predicate in Fig. 3 is refereed as \bar{p}_3 . A binary search can be used by SP to find out the partition the new encrypted tuple belongs to: SP first uses the encrypted predicate in the middle \bar{p}_m , where $m = \lfloor \frac{k}{2} \rfloor$, to determine whether the encrypted tuple belongs to the first half or the second half of POP_k^C ; then recursively reduces the list by half until only one partition remains and this partition is where the new encrypted tuple belongs to.

It takes $O(\lg k)$ time to update PRKB for the new encrypted tuple. Let β be number of attributes with indexing. The total update cost is then $O(\beta \lg k)$.

7.2 Deletion Handling

Deletion handling is easy as SP simply removes the corresponding encrypted tuple from the corresponding partitions. When there is no tuple remained in a partition of POP_k^C , the partition is removed from POP_k^C , i.e., the knowledge of partial order partitions becomes POP_{k-1}^C .

8 EMPIRICAL STUDIES

There are two purposes in our experiments. First, as we mentioned in Sec. 3.3, SP can observe partial order information in existing EDBMS (even without implementing PRKB). We want to evaluate whether existing EDBMS model is acceptable in practice. Second, we empirically evaluate the performance of our indexing method, PRKB.

The experiment settings and its result for the first purpose is presented in Sec. 8.1. Information of experiments for the second purpose is presented in Sec. 8.2.

		Number of queries				
Victims	Size	250	1K	10K	100K	1M
Hospital	2,426,516	0.007	0.020	0.115	0.605	2.846
Labor	6,156,470	0.042	0.117	0.484	1.673	5.807
Latitude	1,122,932	0.008	0.025	0.212	1.650	11.167
Longitude	1,122,932	0.011	0.038	0.331	2.440	13.592

Table 2: Recovered portion of ordering information (RPOI) (%) on real datasets varying number of queries observed by attacker

8.1 Experiment on security of EDBMS model revealing selection result

As discussed in Sec. 3.3, we want to see how much partial order information can be derived by SP/attacker in existing EDBMS model in practice. To quantify how close the recovered partial order is to total order, we define *recovered portion of ordering information* (RPOI) as $\frac{\text{Recovered partial order length}}{\text{Total order length}}$. (Partial order length is the size of the longest chain, e.g., the length of total order is n for a dataset of n distinct numbers.)

We follow the scenario used in [24] to perform the experiment. SP is able to receive certain number of queries, randomly generated by DO. Unlike [24], SP in our case receives limited number of queries only and we pick attributes with large domain sizes as victims. Each query has has one encrypted predicate. We vary number of queries from 250 to 1M and measure RPOI in these cases. We tested on 4 victim attributes from 3 different real datasets:

- (1) **Hospital Charges:** Hospital Inpatient Discharges 2013 dataset⁶
- (2) **Labor Salary:** US Labor Statistic 2017⁷
- (3) **Latitude:** US Buildings dataset⁸
- (4) **Longitude:** US Buildings dataset

The result is presented in Table 2.

The result shows that the partial order information observed by SP is still far from complete as the total order. RPOI increases at decreasing speed as SP observes more queries. It is because it gets harder for SP to observe a useful query to enhance the partial order knowledge. According to Quantcast⁹, it could take weeks for a top-1000 website to get a million of traffic, which is still far away from recovering the total order in an attack attempt. We consider our current model of EDBMS revealing selection result as practically secure for large domain data. In contrast, if OPE is used, e.g., in CryptDB [29], RPOI is 100% even SP has not yet processed any query.

8.2 Performance evaluation of PRKB

8.2.1 Algorithm implementation. We separately evaluate single-dimensional (SD) query and multi-dimensional (MD) range query. Note that there are different processing techniques in using PRKB. To differentiate them, we use (i) ‘PRKB(SD)’ to denote the processing method for single-dimensional query (Sec. 5), (ii) ‘PRKB(SD+)’ to denote the naive extension of PRKB(SD) for multi-dimensional range query (see Sec. 6), and (iii) ‘PRKB(MD)’ to denote the algorithm designed for multi-dimensional range query (see Sec. 6.2).

⁶<https://health.data.ny.gov/>

⁷<https://catalog.data.gov/>

⁸<http://www.geonames.org/>

⁹<https://www.quantcast.com/top-sites>

As a competitor, we implemented the indexing method ‘Logarithmic-SRC-i’ in [12]. Note that Logarithmic-SRC-i may return false positives to DO. DO needs to decrypt them to confirm whether they are actual answer in the selection result. This may require a significant amount of DO’s involvement to process the query. In our implementation, we deployed a trusted machine (TM), like Cipherbase [2], to perform this confirmation process on behalf of DO. In PRKB, we use the same confirmation process as QPF, i.e., SP sends the encrypted data to TM; TM decrypts and returns the QPF output of the encrypted tuple. Besides, Logarithmic-SRC-i is an encrypted index computed and maintained by DO. This is also done by TM in our implementation. In our experiment, both TM and SP equip with a machine with the same power. We also compare with the case where no indexing is used, denoted as Baseline.

PRKB replies on past queries to operate effectively. In all experiments, number of queries is limited to small values (at most 600) so as to show that PRKB is effective even without a lot of past result knowledge.

All algorithms were implemented in C/C++. All machines in the experiment equip with 2GHz CPU and 4GB RAM running Linux platform.

8.2.2 Datasets and Tests. We performed our experiments on both synthetic and real datasets. We performed most of the experiments on synthetic datasets to evaluate the performance varying different parameters, e.g., number of tuples and selectivity. In the synthetic datasets, the data domain of all attributes is set to be integers in $[1, 30M]$. The plain value on each attribute of each tuple is randomly generated¹⁰.

We simulated a use case on a real dataset. The US buildings dataset contains 1,122,932 records about information of buildings in US, including location (latitude and longitude). A tourist (user) is interested to know what buildings are around the location he will visit. The user issues a range query to retrieve all buildings within a $1km \times 1km$ region in the dataset, i.e., it is a 2D range query.

We measure the average number of QPF uses¹¹ (# QPF use) and average execution time out of 20 runs for each experiment.

8.2.3 Experiment on Building PRKB. This experiment simulates SP building PRKB from scratch on a synthetic dataset with 10M tuples. We assume SP receives 600 distinct queries, each with one comparison predicate, and we monitor the performance of query processing cost. For reference, the performance of Baseline and Logarithmic-SRC-i is also shown. Fig. 8 shows the result of query cost and Table 3 shows the space consumption of PRKB.

We make the following observations from the result:

- (1) In the beginning, PRKB has no knowledge. Query processing is as slow as Baseline. However, when SP receives queries, the cost drops fast. At 50-th query, the cost has already dropped by an order of magnitude and PRKB has almost the same performance as Logarithmic-SRC-i. At 600-th query, the query time of PRKB is one order of magnitude smaller than Logarithmic-SRC-i. It shows that PRKB is practical, reducing the query processing cost significantly with a small amount of past result knowledge.

¹⁰We have tested on data generated with different distributions, including uniform, normal, correlated and anti-correlated. The results are similar and so we just present the results for uniform distribution in this paper.

¹¹Since majority of actions in Logarithmic-SRC-i are related to its index structure, we do not show # QPF use for Logarithmic-SRC-i.

Figure 8: Performance of Query with growing PRKB on 10M tuples (1% Selectivity)

Method	Dataset size (in millions)					
	10	12	14	16	18	20
PRKB-250	38.2	45.8	53.4	61.0	68.7	76.3
PRKB-600	38.2	45.9	53.5	61.1	68.8	76.4
Logarithmic-SRC-i	3589	4050	4493	4918	6356	6758

Table 3: Storage size of the index (in MB)

Figure 9: Performance on single-dimensional query varying dataset size (1% selectivity)

- (2) PRKB occupies a small space, as PRKB is simply partition information of encrypted tuples. There is a slight increase in space consumption (from 76.3MB to 76.4MB for 20M dataset) of PRKB. It is because SP needs to keep more encrypted predicates to handle database update (see Sec. 7). The increase in space consumption is negligible. Logarithmic-SRC-i requires much more space due to its more complex index structure.
- (3) The query processing cost is consistent with number of QPF uses. This shows that QPF computation is the dominant cost in EDBMS. Reducing number of QPF uses can help to reduce the overall query cost.

8.2.4 Experiment for Single-dimensional Query. We tested the performance of algorithms in handling a single-dimensional query under different settings. The query is in the form of “SELECT * FROM Dataset WHERE $lb < X < ub$ ”. X is an attribute on synthetic dataset. lb and ub are two parameters generated randomly according to selectivity. We use a static PRKB with 250 partitions for the experiment. There are 2 parameters in the experiment: (i) dataset size, varying from 10M to 20M tuples; (ii) selectivity, varying from 1% to 10%.

Fig. 9 and Fig. 10 show the results of experiments in varying dataset size and selectivity respectively.

We make the following observations from the results.

- (1) All algorithms scale well with increasing number of tuples. Cost reduction of PRKB(SD) over Baseline and Logarithmic-SRC-i is consistent, at about two orders of magnitude and a factor of 4, respectively.
- (2) PRKB(SD) shows a steady performance no matter how selectivity increases. It is because PRKB simply requires SP to examine two NS-Pairs defining the boundary of the

Figure 10: Performance on single-dimensional query varying selectivity (dataset of 10M tuples)

Figure 11: Performance on multi-dimensional query varying dataset size (Dimensionality of 3, 2% selectivity per dimension)

Figure 12: Performance on multi-dimensional query varying dimensionality (Dataset of 5M tuples, 2% selectivity per dimension)

answer set. All encrypted tuples in partitions between the two NS-Pairs can be returned as answer without applying QPF on them. The cost of PRKB is independent to size of answer set.

8.2.5 Experiment for Multi-dimensional Range Query. In this experiment, we study the difference in performance between PRKB(SD+), PRKB(MD) and Logarithmic-SRC-i under different settings to validate the importance of our optimization method for handling multi-dimensional range query. The range query tested is in the form of “SELECT * FROM Dataset WHERE $lb_1 < X_1 < ub_1$ AND ... AND $lb_d < X_d < ub_d$ ”. X_i is an attribute in the synthetic dataset. lb_i and ub_i are generated randomly according to selectivity (per dimension), which is set to be 2%. Both algorithms use a static PRKB with 250 partitions. There are 2 parameters in the experiment: (i) dimensionality d , varying from 2 to 6, and (ii) dataset size, varying from 1M to 10M tuples.

Figure 11 and 12 show the results. Improvement of PRKB(MD) over PRKB(SD+) and Logarithmic-SRC-i is consistent with increasing dataset size. The cost of PRKB(SD+) increases as number of dimensions increases because PRKB(SD+) processes each dimension separately. However, number of results actually decreases with more comparison predicates. Logarithmic-SRC-i sent a set of hashed values for keyword search for each dimensions. The cost of Logarithmic-SRC-i is getting closer to PRKB(SD+) in Figure 12. PRKB(MD), on the other hand, can make use of the fact that more comparison predicates filter more candidate tuples. Thus, the cost of PRKB(MD) decreases with

Figure 13: Performance of Query with growing PRKB on US buildings dataset (2% selectivity)

Method	Batch				
	1	2	3	4	5
PRKB	32,356	32,104	32,117	32,167	32,168
Logarithmic-SRC-i	2,936	2,967	2,967	2,935	2,937

Table 4: Average throughput (Tuples / Second) of inserting 5 batches (each with 2M tuples) of data to PRKB with 10M tuples

increasing number of dimensions. PRKB(MD) can perform well even for higher dimensional range queries.

8.2.6 Experiment on Real Dataset. We tested PRKB and Logarithmic-SRC-i in a simulated use case (described in Sec. 8.2.2) on real dataset to validate its practicality.

In this dataset, the space consumed by PRKB is less than 1% of the size of encrypted dataset ($\frac{8.81MB}{1.04GB}$) while Logarithmic-SRC-i consumed more than 43% space ($\frac{441.346MB}{1.04GB}$).

Similar to the experiments on synthetic datasets, the query processing time is high in the beginning. Initially, the query time of Logarithmic-SRC-i is smaller than that of PRKB. After answering 50 queries, the query time of PRKB is already below 100ms and performs better than Logarithmic-SRC-i. After answering 600 queries, the query time of PRKB is further reduced to 9ms. In contrast, if EBDMS does not use any index, it takes 15.9s to process a query, which is impractical in reality. Besides, if DO wants to avoid the poor performance of EBDMS using PRKB in the beginning, DO can arbitrarily generates queries (as few as 50 queries in this case) to help SP to build an initiate PRKB.

8.2.7 Experiment for Handling Database Update. In this experiment, we evaluate the cost of SP updating PRKB in handling database update. Since deletion is simple, we only show the results for insertion here. PRKB has 250 partitions. The experiment is done on a synthetic dataset with 10M tuples. We inserted 5 batches, each with 2M new tuples, to the database, i.e., the database contains 20M tuples in the end. We measure the average throughput (number of tuples inserted per second) achieved by PRKB in each batch. For comparison, we measure the throughput of Logarithmic-SRC-i in the same setting. Table 4 shows the result.

The throughput of PRKB remains almost the same. The observation can be explained in our analysis in Sec. 7.1, as the update cost is independent to database size. SP can easily bear the update cost to maintain PRKB for optimizing query processing.

9 CONCLUSIONS AND FUTURE WORK

In this paper, we proposed a novel indexing method - past result knowledge base (PRKB) for EDBMS. Unlike traditional indexing problem for encrypted data, PRKB is built solely by SP based on results of past queries. None of existing indexing methods work without DO’s involvement or customized encryption method.

We showed that PRKB is effective in reducing the processing cost of new queries. Our experiments showed that PRKB consistently outperforms a state-of-the-art competitor in [12] and PRKB achieves a speed-up of at least an order of magnitude compared to EDBMS without implementing PRKB. Since SP is just making use the information that is already available to SP to build PRKB, security of PRKB is ensured. In the future, we plan to extend PRKB to incorporate different query result and to support more query types. The partial order information in PRKB can also be used in optimizing queries like Min, Max or Skyline queries.

A SUPPORTING BETWEEN OPERATOR

Some methods, e.g., [12], support specifically BETWEEN operator. BETWEEN operator returns the overall result of whether the encrypted tuple falls into the range instead of two results of two comparisons, i.e., SP observes less information for BETWEEN. In fact, as we will show below, BETWEEN is equivalent to two separate comparisons, w.r.t. building PRKB, in most cases.

Say SP has $POP_5^C : P_1 \xrightarrow{C} P_2 \xrightarrow{C} P_3 \xrightarrow{C} P_4 \xrightarrow{C} P_5$. Let \bar{p} be an encrypted predicate that computes 'X BETWEEN a and b'. We can derive a similar observation like lemma 4.5 that, in general, Θ returns 1 for encrypted tuples in partitions in the middle and 0 for encrypted tuples in partitions in the two ends. Say (i) P_3 is T-homogeneous, (ii) P_1, P_5 are F-homogenous, and (iii) P_2 and P_4 are non-homogeneous. Each of P_2 and P_4 is divided into two partitions and we have P_{2T}, P_{2F}, P_{4T} , and P_{4F} where P_{iT} (P_{iF} resp.) denotes the set of tuples in P_i that get 1 (0 resp.) from Θ . SP obtains $POP_7^C : P_1 \xrightarrow{C} P_{2F} \xrightarrow{C} P_{2T} \xrightarrow{C} P_3 \xrightarrow{C} P_{4T} \xrightarrow{C} P_{4F} \xrightarrow{C} P_5$. SP obtains the same POP_7^C as if SP obtains two encrypted predicates for ' $X \geq a$ ' and ' $X \leq b$ '. The BETWEEN predicate reveals the same partial order information to SP as two separate comparison predicates in this scenario.

Only when the range in the BETWEEN operator is very small such that only some encrypted tuples in one partition get 1 from Θ , SP cannot determine the order information of other tuples in this partition.

Computing a BETWEEN operator using PRKB is similar to comparison handling. SP looks for two separating points using the samples of partitions, like *QFilter*. When a sample encrypted tuple with QPF output 1 is found, two binary searches are performed to find two NS-pairs, each containing a separating point on the two ends of the range of BETWEEN predicate. The process after that is the same as comparison handling. However, when no sample with QPF output 1 is found, SP cannot conclude whether other tuples will return 1 or 0 from QPF due to the existence of the above exceptional case. SP needs to draw more samples from partitions. The worst case is that SP finds that there is no satisfying tuple after scanning all encrypted tuples.

ABSTRACT

To maintain the accuracy of supervised learning models in the presence of evolving data streams, we provide temporally-biased sampling schemes that weight recent data most heavily, with inclusion probabilities for a given data item decaying exponentially over time. We then periodically retrain the models on the current sample. This approach speeds up the training process relative to training on all of the data. Moreover, time-biasing lets the models adapt to recent changes in the data while—unlike in a sliding-window approach—still keeping some old data to ensure robustness in the face of temporary fluctuations and periodicities in the data values. In addition, the sampling-based approach allows existing analytic algorithms for static data to be applied to dynamic streaming data essentially without change. We provide and analyze both a simple sampling scheme (T-TBS) that probabilistically maintains a target sample size and a novel reservoir-based scheme (R-TBS) that is the first to provide both complete control over the decay rate and a guaranteed upper bound on the sample size, while maximizing both expected sample size and sample-size stability. The latter scheme rests on the notion of a “fractional sample” and, unlike T-TBS, allows for data arrival rates that are unknown and time varying. R-TBS and T-TBS are of independent interest, extending the known set of unequal-probability sampling schemes. We discuss distributed implementation strategies; experiments in Spark illuminate the performance and scalability of the algorithms, and show that our approach can increase machine learning robustness in the face of evolving data.

1 INTRODUCTION

A key challenge for machine learning (ML) is to keep ML models from becoming stale in the presence of evolving data. In the context of the emerging Internet of Things (IoT), for example, the data comprises dynamically changing sensor streams [26], and a failure to adapt to changing data can lead to a loss of predictive power.

One way to deal with this problem is to re-engineer existing static supervised learning algorithms to become adaptive. Some parametric algorithms such as SVM can indeed be re-engineered so that the parameters are time-varying, but for non-parametric algorithms such as kNN-based classification, it is not at all clear how re-engineering can be accomplished. We therefore consider alternative approaches in which we periodically retrain ML models, allowing static ML algorithms to be used in dynamic settings essentially as-is. There are several possible retraining approaches.

Retraining on cumulative data: Periodically retraining a model on all of the data that has arrived so far is clearly infeasible because of the huge volume of data involved. Moreover, recent

data is swamped by the massive amount of past data, so the retrained model is not sufficiently adaptive.

Sliding windows: A simple sliding-window approach would be to, e.g., periodically retrain on the data from the last two hours. If the data arrival rate is high and there is no bound on memory, then one must deal with long retraining times caused by large amounts of data in the window. The simplest way to bound the window size is to retain the last n items. Alternatively, one could try to subsample within the time-based window [14]. The fundamental problem with all of these bounding approaches is that old data is completely forgotten; the problem is especially severe when the data arrival rate is high. This can undermine the robustness of an ML model in situations where old patterns can reassert themselves. For example, a singular event such as a holiday, stock market drop, or terrorist attack can temporarily disrupt normal data patterns, which will reestablish themselves once the effect of the event dies down. Periodic data patterns can lead to the same phenomenon. Another example, from [27], concerns influencers on Twitter: a prolific tweeter might temporarily stop tweeting due to travel, illness, or some other reason, and hence be completely forgotten in a sliding-window approach. Indeed, in real-world Twitter data, almost a quarter of top influencers were of this type, and were missed by a sliding window approach.

Temporally biased sampling: An appealing alternative is a temporally biased sampling-based approach, i.e., maintaining a sample that heavily emphasizes recent data but also contains a small amount of older data, and periodically retraining a model on the sample. By using a time-biased sample, the retraining costs can be held to an acceptable level while not sacrificing robustness in the presence of recurrent patterns. This approach was proposed in [27] in the setting of graph analysis algorithms, and has recently been adopted in the MacroBase system [3]. The orthogonal problem of choosing when to retrain a model is also an important question, and is related to, e.g., the literature on “concept drift” [13]; in this paper we focus on the problem of how to efficiently maintain a time-biased sample.

In more detail, our time-biased sampling algorithms ensure that the “appearance probability” for a given data item—i.e., the probability that the item appears in the current sample—decays over time at a controlled exponential rate. Specifically, we assume that items arrive in batches (see the next section for more details), and our goal is to ensure that (i) our sample is representative in that all items in a given batch are equally likely to be in the sample, and (ii) if items i and j belong to batches that have arrived at (wall clock) times t' and t'' with $t' \leq t''$, then for any time $t \geq t''$ our sample S_t is such that

$$\Pr[i \in S_t] / \Pr[j \in S_t] = e^{-\lambda(t''-t')}. \quad (1)$$

Thus items with a given timestamp are sampled uniformly, and items with different timestamps are handled in a carefully controlled manner. The criterion in (1) is natural and appealing in applications and, importantly, is interpretable and understandable to users. As discussed in [27], the value of the decay rate λ can be chosen to meet application-specific criteria. For example, by setting $\lambda = 0.058$, around 10% of the data items from 40 batches

*Work performed at IBM Research – Almaden

ago are included in the current analysis. As another example, suppose that, $k = 150$ batches ago, an entity such as a person or city was represented by $n = 1000$ data items and we want to ensure that, with probability $q = 0.01$, at least one of these data items remains in the current sample. Then we would set $\lambda = -k^{-1} \ln(1 - (1 - q)^{1/n}) \approx 0.077$. If training data is available, λ can also be chosen to maximize accuracy via cross validation.

The exponential form of the decay function has been adopted by the majority of time-biased-sampling applications in practice because otherwise one would typically need to track the arrival time of every data item—both in and outside of the sample—and decay each item individually at an update, which would make the sampling operation intolerably slow. (A “forward decay” approach that avoids this difficulty, but with its own costs, has been proposed in [9]; we plan to investigate forward decay in future work.) Exponential decay functions make update operations fast and simple.

For the case in which the item-arrival rate is high, the main issue is to keep the sample size from becoming too large. On the other hand, when the incoming batches become very small or widely spaced, the sample sizes for all of the time-biased algorithms that we discuss (as well as for sliding-window schemes based on wall-clock time) can become small. This is a natural consequence of treating recent items as more important, and is characteristic of any sampling scheme that satisfies (1). We emphasize that—as shown in our experiments—a smaller, but carefully time-biased sample typically yields greater prediction accuracy than a sample that is larger due to overloading with too much recent data or too much old data. I.e., more sample data is not always better. Indeed, with respect to model management, this decay property can be viewed as a feature in that, if the data stream dries up and the sample decays to a very small size, then this is a signal that there is not enough new data to reliably retrain the model, and that the current version should be kept for now.

It is surprisingly hard to both enforce (1) and to bound the sample size. As discussed in detail in Section 7, prior algorithms that bound the sample size either cannot consistently enforce (1) or cannot handle wall-clock time. Examples of the former include algorithms based on the A-Res scheme of Efraimidis and Spirakis [12], and Chao’s algorithm [5]. A-Res enforces conditions on the *acceptance* probabilities of items; this leads to appearance probabilities which, unlike (1), are both hard to compute and not intuitive. A similar example is provided by Chao’s algorithm [5]. In Appendix D of [16] we demonstrate how the algorithm can be specialized to the case of exponential decay and modified to handle batch arrivals. We then show that the resulting algorithm fails to enforce (1) either when initially filling up an empty sample or in the presence of data that arrives slowly relative to the decay rate, and hence fails if the data rate fluctuates too much. The second type of algorithm, due to Aggarwal [1] can only control appearance probabilities based on the indices of the data items. For example, after n items arrive, one could require that, with 95% probability, the $(n-k)$ th item should still be in the sample for some specified $k < n$. If the data arrival rate is constant, then this might correspond to a constraint of the form “with 95% probability a data item that arrived 10 hours ago is still in the sample”, which is often more natural in applications. For varying arrival rates, however, it is impossible to enforce the latter type of constraint, and a large batch of arriving data can prematurely flush out older data. Thus our new sampling schemes are interesting in their

own right, significantly expanding the set of unequal-probability sampling techniques.

T-TBS: We first provide and analyze Targeted-Size Time-Biased Sampling (T-TBS), a simple algorithm that generalizes the sampling scheme in [27]. T-TBS allows complete control over the decay rate (expressed in wall-clock time) and probabilistically maintains a target sample size. That is, the expected and average sample sizes converge to the target and the probability of large deviations from the target decreases exponentially or faster in both the target size and the deviation size. T-TBS is simple and highly scalable when applicable, but only works under the strong restriction that the mean data arrival rate is known and constant. There are scenarios where T-TBS might be a good choice (see Section 3), but many applications have non-constant, unknown mean arrival rates or cannot tolerate sample overflows.

R-TBS: We then provide a novel algorithm, Reservoir-Based Time-Biased Sampling (R-TBS), that is the first to simultaneously enforce (1) at all times, provide a guaranteed upper bound on the sample size, and allow unknown, varying data arrival rates. Guaranteed bounds are desirable because they avoid memory management issues associated with sample overflows, especially when large numbers of samples are being maintained—so that the probability of *some* sample overflowing is high—or when sampling is being performed in a limited memory setting such as at the “edge” of the IoT. Also, bounded samples reduce variability in retraining times and do not impose upper limits on the incoming data flow.

The idea behind R-TBS is to adapt the classic reservoir sampling algorithm, which bounds the sample size but does not allow time biasing. Our approach rests on the notion of a “fractional” sample whose nonnegative size is real-valued in an appropriate sense. We show that, over all sampling algorithms having exponential decay, R-TBS maximizes the expected sample size whenever the data arrival rate is low and also minimizes the sample-size variability.

Distributed implementation: Both T-TBS and R-TBS can be parallelized. Whereas T-TBS is relatively straightforward to implement, an efficient distributed implementation of R-TBS is nontrivial. We exploit various implementation strategies to reduce I/O relative to other approaches, avoid unnecessary concurrency control, and make decentralized decisions about which items to insert into, or delete from, the reservoir.

Organization: The rest of the paper is organized as follows. In Section 2 we formally describe our batch-arrival problem setting and discuss two prior simple sampling schemes: a simple Bernoulli scheme as in [27] and the classical reservoir sampling scheme, modified for batch arrivals. These methods either bound the sample size but do not control the decay rate, or control the decay rate but not the sample size. We next present and analyze the T-TBS and R-TBS algorithms in Section 3 and Section 4. We describe the distributed implementation in Section 5, and Section 6 contains experimental results. We review the related literature in Section 7 and conclude in Section 8.

2 SETTING AND PRIOR SCHEMES

After introducing our problem setting, we discuss two prior sampling schemes that provide context for our current work: simple Bernoulli time-biased sampling (B-TBS) with no sample-size control and the classical reservoir sampling algorithm (with no time biasing), modified for batch arrivals (B-RS).

Setting: Items arrive in *batches* $\mathcal{B}_1, \mathcal{B}_2, \dots$, at time points $t = 1, 2, \dots$, where each batch contains 0 or more items. This

simple integer batch sequence often arises from the discretization of time [24, 28]. Specifically, the continuous time domain is partitioned into intervals of length Δ , and the items are observed only at times $\{k\Delta : k = 0, 1, 2, \dots\}$. All items that arrive in an interval $[k\Delta, (k+1)\Delta)$ are treated as if they arrived at time $k\Delta$, i.e., at the start of the interval, so that all items in batch \mathcal{B}_i have time stamp $i\Delta$, or simply time stamp i if time is measured in units of length Δ . As discussed below, our results can straightforwardly be extended to arbitrary real-valued batch-arrival times.

Our goal is to generate a sequence $\{S_t\}_{t \geq 0}$, where S_t is a sample of the items that have arrived at or prior to time t , i.e., a sample of the items in $U_t = S_0 \cup (\bigcup_{i=1}^t \mathcal{B}_i)$. Here we allow the initial sample S_0 to start out nonempty. These samples should be biased towards recent items so as to enforce (1) for $i \in \mathcal{B}_t$ and $j \in \mathcal{B}_{t'}$ while keeping the sample size as close as possible to (and preferably never exceeding) a specified target n .

Our assumption that batches arrive at integer time points can easily be dropped. In all of our algorithms, inclusion probabilities—and, as discussed later, closely related item “weights”—are updated at a batch arrival time t' with respect to their values at the previous time $t = t' - 1$ via multiplication by $e^{-\lambda}$. To extend our algorithms to handle arbitrary successive batch arrival times t and t' , we simply multiply instead by $e^{-\lambda(t'-t)}$. Thus our results can be applied to arbitrary sequences of real-valued batch arrival times, and hence to an arbitrary sequences of item arrivals (since batches can comprise single items).

Bernoulli Time-Biased Sampling (B-TBS): In the simplest sampling scheme, at each time t , we accept each incoming item $x \in \mathcal{B}_t$ into the sample with probability 1. At each subsequent time $t' > t$, we flip a coin independently for each item currently in the sample: an item is retained in the sample with probability $p = e^{-\lambda}$ and removed with probability $1 - p$. It is straightforward to adapt the algorithm to batch arrivals; see Appendix A of [16], where we show that $\Pr[x \in S_{t'}] = e^{-\lambda(t'-t)}$ for $x \in \mathcal{B}_t$, implying (1). This is essentially the algorithm used, e.g., in [27] to implement time-biased edge sampling in dynamic graphs. The user, however, cannot independently control the expected sample size, which is completely determined by λ and the sizes of the incoming batches. In particular, if the batch sizes systematically grow over time, then sample size will grow without bound. Arguments in [27] show that if $\sup_t |\mathcal{B}_t| < \infty$, then the sample size can be bounded, but only probabilistically. See Remark 1 below for extensions and refinements of these results.

Batched Reservoir Sampling (B-RS): The classic reservoir sampling algorithm can be modified to handle batch arrivals; see Appendix B of [16]. Although B-RS guarantees an upper bound on the sample size, it does not support time biasing. The R-TBS algorithm (Section 4) maintains a bounded reservoir as in B-RS while simultaneously allowing time-biased sampling.

3 TARGETED-SIZE TBS

As a first step towards time-biased sampling with a controlled sample size, we describe the simple T-TBS scheme, which improves upon the simple Bernoulli sampling scheme B-TBS by ensuring the inclusion property in (1) while providing probabilistic guarantees on the sample size. We require that the mean batch size equals a constant b that is both known in advance and “large enough” in that $b \geq n(1 - e^{-\lambda})$, where n is the target sample size and λ is the decay rate as before. The requirement on b ensures that, at the target sample size, items arrive on average at least as fast as they decay.

Algorithm 1: Targeted-size TBS (T-TBS)

```

1  $\lambda$ : decay factor ( $\geq 0$ )
2  $n$ : target sample size
3  $b$ : assumed mean batch size such that  $b \geq n(1 - e^{-\lambda})$ 
4 Initialize:  $S \leftarrow S_0$ ;  $p \leftarrow e^{-\lambda}$ ;  $q \leftarrow n(1 - e^{-\lambda})/b$ 
5 for  $t \leftarrow 1, 2, \dots$  do
6    $m \leftarrow \text{BINOMIAL}(|S|, p)$  //simulate  $|S|$  trials
7    $S \leftarrow \text{SAMPLE}(S, m)$  //retain  $m$  random elements
8    $k \leftarrow \text{BINOMIAL}(|\mathcal{B}_t|, q)$ 
9    $B'_t \leftarrow \text{SAMPLE}(\mathcal{B}_t, k)$  //down-sample new batch
10   $S \leftarrow S \cup B'_t$ 
11  output  $S$ 

```

The pseudocode is given as Algorithm 1. T-TBS is similar to B-TBS in that we downsample by performing a coin flip for each item with retention probability p . Unlike B-TBS, we downsample the incoming batches at rate $q = n(1 - e^{-\lambda})/b$, which ensures that n becomes the “equilibrium” sample size. Specifically, when the sample size equals n , the expected number $n(1 - e^{-\lambda})$ of current items deleted at an update equals the expected number qb of inserted new items, which causes the sample size to drift towards n . Arguing similarly to Appendix A of [16], we have for $t' \geq t \geq 1$ and $x \in \mathcal{B}_t$ that $\Pr[x \in S_{t'}] = qe^{-\lambda(t'-t)}$, so that the key relative appearance property in (1) holds.

For efficiency, the algorithm exploits the fact that for k independent trials, each having success probability r , the total number of successes has a binomial distribution with parameters k and r . Thus, in lines 6 and 8, the algorithm simulates the coin tosses by directly generating the number of successes m or k —which can be done using standard algorithms [17]—and then retaining m or k randomly chosen items. So the function $\text{BINOMIAL}(j, r)$ returns a random sample from the binomial distribution with j independent trials and success probability r per trial, and the function $\text{SAMPLE}(A, m)$ returns a uniform random sample, without replacement, containing $\min(m, |A|)$ elements of the set A ; note that the function call $\text{SAMPLE}(A, 0)$ returns an empty sample for any empty or nonempty A .

Theorem 3.1 below precisely describes the behavior of the sample size; the proof—along with the proofs of most other results in the paper—is given in Appendix C of [16]. Denote by $B_t = |\mathcal{B}_t|$ the (possibly random) size of \mathcal{B}_t for $t \geq 1$ and by $C_t = |S_t|$ the sample size at time t for $t \geq 0$; assume that C_0 is a finite deterministic constant. Define the *upper-support ratio* for a random batch size B as $r = b^*/b \geq 1$, where $b = E[B]$ and b^* is the smallest positive number such that $P[B \leq b^*] = 1$; set $r = \infty$ if B can be arbitrarily large. For $r \in [1, \infty)$, set

$$v_{\epsilon, r}^+ = (1 + \epsilon) \ln((1 + \epsilon)/r) - (1 + \epsilon - r).$$

for $\epsilon > 0$ and

$$v_{\epsilon, r}^- = (1 - \epsilon) \ln((1 - \epsilon)/r) - (1 - \epsilon - r)$$

for $\epsilon \in (0, 1)$. Note that $v_{\epsilon, r}^+ > 0$ and is strictly increasing in ϵ for $\epsilon > r - 1$, and that $v_{\epsilon, r}^-$ increases from $r - 1 - \ln r$ to r as ϵ increases from 0 to 1. Write “i.o.” to denote that an event occurs “infinitely often”, i.e., for infinitely many values of t , and write “w.p.1” for “with probability 1”.

THEOREM 3.1. *Suppose that the batch sizes $\{B_t\}_{t \geq 1}$ are i.i.d with common mean $b \geq n(1 - e^{-\lambda})$, finite variance, and upper support ratio r . Then, for any $p = e^{-\lambda} < 1$,*

- (i) for all $m \geq 0$, we have $\Pr[C_t = m \text{ i.o.}] = 1$;
- (ii) $E[C_t] = n + p^t(C_0 - n)$ for $t > 0$;

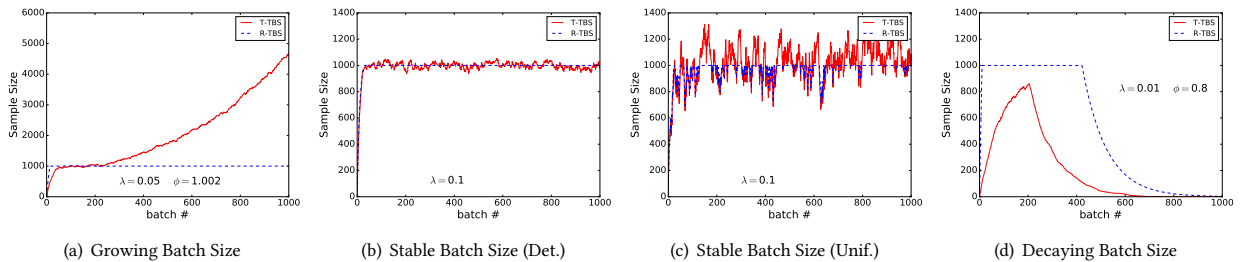

Figure 1: Targeted TBS: Sample Size Behavior, $\lambda =$ decay rate and $\phi =$ batch size multiplier.

- (iii) $\lim_{t \rightarrow \infty} (1/t) \sum_{i=0}^t C_i = n$ w.p.1;
 - (iv) if $C_0 = n$ and $r < \infty$, then
 - (a) $\Pr[C_t \geq (1 + \epsilon)n] \leq e^{-n v_{\epsilon, r}^+ (1 + O(n \epsilon p^t))}$ and
 - (b) $\Pr[C_t \leq (1 - \epsilon)n] \leq e^{-n v_{\epsilon, r}^- (1 + O(n(1 - \epsilon)p^t))}$
- for (a) $\epsilon, t > 0$ and (b) $\epsilon \in (0, 1)$ and $t \geq \ln \epsilon / \ln p$.

In Appendix C of [16], we actually prove a stronger version of the theorem in which the assumption in (iv) that $r < \infty$ is dropped.

Thus, from (ii), $\lim_{t \rightarrow \infty} E[C_t] = n$ so that the expected sample size converges to the target size n as t becomes large; indeed, if $C_0 = n$ then the expected sample size equals n for all $t > 0$. By (iii), an even stronger property holds in that, w.p.1, the average sample size—averaged over the first t batch-arrival times—converges to n as t becomes large. For typical batch-size distributions, the assertions in (iv) imply that, at any given time t , the probability that the sample size deviates from n by more than 100% decreases exponentially with n and—in the case of a positive deviation as in (iv)(a)—super-exponentially in ϵ . However, the assertion in (i) implies that any sample size m , no matter how large, will be exceeded infinitely often w.p.1; indeed, it follows from the proof that the mean times between successive exceedances are not only finite, but are uniformly bounded over time. In summary, the sample size is generally stable and close to n on average, but is subject to infrequent, but unboundedly large spikes in the sample size, so that sample-size control is incomplete.

Indeed, when batch sizes fluctuate in a non-predictable way, as often happens in practice, T-TBS can break down; see Figure 1, in which we plot sample sizes for T-TBS and, for comparison, R-TBS. The problem is that the value of the mean batch size b must be specified in advance, so that the algorithm cannot handle dynamic changes in b without losing control of either the decay rate or the sample size.

In Figure 1(a), for example, the (deterministic) batch size is initially fixed and the algorithm is tuned to a target sample size of 1000, with a decay rate of $\lambda = 0.05$. At $t = 200$, the batch size starts to increase (with $B_{t+1} = \phi B_t$ where $\phi = 1.002$), leading to an overflowing sample, whereas R-TBS maintains a constant sample size.

Even in a stable batch-size regime with constant batch sizes (or, more generally, small variations in batch size), R-TBS can maintain a constant sample size whereas the sample size under T-TBS fluctuates in accordance with Theorem 3.1; see Figure 1(b) for the case of a constant batch size $B_t \equiv 100$ with $\lambda = 0.1$.

Large variations in the batch size lead to large fluctuations in the sample size for T-TBS; in this case the sample size for R-TBS is bounded above by design, but large drops in the batch size can cause drops in the sample size for both algorithms; see Figure 1(c) for the case of $\lambda = 0.1$ and i.i.d. uniformly distributed batch sizes on $[0, 200]$ so that $E[B_t] \equiv 100$. Similarly, as shown in Figure 1(d), systematically decreasing batch sizes will cause the

sample size to shrink for both T-TBS and R-TBS. Here, $\lambda = 0.01$ and, as with Figure 1(a), the batch size is initially fixed and then starts to change at time $t = 200$, with $\phi = 0.8$ in this case. This experiment—and others, not reported here, with varying values of λ and ϕ —indicate that R-TBS is more robust to sample underflows than T-TBS.

Overall, however, T-TBS is of interest because, when the mean batch size is known and constant over time, and when some sample overflows are tolerable, T-TBS is simple to implement and parallelize, and is very fast (see Section 6). For example, if the data comes from periodic polling of a set of robust sensors, the data arrival rate will be known a priori and will be relatively constant, except for the occasional sensor failure, and hence T-TBS might be appropriate. On the other hand, if data is coming from, e.g., a social network, then batch sizes may be hard to predict.

REMARK 1. When $q = 1$, Theorem 3.1 provides a description of sample-size behavior for B-TBS. Under the conditions of the theorem, the expected sample size converges to $n = b/(1 - e^{-\lambda})$, which illustrates that the sample size and decay rate cannot be controlled independently. The actual sample size fluctuates around this value, with large deviations above or below being exponentially or super-exponentially rare. Thus Theorem 3.1 both complements and refines the analysis in [27].

4 RESERVOIR-BASED TBS

Targeted time-biased sampling (T-TBS) controls the decay rate but only partially controls the sample size, whereas batched reservoir sampling (B-RS) bounds the sample size but does not allow time biasing. Our new reservoir-based time-biased sampling algorithm (R-TBS) combines the best features of both, controlling the decay rate while ensuring that the sample never overflows and has optimal sample size and stability properties. Importantly, unlike T-TBS, the R-TBS algorithm can handle any sequence of batch sizes.

4.1 The R-TBS Algorithm

To maintain a bounded sample, R-TBS combines the use of a reservoir with the notion of item *weights*. In R-TBS, the weight of an item initially equals 1 but then decays at rate λ , i.e., the weight of an item $i \in \mathcal{B}_t$ at time $t' \geq t$ is $w_{t'}(i) = e^{-\lambda(t'-t)}$. All items arriving at the same time have the same weight, so that the *total weight* of all items seen up through time t is $W_t = \sum_{j=1}^t B_j e^{-\lambda(t-j)}$, where, as before, $B_j = |\mathcal{B}_j|$ is the size of the j th batch.

R-TBS generates a sequence of latent “fractional samples” $\{L_t\}_{t \geq 0}$ such that (i) the “size” of each L_t equals the *sample weight* C_t , defined as $C_t = \min(n, W_t)$, and (ii) L_t contains $\lfloor C_t \rfloor$ “full” items and at most one “partial” item. For example, a latent sample of size $C_t = 3.6$ contains three “full” items that belong to the actual sample S_t with probability 1 and one partial item that

Algorithm 2: Reservoir-based TBS (R-TBS)

```

1  $\lambda$ : decay factor ( $\geq 0$ )
2  $n$ : maximum sample size
3 Initialize:  $A \leftarrow A_0; W \leftarrow C \leftarrow |A_0|; \pi \leftarrow \emptyset$  //  $|A_0| \leq n$ 
4 for  $t \leftarrow 1, 2, \dots$  do
5   if  $W < n$  then //has been unsaturated
6      $W \leftarrow e^{-\lambda} W$  //decay current items
7     if  $W > 0$  then
8        $(A, \pi, C) \leftarrow \text{DSAMPLE}((A, \pi, C), W)$ 
9        $A \leftarrow A \cup \mathcal{B}_t$  //accept all items in  $\mathcal{B}_t$ 
10       $W \leftarrow W + |\mathcal{B}_t|$  //update total weight
11      if  $W > n$  then //sample is now saturated
12        //adjust for overshoot
13         $(A, \pi, C) \leftarrow \text{DSAMPLE}((A, \pi, W), n)$ 
14      else //has been saturated
15         $W \leftarrow e^{-\lambda} W + |\mathcal{B}_t|$  //new total weight
16        if  $W \geq n$  then //still saturated
17           $m \leftarrow \text{STOCHROUND}(|\mathcal{B}_t|n/W)$ 
18          //replace  $m$   $A$ -items with  $m$   $\mathcal{B}_t$ -items
19           $A \leftarrow A \setminus \text{SAMPLE}(A, m) \cup \text{SAMPLE}(\mathcal{B}_t, m)$ 
20        else //now unsaturated
21          //adjust for undershoot
22           $(A, \pi, C) \leftarrow \text{DSAMPLE}((A, \pi, n), W - |\mathcal{B}_t|)$ 
23           $A \leftarrow A \cup \mathcal{B}_t$  //all batch items are full
24     $S \leftarrow \text{GETSAMPLE}(A, \pi, C)$ 
25  output  $S$ 

```

Figure 2: Latent sample L_t (sample weight $C_t = 3.6$) and possible realized samples.

belongs to S_t with probability 0.6. Thus S_t is obtained by including each full item and then including the partial item according to its associated probability, so that C_t represents the expected size of S_t . E.g., in our example, the sample S_t will contain either three or four items with respective probabilities 0.4 and 0.6, so that the expected sample size is 3.6; see Figure 2. Note that if $C_t = k$ for some $k \in \{0, 1, \dots, n\}$, then with probability 1 the sample contains precisely k items, and C_t is the actual size of S_t , rather than just the expected size. Since each C_t by definition never exceeds n , no sample S_t ever contains more than n items.

More precisely, given a set U of items, a *latent sample* of U with sample weight C is a triple $L = (A, \pi, C)$, where $A \subseteq U$ is a set of $\lfloor C \rfloor$ *full* items and $\pi \subseteq U$ is a (possibly empty) set containing at most one *partial* item. At each time t , we randomly generate S_t from $L_t = (A_t, \pi_t, C_t)$ by sampling such that

$$S_t = \begin{cases} A_t \cup \pi & \text{with probability } \text{frac}(C_t); \\ A_t & \text{with probability } 1 - \text{frac}(C_t), \end{cases} \quad (2)$$

where $\text{frac}(x) = x - \lfloor x \rfloor$. That is, each full item is included with probability 1 and the partial item is included with probability $\text{frac}(C_t)$. Thus

$$\begin{aligned} \mathbb{E}[|S_t|] &= \lceil C_t \rceil \text{frac}(C_t) + \lfloor C_t \rfloor (1 - \text{frac}(C_t)) \\ &= (\lceil C_t \rceil - \lfloor C_t \rfloor) \text{frac}(C_t) + \lfloor C_t \rfloor \\ &= \text{frac}(C_t) + \lfloor C_t \rfloor = C_t \end{aligned} \quad (3)$$

as previously asserted. By allowing at most one partial item, we minimize the latent sample’s footprint: $|A_t \cup \pi_t| \leq \lfloor C_t \rfloor + 1$.

The key goal of R-TBS is to maintain the invariant

$$\Pr[i \in S_t] = (C_t/W_t)w_t(i) \quad (4)$$

for each $t \geq 0$ and each item $i \in U_t$, where, as before, U_t denotes the set of all items that arrive up through time t , so that the appearance probability for an item i at time t is proportional to its weight $w_t(i)$. This immediately implies the desired relative-inclusion property (1). Since $w_t(i) = 1$ for an arriving item $i \in \mathcal{B}_t$, the equality in (4) implies that the initial acceptance probability for this item is

$$\Pr[i \in S_t] = C_t/W_t. \quad (5)$$

The pseudocode for R-TBS is given as Algorithm 2. Suppose the sample is *unsaturated* at time $t - 1$ in that $W_{t-1} < n$ and hence $C_{t-1} = W_{t-1}$ (line 5). The decay process first reduces the total weight (and hence the sample weight) to $W'_{t-1} = C'_{t-1} = e^{-\lambda}W_{t-1}$ (line 6). R-TBS then *downsamples* L_{t-1} (line 8) to reflect this decay and maintain a minimal sample footprint; the downsampling method, described in Section 4.2, is designed to maintain the invariant in (4). If the weight of the arriving batch does not cause the sample to overflow, i.e., $C'_{t-1} + |\mathcal{B}_t| < n$, then $C_t = C'_{t-1} + |\mathcal{B}_t| = W'_{t-1} + |\mathcal{B}_t| = W_t$. The relation in (5) then implies that all newly arrived items are accepted into the sample with probability 1 (line 9); see Figure 3(a) for an example of this scenario. The situation is more complicated if the weight of the arriving batch would cause the sample to overflow. It turns out that the simplest way to deal with this scenario is to initially accept all incoming items as in line 9, and then run an additional round of downsampling to reduce the sample weight to n (line 12), so that the sample is now saturated; see Figure 3(b). Note that these two steps can be executed without ever causing the sample footprint to exceed n .

Now suppose that the sample is *saturated* at time $t - 1$, so that $W_{t-1} \geq n$ and hence $C_{t-1} = |S_{t-1}| = n$. The new total weight is $W_t = W'_{t-1} + |\mathcal{B}_t|$ as before (line 14). If $W_t \geq n$, then the weight of the arriving batch exceeds the weight loss due to decay, and the sample remains saturated. Then (5) implies that each item in \mathcal{B}_t is accepted into the sample with probability $p = n/W_t$. Letting $I_j = 1$ if item $j \in \mathcal{B}$ is accepted and $I_j = 0$ otherwise, we see that the expected number of accepted items is

$$m = \mathbb{E}\left[\sum_{j \in \mathcal{B}_t} I_j\right] = \sum_{j \in \mathcal{B}_t} \mathbb{E}[I_j] = \sum_{j \in \mathcal{B}_t} \Pr[I_j = 1] = B_t n/W_t.$$

There are a number of possible ways to carry out this acceptance operation, e.g., via independent coin flips. To minimize the variability of the sample size (and hence the likelihood of severely small samples), R-TBS uses *stochastic rounding* in line 16 and accepts a random number of items M such that $M = \lfloor m \rfloor$ with probability $\lceil m \rceil - m$ and $M = \lceil m \rceil$ with probability $m - \lfloor m \rfloor$, so that $\mathbb{E}[M] = m$ by an argument essentially the same as in (3). To maintain the bound on the sample size, the M accepted items replace M randomly selected “victims” in the current sample (line 17). If $W_t < n$, then the sample weight decays to W'_{t-1} and the weight of the arriving batch is not enough to fill the sample back up. Moreover, (5) implies that all arriving items are accepted with probability 1. Thus we downsample to the decayed weight of $W'_{t-1} = W_t - |\mathcal{B}_t|$ in line 19 and then insert the arriving items in line 20.

4.2 Downsampling

Before describing Algorithm 3, the downsampling algorithm, we intuitively motivate a key property that any such procedure must have. For any item $i \in L$, the relation in (4) implies that we must have $\Pr[i \in S] = (C/W)w_i$ and $\Pr[i \in S'] = (C'/W')w'_i$, where W and w_i represent the total and item weight before decay and

Figure 3: R-TBS scenarios for $n = 4$ and $e^{-\lambda} = 0.5$. For simplicity, we take $W_{t-1} = C_{t-1}$. “DS” denotes downsampling.

Algorithm 3: Downsampling

```

1  $L = (A, \pi, C)$ : input latent sample
2  $C'$ : input target weight with  $0 < C' < C$ 
3  $L' = (A', \pi', C')$ : output latent sample
4  $U \leftarrow \text{UNIFORM}()$ 
5 if  $\lfloor C' \rfloor = 0$  then //no full items retained
6   if  $U > \text{frac}(C)/C$  then
7      $(A', \pi') \leftarrow \text{SWAP1}(A, \pi)$ 
8      $A' \leftarrow \emptyset$ 
9 else if  $0 < \lfloor C' \rfloor = \lfloor C \rfloor$  then //no items deleted
10  if  $U > (1 - (C'/C) \text{frac}(C)) / (1 - \text{frac}(C'))$  then
11     $(A', \pi') \leftarrow \text{SWAP1}(A, \pi)$ 
12 else //items deleted:  $0 < \lfloor C' \rfloor < \lfloor C \rfloor$ 
13  if  $U \leq (C'/C) \text{frac}(C)$  then
14     $A' \leftarrow \text{SAMPLE}(A, \lfloor C' \rfloor)$ 
15     $(A', \pi') \leftarrow \text{SWAP1}(A', \pi)$ 
16  else
17     $A' \leftarrow \text{SAMPLE}(A, \lfloor C' \rfloor + 1)$ 
18     $(A', \pi') \leftarrow \text{MOVE1}(A', \pi)$ 
19 if  $C' = \lfloor C' \rfloor$  then //no fractional item
20    $\pi' \leftarrow \emptyset$ 

```

downsampling, and W' and w'_i represent the weights afterwards. Since decay affects all items equally, we have $w/W = w'/W'$, and it follows that

$$\Pr[i \in S'] = (C'/C) \Pr[i \in S]. \quad (6)$$

That is, the inclusion probabilities for all items must be scaled down by the same fraction, namely C'/C . Theorem 4.1 (later in this section) asserts that Algorithm 3 satisfies this property.

In the pseudocode for Algorithm 3, the function $\text{UNIFORM}()$ generates a random number uniformly distributed on $[0, 1]$. The subroutine $\text{SWAP1}(A, \pi)$ moves a randomly selected item from A to π and moves the current item in π (if any) to A . Similarly, $\text{MOVE1}(A, \pi)$ moves a randomly selected item from A to π , replacing the current item in π (if any). More precisely, $\text{SWAP1}(A, \pi)$ executes the operations $I \leftarrow \text{SAMPLE}(A, 1)$, $A \leftarrow (A \setminus I) \cup \pi$, and $\pi \leftarrow I$, and $\text{MOVE1}(A, \pi)$ executes the operations $I \leftarrow \text{SAMPLE}(A, 1)$, $A \leftarrow A \setminus I$, and $\pi \leftarrow I$.

To gain some intuition for why the algorithm works, consider a simple special case, where the goal is to form a fractional sample $L' = (A', \pi', C')$ from a fractional sample $L = (A, \pi, C)$ of integral size $C > C'$; that is, L comprises exactly C full items. Assume that C' is non-integral, so that L' contains a partial item. In this case, we simply select an item at random (from A) to be the partial item in L' and then select $\lfloor C' \rfloor$ of the remaining $C - 1$ items at random to be the full items in L' ; see Figure 4(a). By symmetry, each item $i \in L$ is equally likely to be included in S' , so that the inclusion probabilities for the items in L are all scaled down by the same fraction, as required for (6). For example, taking $t = 0$ in Figure 4(a), item a appears in S_t with probability 1 since it is a full item. In S'_t , where the weights have been reduced by 50%, item a (either as a full or partial item, depending on the random outcome) appears with probability $2 \cdot (1/6) + 2 \cdot (1/6) \cdot 0.5 = 0.5$, as expected. This scenario corresponds to lines 17 and 18 in the

algorithm, where we carry out the above selections by randomly sampling $\lfloor C' \rfloor + 1$ items from A to form A' and then choosing a random item in A' as the partial item by moving it to π .

In the case where L contains a partial item i^* that appears in S with probability $\text{frac}(C)$, it follows from (6) that i^* should appear in S' with probability $p = (C'/C)P[i^* \in S] = (C'/C) \text{frac}(C)$. Thus, with probability p , lines 13–15 retain i^* and convert it to a full item so that it appears in S' . Otherwise, in lines 17 and 18, i^* is removed from the sample when it is overwritten by a random item from A' ; see Figure 4(b). Again, a new partial item is chosen from A in a random manner to uniformly scale down the inclusion probabilities. For instance, in Figure 4(b), item d appears in S_t with probability 0.2 (because it is a partial item) and in S'_t appears with probability $3 \cdot (0.1/3) = 0.1$. Similarly, item a appears in S_t with probability 1 and in S'_t with probability $(1.8)/6 + 0.6 \cdot (1.8/6) + 0.6 \cdot (0.1/3) = 0.5$.

The if-statement in line 5 corresponds to the corner case in which L' does not contain a full item. The partial item $i^* \in L$ either becomes full or is swapped into A' and then immediately ejected; see Figure 4(c).

The if-statement in line 9 corresponds to the case in which no items are deleted from the latent sample, e.g., when $C = 4.7$ and $C' = 4.2$. In this case, i^* either becomes full by being swapped into A' or remains as the partial item for L' . Denoting by ρ the probability of *not* swapping, we have $P[i^* \in S'] = \rho \cdot \text{frac}(C') + (1 - \rho) \cdot 1$. On the other hand, (6) implies that $P[i^* \in S'] = (C'/C) \text{frac}(C)$. Equating these expressions shows that ρ must equal the expression on the right side of the inequality on line 10; see Figure 4(d).

Formally, we have the following result.

THEOREM 4.1. For $0 < C' < C$, let $L' = (A', \pi', C')$ be the latent sample produced from a latent sample $L = (A, \pi, C)$ via Algorithm 3, and let S' and S be samples produced from L' and L via (2). Then $\Pr[i \in S'] = (C'/C) \Pr[i \in S]$ for all $i \in L$.

4.3 Properties of R-TBS

Theorem 4.2 below asserts that R-TBS satisfies (4) and hence (1), thereby maintaining the correct inclusion probabilities; see Appendix C of [16] for the proof. Theorems 4.3 and 4.4 assert that, among all sampling algorithms with exponential time biasing, R-TBS both maximizes the expected sample size in unsaturated scenarios and minimizes sample-size variability. Thus R-TBS tends to yield more accurate results (from more training data) and greater stability in both result quality and retraining costs.

THEOREM 4.2. The relation $\Pr[i \in S_t] = (C_t/W_t)w_t(i)$ holds for all $t \geq 1$ and $i \in U_t$.

THEOREM 4.3. Let H be any sampling algorithm that satisfies (1) and denote by S_t and S_t^H the samples produced at time t by R-TBS and H . If the total weight at some time $t \geq 1$ satisfies $W_t < n$, then $E[|S_t^H|] \leq E[|S_t|]$.

PROOF. Since H satisfies (1), it follows that, for each time $j \leq t$ and $i \in \mathcal{B}_j$, the inclusion probability $\Pr[i \in S_t^H]$ must be of the

Figure 4: Downsampling examples ($t = 0$).

form $r_t e^{-\lambda(t-j)}$ for some function r_t independent of j . Taking $j = t$, we see that $r_t \leq 1$. For R-TBS in an unsaturated state, (4) implies that $r_t = C_t/W_t = 1$, so that $\Pr[i \in S_t^H] \leq \Pr[i \in S_t]$, and the desired result follows directly. \square

THEOREM 4.4. *Let H be any sampling algorithm that satisfies (1) and has maximal expected sample size C_t and denote by S_t and S_t^H the samples produced at time t by R-TBS and H . Then $\text{Var}[|S_t^H|] \geq \text{Var}[|S_t|]$ for any time $t \geq 1$.*

PROOF. Considering all possible distributions over the sample size having a mean value equal to C_t , it is straightforward to show that variance is minimized by concentrating all of the probability mass onto $\lfloor C_t \rfloor$ and $\lceil C_t \rceil$. There is precisely one such distribution, namely the stochastic-rounding distribution, and this is precisely the sample-size distribution attained by R-TBS. \square

5 DISTRIBUTED TBS ALGORITHMS

In this section, we describe how to implement distributed versions of T-TBS and R-TBS to handle large volumes of data.

5.1 Overview of Distributed Algorithms

The distributed T-TBS and R-TBS algorithms, denoted as D-T-TBS and D-R-TBS respectively, need to distribute large data sets across the cluster and parallelize the computation on them.

Overview of D-T-TBS: The implementation of the D-T-TBS algorithm is very similar to the simple distributed Bernoulli time-biased sampling algorithm in [27]. It is embarrassingly parallel, requiring no coordination. At each time point t , each worker in the cluster subsamples its partition of the sample with probability p , subsamples its partition of \mathcal{B}_t with probability q , and then takes a union of the resulting data sets.

Overview of D-R-TBS: This algorithm, unlike D-T-TBS, maintains a bounded sample, and hence cannot be embarrassingly parallel. D-R-TBS first needs to aggregate local batch sizes to compute the incoming batch size $|\mathcal{B}_t|$ to maintain the total weight W . Then, based on $|\mathcal{B}_t|$ and the previous total weight W , D-R-TBS determines whether the reservoir was previously saturated and whether it will be saturated after processing \mathcal{B}_t . For each possible situation, D-R-TBS chooses the items in the reservoir to delete through downsampling and the items in \mathcal{B}_t to insert into the reservoir. This process requires the master to coordinate among the workers. In Section 5.3, we introduce two alternative approaches to determine the deleted and inserted items. Finally, the algorithm applies the deletes and inserts to form the new reservoir, and computes the new total weight W .

Both D-T-TBS and D-R-TBS periodically checkpoint the sample as well as other system state variables to ensure fault tolerance. The implementation details for D-T-TBS are mostly subsumed by those for D-R-TBS, so we focus on the latter.

Figure 5: Design choices for implementing the reservoir

Figure 6: Retrieving insert items

5.2 Distributed Data Structures

There are two important data structures in the D-R-TBS algorithm: the incoming batch and the reservoir. Conceptually, we view an incoming batch \mathcal{B}_t as an array of slots numbered from 1 through $|\mathcal{B}_t|$, and the reservoir as an array of slots numbered from 1 through $\lfloor C \rfloor$ containing full items plus a special slot for the partial item. For both data structures, data items need to be distributed into partitions due to the large data volumes. Therefore, the slot number of an item maps to a specific partition ID and a position inside the partition.

The incoming batch usually comes from a distributed streaming system, such as Spark Streaming; the actual data structure is specific to the streaming system (e.g. an incoming batch is stored as an RDD in Spark Streaming). As a result, the partitioning strategy of the incoming batch is opaque to the D-R-TBS algorithm. Unlike the incoming batch, which is read-only and discarded at the end of each time period, the reservoir data structure must be continually updated. An effective strategy for storing and operating on the reservoir is thus crucial for good performance. We now explore alternative approaches to implementing the reservoir.

Distributed in-memory key-value store: One quite natural approach implements the reservoir using an off-the-shelf distributed in-memory key-value store, such as Redis [25] or Memcached [23]. In this scheme, each item in the reservoir is stored as a key-value pair, with the slot number as the key and the item as the value. Inserts and deletes to the reservoir naturally translate into put and delete operations to the key-value store.

There are two major limitations to this approach. Firstly, the hash-based or range-based data-partitioning scheme used by a distributed key-value store yields reservoir partitions that do not correlate with the partitions of incoming batch. As illustrated in Figure 5(a), when items from a given partition of an incoming batch are inserted into the reservoir, the inserts touch many (if not all) partitions of the reservoir, incurring heavy network I/O. Secondly, key-value stores incur needless concurrency-control overhead. For each batch, D-R-TBS already carefully coordinates the deletes and inserts so that no two delete or insert operations access the same slots in the reservoir and there is no danger of write-write or read-write conflicts.

Co-partitioned reservoir: In the alternative approach, we implement a distributed in-memory data structure for the reservoir so as to ensure that the reservoir partitions coincide with the partitions from incoming batches, as shown in Figure 5(b). This can be achieved in spite of the unknown partitioning scheme of the streaming system. Specifically, the reservoir is initially empty, and all items in the reservoir are from the incoming batches. Therefore, if an item from a given partition of an incoming batch is always inserted into the corresponding “local” reservoir partition and deletes are also handled locally, then the co-partitioning and co-location of the reservoir and incoming batch partitions is automatic. For our experiments, we implemented the co-partitioned reservoir in Spark using the in-place updating technique for RDDs in [27]; see Appendix E of [16].

Note that, at any point in time, a given slot number in the reservoir maps to a specific partition ID and a position inside the partition. Thus the slot number for a given full item may change over time due to reservoir insertions and deletions. This does not cause any statistical issues, because the functioning of the set-based R-TBS algorithm is oblivious to specific slot numbers.

5.3 Choosing Items to Delete and Insert

In order to bound the reservoir size, D-R-TBS requires careful coordination when choosing the set of items to delete from, and insert into, the reservoir. At the same time, D-R-TBS must ensure the statistical correctness of random number generation and random permutation operations in the distributed environment. We consider two possible approaches.

Centralized decisions: In the most straightforward approach, the master makes centralized decisions about which items to delete and insert. For deletes, the driver generates slot numbers of the items in the reservoir to be deleted, which are then mapped to the actual data locations in a manner that depends on the representation of the reservoir (key-value store or co-partitioned reservoir). For inserts, the driver generates the slot numbers of the incoming items \mathcal{B}_t at time t that need to be inserted into the reservoir. Suppose that \mathcal{B}_t comprises $k \geq 1$ partitions. Each generated slot number $i \in \{1, 2, \dots, |\mathcal{B}_t|\}$ is mapped to a partition p_i of the \mathcal{B}_t (where $0 \leq p_i \leq k - 1$) and a position r_i inside partition p_i . Denote by Q the set of “item locations”, i.e., the set of (p_i, r_i) pairs. In order to perform the inserts, we need to first retrieve the actual items based on the item locations. This can be achieved with a join-like operation between Q and \mathcal{B}_t , with the (p_i, r_i) pair matching the actual location of an item inside \mathcal{B}_t . To optimize this operation, we make Q a distributed data structure and use a customized partitioner to ensure that all pairs (p_i, r_i) with $p_i = j$ are co-located with partition j of \mathcal{B}_t for $j = 0, 1, \dots, k - 1$. Then a co-partitioned and co-located join can be carried out between Q and \mathcal{B}_t , as illustrated in Figure 6(a)

for $k = 3$. The resulting set of retrieved insert items, denoted as S , is also co-partitioned with \mathcal{B}_t as a by-product. After that, the actual deletes and inserts are then carried out depending on how reservoir is stored, as discussed below.

When the reservoir is implemented as a key-value store, the deletes can be directly applied based on the slot numbers. For inserts, the master takes each generated slot number of an item in \mathcal{B}_t and chooses a companion destination slot number in the reservoir into which the \mathcal{B}_t item will be inserted. This destination reservoir slot might currently be empty due to an earlier deletion, or might contain an item that will now be replaced by the newly inserted batch item. After the actual items to insert are retrieved as described previously, the destination slot numbers are used to put the items into the right locations in the key-value store.

When the co-partitioned reservoir is used, the delete slot numbers in the reservoir are mapped to (p_i, r_i) pairs of partitions of the reservoir and positions inside the partitions. As with inserts, we again use a customized partitioner for the set of pairs \mathcal{R} such that deletes are co-located with the corresponding reservoir partitions. Then a join-like operation on \mathcal{R} and the reservoir performs the actual delete operations on the reservoir. For inserts, we simply use another join-like operation on the set of retrieved insert items S and the reservoir to add the corresponding insert items to the co-located partition of the reservoir. In this approach, we don’t need the master to generate destination reservoir slot numbers for these insert items, because we view the reservoir as a set when using co-partitioned reservoir data structure.

Distributed decisions: The above approach requires generating a large number of slot numbers inside the master, so we now explore an alternative approach that offloads the slot number generation to the workers while still ensuring the statistical correctness of the computation. This approach has the master choose only the number of deletes and inserts per worker according to appropriate multivariate hypergeometric distributions. For deletes, each worker chooses random victims from its local partition of the reservoir based on the number of deletes given by the master. For inserts, the worker randomly and uniformly selects items from its local partition of the incoming batch \mathcal{B}_t given the number of inserts. Figure 6(b) depicts how the insert items are retrieved under this decentralized approach. We use the technique in [15] for parallel pseudo-random number generation.

Note that this distributed decision making approach works only when the co-partitioned reservoir data structure is used. This is because the key-value store representation of the reservoir requires a target reservoir slot number for each insert item from the incoming batch, and the target slot numbers have to be generated in such a way as to ensure that, after the deletes and inserts, all of the slot numbers are still unique and contiguous in the new reservoir. This requires a lot of coordination among the workers, which inhibits truly distributed decision making.

6 EXPERIMENTS

In this section, we study the empirical performance of D-R-TBS and D-T-TBS, and demonstrate the potential benefit of using them for model retraining in online model management. We implemented D-R-TBS and D-T-TBS on Spark (refer to Appendix E of [16] for implementation details).

Experimental Setup: All performance experiments were conducted on a cluster of 13 IBM System x iDataPlex dx340 servers. Each has two quad-core Intel Xeon E5540 2.8GHz processors and 32GB of RAM. Servers are interconnected using a 1Gbit Ethernet and each server runs Ubuntu Linux, Java 1.7 and Spark 1.6.

One server is dedicated to run the Spark coordinator and, each of the remaining 12 servers runs Spark workers. There is one worker per processor on each machine, and each worker is given all 4 cores to use, along with 8 GB of dedicated memory. All other Spark parameters are set to their default values. We used Memcached 1.4.33 as the key-value store in our experiments.

For all experiments, data was streamed in from HDFS using Spark Streaming’s microbatches. We report run time per round as the average over 100 rounds, discarding the first round from this average because of Spark startup costs. Unless otherwise stated, each batch contains 10 million items, the target reservoir size is 20 million elements, and the decay parameter is $\lambda = 0.07$.

Figure 7: Per-batch distributed runtime comparison

Figure 8: Scale out of D-R-TBS

Figure 9: Scale up of D-R-TBS

6.1 Runtime Performance

Comparison of TBS Implementations: Figure 7 shows the average runtime per batch for five different implementations of distributed TBS algorithms. The first four (colored black) are D-R-TBS implementations with different design choices: whether to use centralized or distributed decisions (abbreviated as “Cent” and “Dist”, respectively) for choosing items to delete and insert, and whether to use key-value store for storing reservoir or co-partitioned reservoir (abbreviated as “KV” and “CP”, respectively). The first two implementations both use the key-value store representation for reservoir together with the centralized decision strategy for determining inserts and deletes. They only differ in how the insert items are actually retrieved when subsampling the incoming batch. The first uses the standard repartition join (abbreviated as “RJ”), whereas the second uses the customized partitioner and co-located join (abbreviated as “CJ”) as described in Section 5.3 and depicted in Figure 6(a). This optimization effectively cuts the network cost in half, but the KV representation of reservoir still requires the insert items to be written across the network to their corresponding reservoir location. The third implementation employs the co-partitioned reservoir instead, resulting in a significant speedup of over 2.6x. The fourth implementation further employs the distributed decision for choosing items to delete and insert. This yields a further 1.6x speedup. We use this D-R-TBS implementation in the remaining experiments.

The fifth implementation (colored grey) in Figure 7 is D-T-TBS using co-partitioned reservoir and the distributed strategy for choosing delete and insert items. Since, D-T-TBS is embarrassingly parallelizable, it’s much faster than the best D-R-TBS implementation. But, as we discussed in Section 3, T-TBS only works under a very strong restriction on the data arrival rate,

and can suffer from occasional memory overflows; see Figure 1. In contrast, D-R-TBS is much more robust and works in realistic scenarios where it is hard to predict the data arrival rate.

Scalability of D-R-TBS: Figure 8 shows how D-R-TBS scales with the number of workers. We increased the batch size to 100 million items for this experiment. Initially, D-R-TBS scales out very nicely with the increasing number of workers. However, beyond 10 workers, the marginal benefit from additional workers is small, because the coordination and communication overheads, as well as the inherent Spark overhead, become prominent. For the same reasons, in the scale-up experiment in Figure 9, the runtime stays roughly constant until the batch size reaches 10 million items and increases sharply at 100 million items. This is because processing the streaming input and maintaining the sample start to dominate the coordination and communication overhead. With 10 workers, R-TBS can handle a data flow comprising 100 million items arriving approximately every 14 seconds.

6.2 Application: Classification using kNN

We now demonstrate the potential benefits of the R-TBS sampling scheme for periodically retraining representative ML models in the presence of evolving data. For each model and data set, we compare the quality of models retrained on the samples generated by R-TBS, a simple sliding window (SW), and uniform reservoir sampling (Unif). Due to limited space, we do not give quality results for T-TBS; we found that whenever it applies—i.e. when the mean batch size is known and constant—the quality is very similar to R-TBS, since they both use time-biased sampling.

Our first model is a kNN classifier, where a class is predicted for each item in an incoming batch by taking a majority vote of the classes of the k nearest neighbors in the current sample, based on Euclidean distance; the sample is then updated using the batch. To generate training data, we first generate 100 class centroids uniformly in a $[0, 80] \times [0, 80]$ rectangle. Each data item is then generated from a Gaussian mixture model and falls into one of the 100 classes. Over time, the data generation process operates in one of two “modes”. In the “normal” mode, the frequency of items from any of the first 50 classes is five times higher than that of items in any of the second 50 classes. In the “abnormal” mode, the frequencies are five times lower. Thus the frequent and infrequent classes switch roles at a mode change. We generate each data point by randomly choosing a ground-truth class c_i with centroid (x_i, y_i) according to relative frequencies that depend upon the current mode, and then generating the data point’s (x, y) coordinates independently as samples from $N(x_i, 1)$ and $N(y_i, 1)$. Here $N(\mu, \sigma)$ denotes the normal distribution with mean μ and standard deviation σ .

In this experiment, the batch sizes are deterministic with $b = 100$ items, and $k = 7$ neighbors for the kNN classifier. The reservoir size for both R-TBS and Unif is 1000, and SW contains the last 1000 items; thus all methods use the same amount of data for retraining. (We choose this value because it achieves near maximal classification accuracies for all techniques. In general, we choose sampling and ML parameters to achieve good learning performance while ensuring fair comparisons.) In each run, the sample is warmed up by processing 100 normal-mode batches before the classification task begins. Our experiments focus on two types of temporal patterns in the data, as described below.

Single change: Here we model the occurrence of a singular event. The data is generated in normal mode up to $t = 10$ (time is measured here in units after warm-up), then switches to abnormal

mode, and finally at $t = 20$ switches back to normal (Figure 10(a)). As can be seen, the misclassification rate (percentage of incorrect classifications) with R-TBS, SW and Unif all increase from around 18% to roughly 50% when the distribution becomes abnormal. Both R-TBS and SW adapt to the change, recovering to around 16% misclassification rate after $t = 16$, with SW adapting slightly better. In comparison, Unif does not adapt at all. But, when the distribution snaps back to normal, the error rate of SW rises sharply to 40% before gradually recovering, whereas R-TBS error rate stays low around 15% throughout. These results prove that R-TBS is indeed more robust: although slightly more sluggish than SW in adapting to changes, R-TBS avoids wild fluctuations in classification error as with SW.

Figure 10: Misclassification rate (percent) for kNN

Periodic change: For this temporal pattern, the changes from normal to abnormal mode are periodic, with δ normal batches alternating with η abnormal batches, denoted as $\text{Periodic}(\delta, \eta)$, or $P(\delta, \eta)$ for short. Figure 10(b) shows the misclassification rate for $\text{Periodic}(10, 10)$. Experiments on other periodic patterns (in Appendix F of [16]) demonstrate similar results. The robust behavior of R-TBS described above manifests itself even more clearly in the periodic setting. Note, for example, how R-TBS reacts significantly better to the renewed appearances of the abnormal mode. Observe that the first 30 batches of $\text{Periodic}(10, 10)$ display the same behavior as in the single event experiment in Figure 10(a). We therefore focus primarily on the $\text{Periodic}(10, 10)$ temporal pattern for the remaining experiments.

Robustness and Effect of Decay Parameter: In the context of online model management, we need a sampling scheme that delivers high overall prediction accuracy and, perhaps even more importantly, robust prediction performance over time. Large fluctuations in the accuracy can pose significant risks in applications, e.g., in critical IoT applications in the medical domain such as monitoring glucose levels for predicting hyperglycemia events. To assess the robustness of the performance results across different sampling schemes, we use a standard risk measure called *expected shortfall (ES)* [22, p. 70]. ES measures downside risk, focusing on worst-case scenarios. Specifically, the $z\%$ ES is the average value of the worst $z\%$ of cases.

For each of 30 runs and for each sampling scheme, we compute the 10% ES of the misclassification rate (expressed as a percentage) starting from $t = 20$, since all three sampling schemes perform poorly (as would be expected) during the first mode change, which finishes at $t = 20$. Table 1 lists both the *accuracy*, measured in terms of the average misclassification rate, and the *robustness*, measured as the average 10% ES, of the kNN classifier over 30 runs across different temporal patterns. To demonstrate the effect of the decay parameter λ on model performance, we also include numbers for different λ values in Table 1.

In terms of accuracy, Unif is always the worst by a large margin. R-TBS and SW have similar accuracies, with R-TBS having a

slight edge in most cases. On the other hand, for robustness, SW is almost always the worst, with ES ranging from 1.4x to 2.7x the maximum ES (over different λ values) of R-TBS. Mostly, Unif is also significantly worse than R-TBS, with ES ratios ranging from 1.4x to 1.7x. The only exception is the single-event pattern: since the data remains in normal mode after the abnormal period, time biasing becomes unimportant and Unif performs well. In general, R-TBS provides both better accuracy and robustness in almost all cases. The relative performance of the sampling schemes in terms of accuracy and robustness tend to be consistent across temporal patterns. Table 1 also shows that different λ values affect the accuracy and robustness, however, R-TBS provides superior results over a fairly wide range of λ values.

Varying batch size: We now examine model quality when the batch sizes are no longer constant. Overall, the results look similar to those for constant batch size. For example, Figure 11(a) shows results for a $\text{Uniform}(0,200)$ batch-size distribution, and Figure 11(b) shows results for a deterministic batch size that grows at a rate of 2% after warm-up. In both experiments, $\lambda = 0.07$ and the data pattern is $\text{Periodic}(10, 10)$. These figures demonstrate the robust performance of R-TBS in the presence of varying data arrival rates. Similarly, the average accuracy and robustness over 30 runs resembles the results in Table 1. For example, pick $\lambda = 0.07$ and a $\text{Periodic}(10, 10)$ pattern. Then, the misclassification rate under uniform/growing batch sizes is 1.16x/1.14x that of R-TBS for SW, and 1.47x/1.40x for Unif. In addition, the ES is 1.82x/1.98x that of R-TBS for SW, and 1.76x/1.78x for Unif.

Table 1: Accuracy and robustness of kNN performance

λ	Single Event		P(10,10)		P(20,10)		P(30,10)	
	Miss%	ES	Miss%	ES	Miss%	ES	Miss%	ES
0.05	19.8	17.7	18.2	24.2	17.9	28.2	15.5	31.6
0.07	19.1	18.7	17.4	23.2	17.2	28.1	14.9	31.0
0.10	18.0	20.0	16.6	24.1	16.6	29.9	15.1	31.0
SW	19.2	53.3	19.0	49.8	18.8	47.3	16.5	44.5
Unif	25.6	19.3	25.4	42.3	25.0	43.2	21.0	47.6

Figure 11: Varying batch sizes for kNN classifier

6.3 Application: Linear Regression

We now assess the effectiveness of R-TBS for retraining regression models. The experimental setup is similar to kNN, with data generated in “normal” and “abnormal” modes. In both modes, data items are generated from the standard linear regression model $y = b_1x_1 + b_2x_2 + \epsilon$, with the noise term ϵ distributed according to a $N(0, 1)$ distribution. In normal mode, $(b_1, b_2) = (4.2, -0.4)$ and in abnormal mode, $(b_1, b_2) = (-3.6, 3.8)$. In both modes, x_1 and x_2 are generated according to $\text{Uniform}(0, 1)$ distribution. As before, the experiment starts with a warm-up of 100 “normal” mode batches and each batch contains 100 items.

Saturated samples: Figure 12(a) shows the performance of R-TBS, SW, and Unif for the $\text{Periodic}(10, 10)$ pattern with a maximum sample size of 1000 for each technique. We note that, for this sample size and temporal pattern, the R-TBS sample is always saturated. (This is also true for all of the prior experiments.) The results echo that of the previous section, with R-TBS exhibiting

slightly better prediction accuracy on average, and significantly better robustness, than the other methods. The mean square errors (MSEs) across all data points for R-TBS, Unif, and SW are 3.51, 4.43, 4.02 respectively, and their 10% ES of the MSEs are 6.04, 10.05, 10.94 respectively.

Unsaturated Samples: We now investigate the case of unsaturated samples for R-TBS. We increase the target sample size to $n = 1600$. With a constant batch size of 100, and a decay rate $\lambda = 0.07$, the reservoir of R-TBS is never full, stabilizing at 1479 items, whereas Unif and SW both have a full sample of 1600 items.

For the Periodic(10, 10) pattern, shown in Figure 12(b), SW has a window size large enough to keep some data from older time periods (up to 16 batches ago), making SW’s robustness comparable to R-TBS (ES of 5.86 for SW and 5.97 for R-TBS). However, this amalgamation of old data also hurts its overall accuracy, with MSE rising to 4.17, as opposed to 3.50 for R-TBS. In comparison, the shape of R-TBS remains almost unchanged from Figure 12(a), and Unif behaves as poorly as before. When the pattern changes to Periodic(16, 16) as shown in Figure 12(c), SW doesn’t contain enough old data, making its prediction performance suffer from huge fluctuations again, and the superiority of R-TBS is more prominent. In both cases, R-TBS provides the best overall performance, despite having a smaller sample size. This backs up our earlier claim that more data is not always better. A smaller but more balanced sample with good ratios of old and new data can provide better prediction performance than a large but unbalanced sample.

6.4 Application: Naive Bayes

In our final experiment, we evaluate the performance of R-TBS for retraining Naive Bayes models with the Usenet2 dataset (mlkd.csd.auth.gr/concept_drift.html), which was used in [18] to study classifiers coping with recurring contexts in data streams. This dataset contains a stream of 1500 messages on different topics from the 20 News Groups Collections [21]. They are sequentially presented to a simulated user who marks whether a message is interesting or not. The user’s interest changes after every 300 messages. More details of the dataset can be found in [18].

Following [18], we use Naive Bayes with a bag of words model, and set the optimal parameters for SW with maximum sample size of 300 and batch size of 50. Since this dataset is rather small and contexts change frequently, we use the optimal value of 0.3 for λ . We find through experiments that R-TBS displays higher prediction accuracy for all λ in the range of [0.1, 0.5], so precise tuning of λ is not critical. In addition, there is not enough data to warm up the models on different sampling schemes, so we report the model performance on all the 30 batches. Similarly, we report 20% ES for this dataset, due to the limited number of batches.

The results are shown in Figure 13. The misprediction rate for R-TBS, SW, and Unif are 26.5%, 30.0%, and 29.5%; and the 20% ES values are 43.3%, 52.7%, and 42.7%. Importantly, for this dataset the changes in the underlying data patterns are less pronounced than in the previous two experiments. Despite this, SW fluctuates wildly, yielding inferior accuracy and robustness. In contrast, Unif barely reacts to the context changes. As a result, Unif is very slightly better than R-TBS with respect to robustness, but at the price of lower overall accuracy. Thus, R-TBS is generally more accurate under mild fluctuations in data patterns, and its superior robustness properties manifest themselves as the changes become more pronounced.

7 RELATED WORK

Time-decay and sampling: Work on sampling with unequal probabilities goes back to at least Lahiri’s 1951 paper [20]. A growing interest in streaming scenarios with weighted and decaying items began in the mid-2000’s, with most of that work focused on computing specific aggregates from such streams, such as heavy-hitters, subset sums, and quantiles; see, e.g., [2, 7, 8]. The first papers on time-biased reservoir sampling with exponential decay are due to Aggarwal [1] and Efraimidis and Spirakis [12]; batch arrivals are not considered in these works. As discussed in Section 1, the sampling schemes in [1] are tied to item sequence numbers rather than the wall clock times on which we focus; the latter are more natural when dealing with time-varying data arrival rates.

Cormode et al. [9] propose a time biased reservoir sampling algorithm based on the A-Res weighted sampling scheme proposed in [12]. Rather than enforcing (1), the algorithm enforces the (different) A-Res biasing scheme. In more detail, if s_i denotes the element at slot i in the reservoir, then the algorithm in [12] implements a scheme where an item x is chosen to be at slot $i + 1$ in the reservoir with probability $w_x / (\sum_{j=1}^x w_j - \sum_{j=1}^i w_{s_j})$. From the form of this equation, it becomes clear that resulting sampling algorithm violates (1). Indeed, Efraimidis [11] gives some numerical examples illustrating this point (in his comparison of the A-Res and A-Chao algorithms). Again, we would argue that the constraint on appearance probabilities in (1) is easier to understand in the setting of model management than the foregoing constraint on initial acceptance probabilities.

The closest solution to ours adapts the weighted sampling algorithm of Chao [5] to batches and time decay; we call the resulting algorithm B-Chao and describe it in Appendix D of [16]. Unfortunately, as discussed, the relation in (1) is violated both during the initial fill-up phase and whenever the data arrival rate becomes slow relative to the decay rate, so that the sample contains “overweight” items. Including overweight items causes over-representation of older items, thus potentially degrading predictive accuracy. The root of the issue is that the sample size is nondecreasing over time. The R-TBS algorithm is the first algorithm to correctly (and optimally) deal with “underflows” by allowing the sample to shrink—thus handling data streams whose flow rates vary unrestrictedly over continuous time. The current paper also explicitly handles batch arrivals and explores parallel implementation issues. The VarOpt sampling algorithm of Cohen et al. [6]—which was developed to solve the specific problem of estimating “subset sums”—can also be modified to our setting. The resulting algorithm is more efficient than Chao, but as stated in [6], it has the same statistical properties, and hence does not satisfy (1).

Model management: A key goal of our work is to support model management; see [13] for a survey on methods for detecting changing data—also called “concept drift” in the setting of online learning—and for adapting models to deal with drift. As mentioned previously, one possibility is to re-engineer the learning algorithm. This has been done, for example, with support-vector machines (SVMs) by developing incremental versions of the basic SVM algorithm [4] and by adjusting the training data in an SVM-specific manner, such as by adjusting example weights as in Klinkenberg [19]. Klinkenberg also considers using curated data selection to learn over concept drift, finding that weighted data selection also improves the performance of learners. Our approach of model retraining using time-biased samples follows this

Figure 12: Mean square error for linear regression

latter approach, and is appealing in that it is simple and applies to a large class of machine-learning models. The recently proposed Velox system for model management [10] ties together online learning and statistical techniques for detecting concept drift. After detecting drift through poor model performance, Velox kicks off batch learning algorithms to retrain the model. Our approach to model management is complementary to the work in [10] and could potentially be used in a system like Velox to help deployed models recover from poor performance more quickly. The developers of the recent MacroBase system [3] have incorporated a time-biased sampling approach to model retraining, for identifying and explaining outliers in fast data streams. MacroBase essentially uses Chao’s algorithm, and so could potentially benefit from the R-TBS algorithm to enforce the inclusion criterion (1) in the presence of highly variable data arrival rates.

8 CONCLUSION

Our experiments with classification and regression algorithms, together with the prior work on graph analytics in [27], indicate the potential usefulness of periodic retraining over time-biased samples to help ML algorithms deal with evolving data streams without requiring algorithmic re-engineering. To this end we have developed and analyzed several time-biased sampling algorithms that are of independent interest. In particular, the R-TBS algorithm allows simultaneous control of both the item-inclusion probabilities and the sample size, even when the data arrival rate is unknown and can vary arbitrarily. R-TBS also maximizes the expected sample size and minimizes sample-size variability over all possible bounded-size algorithms with exponential decay. Using techniques from [9], we intend to generalize these properties of R-TBS to hold under arbitrary forms of temporal decay.

We have also provided techniques for distributed implementation of R-TBS and T-TBS, and have shown that use of time-biased sampling together with periodic model retraining can improve model robustness in the face of abnormal events and periodic behavior in the data. In settings where (i) the mean data arrival rate is known and (roughly) constant, as with a fixed set of sensors, and (ii) occasional sample overflows can be easily dealt with by allocating extra memory, we recommend use of T-TBS to precisely control item-inclusion probabilities. In many applications, however, we expect that either (i) or (ii) will be violated, in which case we recommend the use of R-TBS. Our experiments showed that R-TBS is superior to sliding windows over a range of λ values, and hence does not require highly precise parameter tuning; this may be because time-biased sampling avoids the all-or-nothing item inclusion mechanism inherent in sliding windows.

ABSTRACT

Database Management Systems (DBMSes) secure data against regular users through defensive mechanisms such as access control, and against privileged users with detection mechanisms such as audit logging. Interestingly, these security mechanisms are built into the DBMS and are thus only useful for monitoring or stopping operations that are executed through the DBMS API. Any access that involves directly modifying database files (at file system level) would, by definition, bypass any and all security layers built into the DBMS itself.

In this paper, we propose and evaluate an approach that detects direct modifications to database files that have already bypassed the DBMS and its internal security mechanisms. Our approach applies forensic analysis to first validate database indexes and then compares index state with data in the DBMS tables. We show that indexes are much more difficult to modify and can be further fortified with hashing. Our approach supports most relational DBMSes by leveraging index structures that are already built into the system to detect database storage tampering that would currently remain undetectable.

1 INTRODUCTION

DBMSes use a combination of defense and detection mechanisms to secure access to data. Defense mechanisms, such as access control, determine the data granularity and system access granted to different database users; defense mechanisms, such as audit logging, monitor all database activity. Regardless of the defense mechanisms, security breaches are still a legitimate concern – sometimes due to unintentional granting of extra access control and sometimes due to outright hacking, such as SQL injection. Security breaches are typically detected through analysis of audit logs. However, audit log analysis is unreliable to detect a breach that originated from privileged users.

Privileged users, by definition, already have the ability to control and modify access permissions. Therefore, audit logs fundamentally cannot be trusted to detect suspicious activity. Additionally, privileged users commonly have access to database files. Consider a system administrator who maliciously, acting as the root, edits a DBMS data file in a Hex editor or through a programming language, such as Python. The DBMS, unaware of external file write activity taking place outside its own programmatic access, cannot log it, and thus the tampering attack remains undetected.

Current DBMSes do not provide tools against insider threats – in general, a built-in security mechanism is vulnerable to insider attacks. While a DBMS will not be able to detect direct

storage changes, file-level modifications potentially create inconsistencies within the auxiliary data structures maintained by a DBMS. Forensics tools that examine file contents can be used to detect such inconsistencies, and determine if insider threats have taken place. Recently we proposed the first database forensic tool, DBCarver, that can be used to detect deleted data from database pages [31]. However, database forensic tools such as DBCarver merely extract forensic artifacts but do not search for inconsistencies within the data structures maintained by a DBMS.

In this paper, we propose a system, DBStorage Auditor, that detects database file tampering by identifying inconsistencies in storage through a direct inspection of internal database structures. DBStorage Auditor utilizes existing database forensic techniques and expands them to extract additional necessary storage artifacts. These artifacts are then used to detect inconsistencies within indexes and between indexes and tables. The underlying premise of our approach is that all relational databases follow patterns in storage over which the privileged user has little or no control. We inspect these storage patterns to detect unusual activity. We motivate DBStorage Auditor through an example:

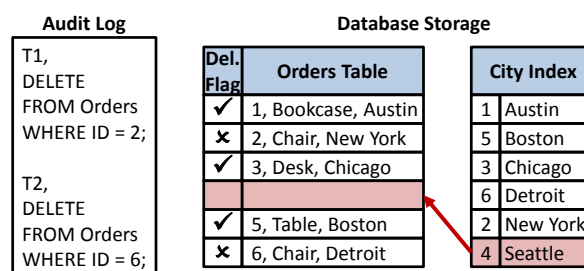

Figure 1: Example attack through DBMS files.

EXAMPLE 1. Malice is the system administrator for a shipping company, FriendlyShipping. Malice is bribed by a competing company to interfere with the orders going to Seattle. Malice **does not** have access to the DBMS, but she **does** have access to the server where the database files reside.

Malice writes a Python script that will open and directly modify the database file containing the Orders table. The script then opens the database file, finds all records containing the string ‘Seattle’, and explicitly overwrites entire records with the NULL ASCII character (decimal value 0).

Figure 1 illustrates the result of Malice’s script actions. Since the record was erased without the DBMS (API has never seen that command) all DBMS security was bypassed, and the operation was never recorded in the log file. When FriendlyShipping investigates the missing Seattle orders, the audit log can only explain deleted orders for (2, Chair, New York) and (6, Chair, Detroit). The audit logs contain no trace of the Seattle order being deleted because it was not deleted but rather wiped out externally.

To simplify in the above example, we have omitted some details of database file tampering, which we expand on later in Section 5. Barring those details in Example 1, the value in the City index

still exists in index storage even though the entire record is erased. Therefore, an inconsistency can be identified by mapping back the index value to the empty gap in table storage. The empty gap in table storage exists because a database only marks a record when it is deleted, and only overwrites the record with data from a newly inserted record. However, making the mapping from the index value to the associated record must be based on the behavioral rules of database storage, such as page and record layout. We use database forensic tools to understand database layout, and using that layout, perform the necessary mapping.

It is not impossible for a scrupulous system administrator to (i) tamper with the index and create a cascade of inconsistencies throughout the index structure, or (ii) for an attacker who has privileges to modify database files to acquire privileges to suspend or kill logging mechanisms at the operating system level if necessary, or (iii) for a knowledgeable adversary to easily avoid corrupting storage and keep checksum values consistent. However, in spite of increased level of threat, we repeatedly show that accurate knowledge about data layout can be used to gather evidence and prove if any malicious activity has taken place.

Previously we developed an approach to detect malicious activity when DBMS logging is disabled [28]. In this approach we analyzed unlogged activity (executed through a proper DBMS API) but strictly assumed that database files were not exposed to tampering. In this paper, we address the tampering vulnerability where the database files are physically altered. Developing an auditing system for DBMSes is part of our larger goal to open up the database system and its storage to users, for performance and forensics investigation.

The rest of the paper is organized as follows: Section 2 covers related work. Section 3 discusses concepts of database storage used throughout the paper. Section 4 defines the adversary we seek to defend against. Section 5 details how to perform database file tampering. Section 6 provides an overview of DBStorageAuditor. Section 7 describes how we utilize database forensics. Section 8 addresses index tampering. Section 9 proposes a method to organize carved index output making our system scalable. Section 10 discusses how to detect file tampering using inconsistencies between carved index data and table data. Section 11 provides a thorough evaluation of our system.

2 RELATED WORK

This paper focuses on the detection of database file tampering. Therefore, we discuss work related to protecting DBMSes against privileged users as well as work that detects regular (non-DBMS) file tampering. We outline why existing file tampering and anti-forensic methods are inapplicable to database files.

2.1 Database Auditing and Security

Database audit log files are of great interest for database security because they can be used to determine whether data was compromised and what records were accessed. Methods to verify log integrity have been proposed to detect log file tampering [18, 25]. Pavlou et al. expanded upon this work to determine the time of log tampering [17]. Sinha et al. used hash chains to verify log integrity in an offline environment without requiring communication with a central server [24]. Crosby et al. proposed a data structure, history tree, to reduce the log size produced by hash chains in an offline environment [2]. Rather than detecting log tampering, Schneider and Kelsey developed an approach to make log files impossible to parse and alter [23]. An event log can be generated using triggers, and the idea of a `SELECT` trigger

was explored for the purpose of logging [3]. ManageEngine’s EventLog Analyzer provides audit log reports and alerts for Oracle and SQL Server based on actions, such as user activity, record modification, schema alterations, and read-only queries [13]. We previously described a method to detect inconsistencies between storage and log files, allowing tampering detection when logging was disabled (i.e., when an operation was excluded from the log) [28]. All of this work assumes that database storage can not be altered directly – an action which bypasses logging mechanisms.

Network-based monitoring methods have received attention in audit log research because they provide independence and generality by residing outside of the DBMS. IBM Security Guardium Express Activity Monitor for Databases [9] monitors incoming packets for suspicious activity. Liu et al. [12] monitored DBAs and other privileged users by identifying and logging network packets containing SQL statements. The benefit of monitoring activity over the network and, therefore, beyond the reach of DBA’s, is the level of independence achieved by these tools. On the other hand, relying on network activity ignores local DBMS connections and requires intimate understanding of SQL commands (i.e., an obfuscated command can fool the system).

2.2 Database Forensics

Stahlberg demonstrated the retention of deleted data and proposed techniques to erase data for a MySQL DBMS [26]. While this work was only ever implemented for MySQL, it validates our threat model by imposing custom DBMS file modifications.

Database page carving [31] is a method for reconstructing the contents of a relational database without relying on the file system or DBMS. Page carving is inspired by traditional file carving [6, 21], which reconstructs data (active and deleted) from disk images or RAM snapshots without the need for a live system. The work in [29] presented a comparative study of the page structure for multiple DBMSes. Subsequent work in [30] described how long forensic evidence resides within a database even after being deleted or reorganized. While a multitude of built-in and third party recovery tools (e.g., [15, 19, 20]) aim to extract database storage, none of these tools are helpful for forensic analysis because they can only recover “active” data. Forensic tools, such as Sleuth Kit [1] and EnCASE Forensic [4], are commonly used by digital investigators to reconstruct file system data, but they are not capable of parsing database files. A database forensic tool (just like a forensic file system tool) should also reconstruct unallocated pieces of data, including deleted rows, auxiliary structures (indexes) or buffer cache space.

Figure 2: DBCarver architecture.

Our storage analysis relies on DBCarver tool described in [31], which was revised to process additional artifacts for this paper. Figure 2 provides an overview of DBCarver, which consists of two main components: the parameter collector(A) and the carver(F).

The parameter detector loads synthetic data into a DBMS(B), captures storage(C), deconstructs pages from storage, and describes the page layout with a set of parameters which are stored in a configuration file(E) – a text file that captures page-level layout information for that particular DBMS. These configuration files are used by the carver(F) to reconstruct DBMS content from disk images, RAM snapshots, or any other input file(G). The carver returns storage artifacts(H), such as user records, metadata describing user data, deleted data, and system catalogs.

2.3 File Tampering and Anti-Forensics

One-way hash functions have been used to detect file tampering at the file system level [7, 11]. However, we expect database files to be regularly modified by legitimate operations. Distinguishing a malicious tampering operation and a legitimate SQL operation would be nearly impossible at the file system level without knowledge of metadata in DBMS storage. Authenticating cached data on untrusted publishers has been explored by Martel [14] and Tamassia [27]. Their threat model defends against an untrusted publisher that provides cached results working with a trusted DBMS and, while our work addresses an untrusted DBMS.

Anti-forensics is defined as a method that seeks to interfere with a forensic process [8]; file tampering threat model we address in this paper exhibits anti-forensics behavioral properties. Two traditional anti-forensics techniques are data wiping and data hiding [5, 10]: 1) data wiping explicitly overwrites data to delete it rather than mark it as deleted, 2) data hiding seeks to hide the message itself. We are not aware of any existing literature that addresses anti-forensics within DBMSes [22]; we consider adding or erasing data through file tampering (that bypasses DBMS itself) to be the equivalent of anti-forensics for DBMSes.

Figure 3: Example page headers.

3 BACKGROUND

The security threats we consider in this paper affect the lowest level of database storage (details of which are hidden from the users by design). In this section, we briefly generalize storage of the RDBMS row-store pages and define terminology used throughout this paper. The concepts formulated in this section apply to (but are not limited to) IBM DB2, SQL Server, Oracle, PostgreSQL, MySQL, Apache Derby, MariaDB, and Firebird.

3.1 Page Layout

When DBMS data is accessed or modified through an API, the DBMS implements data changes within pages and maintains a variety of additional metadata. While each DBMS employs its own storage engine, there are many conceptual commonalities between DBMSes in how data is stored and maintained. Every DBMS uses fixed-size pages with three main structures: header, row directory, and row data.

A DBMS page header stores metadata describing user records stored in the page. The metadata of interest (to this paper) are the checksum, object identifier, page identifier, free space pointer, and record count. Figure 3 demonstrates an example of how this metadata could be positioned in an 8K page. The checksum(A) detects data corruption within a page; whenever a page is modified, the checksum is updated. The object identifier(B) represents the database object to which the page belongs (the object name is stored in a separate system table). In Figure 3, Pages 1-3 have the object identifier 101, and Page 4 has the object identifier 105. The page identifier(C) is unique to each page for either an object, a file, or across all files. In Figure 3, the page identifier is unique for each object because the value 1 occurs for both objects 101 and 105. The free space pointer(D) references unallocated space within the page where a new record can be added. If the page is full, the free space pointer is NULL (decimal value 0). In Figure 3, Page1 is full since it has a NULL free space pointer, while Pages 2, 3, and 4 point to unallocated space. The record count(E) refers to the number of *active* records in a page. If a record is deleted, the record count will be decremented by one, and if a record is added to a page, it will be incremented by one. In Figure 3, Page1 has 80 active records, and Page2 has 81 active records.

Figure 4: Example row directory and row data layouts.

The row directory stores pointers to each page record (row) – when a record is added to a page, a pointer is added to the row directory. Figure 4 shows one example of how the row directory (A) could be positioned; the row directory in this example has two pointers referencing records within the row data.

The row data stores the user data along with additional metadata. Figure 4 shows an example of how the row data may be structured (with some minor DBMS-specific variations). Each record stores the user data values (E), a row delimiter that separates the records (B), the number of columns for the record (C), and the size of each string (D).

Deleted Data. When a record is deleted, a DBMS either overwrites the row directory pointer for that record or marks the record itself in the row data – it is important to note that the record entry is not erased. Figure 4 shows an example of when the row metadata is marked for a deleted record (F). Deleted records become unallocated space, and DBMS settings and operations dictate when records are (eventually) overwritten by new data.

Index Pages. Index value-pointer pairs are stored in pages, which are similar to table pages including a header, row directory, and row data. The only significant difference between table and index pages is the layout of records – index pages store value-pointer pairs in the row data. Furthermore, in practice, index values are *not* marked as unallocated space when a corresponding table record is deleted. Stale index values persist in storage, typically until the B-Tree is explicitly rebuilt by the user and long after the table record was overwritten.

4 THREAT MODEL

In this section, we define the attack vectors, different possible adversary types, and the privileges we expect them to wield. We consider two types of privileged users: database administrator (DBA) and system administrator (SA). A DBA can issue privileged SQL commands against the DBMS including disabling logs or granting privileges to users. However, a DBA would not have administrative access to the server OS. The SA has administrative access to the server OS including the ability to suspend processes and read/write access to all files, but no access to privileged SQL commands in the DBMS. The SA can still have a regular DB user account without affecting our assumptions.

Since a DBA can bypass DBMS defense mechanisms, detection mechanisms are best suited to identify anomalous behavior. An audit log containing a history of SQL commands is accepted as one of the best detection mechanisms for a DBMS. In Section 2, we discussed prior work designed to prevent audit log tampering and detect malicious behavior in the event that logging was disabled. In this paper, we focus on a detection mechanism for a user often ignored in DBMS security, the SA.

The SA can bypass all DBMS security defense and detection mechanisms by reading and editing a database file with a tool other than the DBMS. For example, a SA could use Python to open a file and change the value 'Hank' to 'Walt'. In Section 5 we discuss additional steps that must be considered to successfully perform such an operation, but it can ultimately be achieved. Since this operation occurs outside of the DBMS, it bypasses all DBMS access control, and it will not be included any of the DBMS log files. Furthermore, one can assume that the SA would have the ability to suspend any logging mechanism in the server OS. Although changes to a file will also be recorded in the file system journal, the SA has the ability to turn off journaling to the file system by using `tune2fs` on Unix or the `FSCTL_DELETE_USN_JOURNAL` control code on NTFS (Windows). However, the file system must be shutdown first in order to prevent possible corruption. Therefore, the SA may have to effect a shutdown of the DBMS before making changes to the database files. The shutting down and restarting of the database instance and the system will generate events that are logged; however, as mentioned earlier, the SA can turn off system logging easily. Moreover, the SA could revise the DBMS log in order to hide evidence of the shutdown and restart. Hence, it would be somewhat involved but not difficult for a SA to cover his/her tracks when tampering with a DBMS file.

5 FILE TAMPERING

The threats to data we consider in this paper occur at the OS level outside of DBMS control. In this section, we formulate the threat and introduce concepts and categories of tampering.

A DBMS allows users and administrators to access and modify data through an API. Access control guarantees that users will be limited to data they are privileged to access. In this section, we discuss how an adversary can perform file tampering. To limit the scope of this paper, we assume that file tampering involves user data and not metadata (changing metadata can easily damage the DBMS but that will not alter any of its records). We define user data as records created by the user or copies of record values that may reside in auxiliary structures (e.g., indexes). File tampering actions that we discuss in this section ultimately produce one of two results in storage: 1) **Extraneous data** is a record or a value that has been added through file tampering or 2) **Erased**

data is a record that has been explicitly overwritten (rather than marked deleted by a command as described in Section 3).

Three things must be considered when performing database file tampering: 1) page checksum, 2) write lock on files, and 3) dirty pages. In Section 3, we discussed the functionality and placing of the page checksum. Figure 5 shows three different page alterations, in all of which the checksum is (also) updated. Some DBMS processes hold write locks on the database files. Therefore, tampering would require that the attacker release or otherwise bypass OS file write locks. DBMSes do not immediately write pages back to disk after they are modified in the buffer cache. That is significant because a maliciously altered page on disk can be overwritten when a dirty page is flushed to disk – or, alternatively, a dirty page could be altered directly in RAM instead (bypassing file locks that way).

Write-Locks. The file locking system API, through the `fcntl` system call in Unix, is set up so that a process can prevent writes to (as well as reads from) a file that it has locked successfully. An attacker can potentially cause the process holding the lock, in this case the DBMS, to release the lock. Otherwise, a sophisticated attacker with root privileges can release the lock without involvement of the process by using kernel code. Once the lock is released, the attacker would lock the file, tamper with its content, and then release the lock. The DBMS would not receive any signal or other indication of the tampering and could continue to use the file as if it were locked after the attacker releases the lock. While the attacker holds the lock, however, DBMS access to the file would be suspended. In order to prevent the DBMS from discovering this condition, the attacker could suspend the DBMS process temporarily until the tampering has been completed. An attacker with root privileges could also mark memory used by the DBMS as shared and tamper directly with memory.

Data Encryption. Different levels of encryption can be employed to protect database files, but they can ultimately be bypassed by an adversary with SA privileges. It is reasonable to assume that the SA would have the ability to decrypt any data that has been encrypted at the OS level. The SA would most likely not have the privileges to decrypt any internal database encryption. However, individual (value or record based encryption) is still subject to tampering since the metadata describing the encrypted values is still readable. Furthermore, column-level encryption values are decrypted when they are read into memory making it possible to map the decrypted values in memory back to the encrypted values in persistent storage.

5.1 Value Modification

The first category of file tampering action we consider is value modification. Value modification is logically similar to a SQL `UPDATE` command; this type of tampering results in extraneous data. Storage space and value encoding (see Section 3) are the main considerations when modifying a value.

If a modified value requires the same storage space as the original entry, no metadata needs to be updated. If the newly modified value requires less storage than the original, then metadata needs to be modified, and other values in the record may need to be shifted. For example, many DBMSes explicitly store string sizes on page – e.g., changing 'Hank' to 'Gus' requires metadata value with the size of the string to be changed from 4 to 3. Furthermore, if the modified value is not the last column in the record, all other columns must be shifted by one byte. Only the columns in the modified record need to be shifted; other records in the page can

remain as-is, leaving a gap (1 byte in our example). Shifting all other records in the page to close the gap would require all of the corresponding row directory addresses and relevant index pointers to be updated. If a value is modified to a value that requires more storage space, the old version of the record must be erased and the new version of the record must be appended to the table. These operations are discussed in the remainder of this section. Shifting the following records to accommodate a large value modification is not practical – unless the modified value happens to be in the last record on the page (and there is free space at the end of the page).

	(1) Starting Page	(2) Value Modification	(3) Record Addition	(4) Record Wiping
0	Checksum	Checksum'	Checksum'	Checksum'
	(A) 8100	8100	8050	8100
	(B) 2	2	3	1
	(C) 8150	8150	8150	8100
	8100	8100	8100	
	Free Space	Free Space	Free Space	Free Space
			44	
			2	
			4 Carl	
			7 Chicago	
8100	(D) 44	44	44	44
	(E) 2	2	2	2
	(F) 3 Bob	3 Bob	3 Bob	3 Bob
8150	(G) 6 Boston	6 Boston	6 Boston	6 Boston
	44	44	44	
	2	2	2	
	5 Alice	4 Andy	5 Alice	
8192	6 Austin	6 Austin n	6 Austin	0

Figure 5: Database file tampering examples.

Figure 5.2 shows an example of a value changed to a smaller size. Since ‘Andy’ is one byte smaller than ‘Alice’, the column size must be changed from 5 to 4. Furthermore, the name is not the last column so next column (‘Austin’) is shifted by one byte, which overwrites the ‘e’ at the end of ‘Alice’ and leaves an unused ‘n’ character from ‘Austin’.

5.2 Record Addition

The next file tampering action we consider is new record addition, which is logically similar to a SQL `INSERT` command. This type of file tampering results in extraneous data generated within the DBMS. When adding a record to a file, metadata in the row data, row directory, and page header must be considered along with the correct value encodings.

When a record is appended to an existing page, the structure of the record must match the proper active record structure for that DBMS. Section 3 discusses metadata that a DBMS uses to store records. For the DBMS to recognize a newly added record, a pointer must be appended to the page row directory. Finally, the free space pointer must be updated and the active record count (if used by the DBMS in question) must be incremented.

Figure 5.3 shows an example of the record (‘Carl’, ‘Chicago’) added to the page. Along with the values themselves, additional metadata is included in the row data. The size of each column, 4 and 7 bytes, is included, the column count, 2, and the row delimiter, 44. Next, a pointer, 8050, is added to the row directory, and the record count is updated to 3. Finally, the free space address is updated since the record was added to free space of the page.

5.3 Record Wiping

The final tampering action category we discuss is record wiping. Record wiping is logically similar to a SQL `DELETE` command, except that it fully erases the record. A proper SQL `DELETE` command will merely mark a record as deleted; record wiping explicitly overwrites the record to destroy the data, even from a forensic recovery tool. Record wiping erases data with no forensic trace as there is no indication that a record existed in a place where it was overwritten. Wiping a record from a file is essentially the reverse operation of adding a record to a file: the metadata in the row data, row directory, and page header must all be altered.

When a record is overwritten in a page, the entire record (including the metadata) is overwritten with the NULL ASCII character (a decimal value of 0). Next, the row directory pointer must also be overwritten in the same way. Finally, the free space pointer must be updated and the active record count (if used by the DBMS) must be decremented.

Figure 5.4 shows an example of the record (‘Alice’, ‘Austin’) erased from the page. Every byte used for the values and their metadata (column sizes, column count, and row delimiter) is overwritten with the decimal value 0. The row directory address for that row is erased and the row directory is defragmented. Finally, the record count is updated to 1.

Record Removal. Rather than explicitly overwriting a record, the record metadata could also be marked to mimic a SQL `DELETE`. We define such changes as a record removal (versus record wiping). We do not address record removal in this paper because such unlogged action can be detected by our previous work in [28] by comparing and flagging inconsistencies between DBMS storage forensic artifacts and the audit logs.

6 APPROACH OVERVIEW

Our goal in this paper is to eliminate a major security vulnerability stemming from file tampering; our solution is envisioned as a component of a comprehensive auditing system that employs database forensics. We have previously built a tool that detects malicious activity when database logging was disabled [28] by comparing forensic artifacts and database logs. That approach relied on forensic artifacts left by SQL commands and assumed no OS level file tampering. DBStorageAudit_{tor} finds inconsistencies that were done by direct file modification. Future work, such as recovering a time line of events or user attribution, would involve expanding upon the current components to the system.

The remainder of the paper describes our system to detect database file tampering, DBStorageAudit_{tor}, followed by an experimental evaluation in Section 11. Figure 6 provides an overview of DBStorageAudit_{tor}, which consists of four components: forensic extraction(A), index integrity verification(B), carved index sorting(C), and tampering detection(D).

The forensic processing component is based on the forensic tool DBCarver [31] described in Section 2. DBCarver retrieves from storage all table records (including deleted records), record metadata, index value-pointer pairs, and several additional storage artifacts. We discuss new functionality that was added to DBCarver for this paper in Section 7 (e.g., a page checksum extraction and comparison, a generalized approach to pointer deconstruction for several RDBMSes).

We first verify the integrity of indexes (discussed in Section 8) because indexes are used later to detect tampering of table data, so it is critical to verify index structure integrity. To achieve that, we evaluate the B-Tree in storage, consider corrupt data that

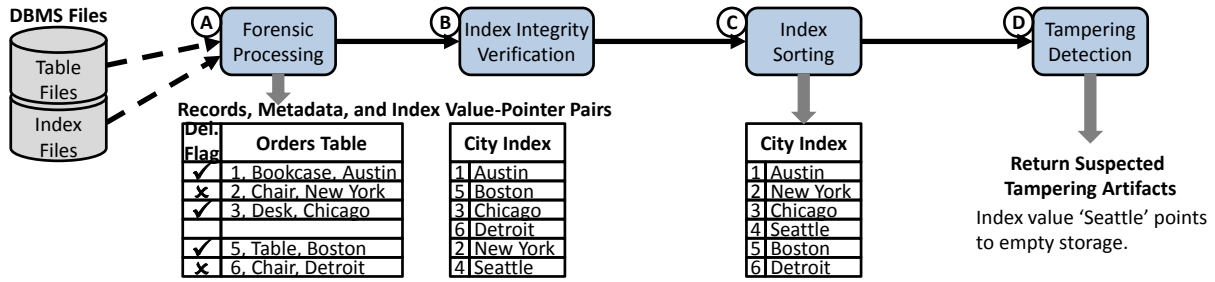

Figure 6: Architecture of the DBStorageAuditor.

matches B-Tree organization, and check for traces of an index rebuild (e.g., *REORG*, *VACUUM* – depending on a DBMS).

We cannot assume that index artifacts can be fully stored in RAM while matching index values to table records. Therefore, the carved index sorting component discussed in Section 9 pre-processes index artifacts to make DBStorageAuditor approach scalable. We approximately sort the index values based on their pointers which correspond to the physical location of records in a file and improves the runtime the matching process.

Finally the tampering detection component discussed in Section 10 detects cases of extraneous and erased data in storage. If a record and its artifacts can not be reconciled with index value-point pairs, such entries are flagged and returned to the user as suspected file tampering.

7 FORENSIC ANALYSIS

Our proposed analysis relies on an expanded version of DBCarver [31] to extract database storage artifacts that can not be queried using the DBMS. These artifacts include record metadata, deleted records, and index value-pointer pairs. In this section, we discuss the addition of a checksum comparison and generalized pointer deconstruction to DBCarver.

7.1 Checksum Comparison

In Section 3, we defined the checksum stored in the page header. Whenever data or metadata in a page is updated, either legitimately or through data tampering, the checksum must be updated accordingly. If the checksum is incorrect, the DBMS will recognize the page as corrupt. This will result in warnings as well as data loss ranging from page to the table or the entire database instance. Therefore, we can assert that if a checksum did not change between time T1 (previous inspection) and T2 (current inspection), then the page has not been modified and the records have not been exposed to tampering.

We implemented a dictionary of checksums taken from the DBMS pages that are to be evaluated by DBCarver (it is possible to inspect any subset of the DBMS for tampering signs – focusing only on data-sensitive tables). Our dictionary stores the checksum values, where the object identifier and page identifier (Section 3) were the key and the checksum was the value. The checksum dictionary should be stored off-site so it is not at risk of tampering.

If the checksum has changed for a given page, the entire page must be inspected and validated by DBCarver. If the checksum did not change for a page, only page metadata was necessary to reconstruct. The metadata is needed to avoid false-positives in Algorithm 2. Some DBMSes (e.g., Oracle, MySQL) allow the page checksum to be disabled. If the checksum is disabled or believed to have been disabled at some point, then a checksum comparison is unreliable and all data must be carved and inspected.

7.2 Index Carving and Pointer Deconstruction

DBStorageAuditor uses index value-pointer pairs to identify inconsistencies in DBMS storage. Therefore, the value-pointer pairs must be inspected. DBMSes do not allow indexes to be queried directly (i.e., indexes can not appear in the *FROM* clause) which is why we use DBCarver to retrieve index contents. However, the pointer parsing by DBCarver was limited and specific to each DBMS; we developed a generalized approach to pointer deconstruction allowing DBStorageAuditor to be compatible with any investigated RDBMS.

We performed an analysis of pointers for 7 commonly used RDBMSes. Table 1 lists these RDBMSes and summarizes our conclusions. We found that all of these DBMSes, except for MySQL, stored a PageID and a Slot#. By default, MySQL creates an indexed organized table (IOT) so the pointer deconstruction process is slightly different. We address index pointers for IOTs later in this section. The PageID refers to page identifier that is stored in table page header (Section 3). The Slot# refers to a records position within a page. SQLServer and Oracle both store a FileID, which refers to file in which the page is located. The DBMSes that do not include a FileID in the pointer, use a file-per-object storage architecture (i.e., each table and index are stored in different files). The FileID for these pointers is the ObjectID or it can be mapped back to the ObjectID if the object name is the file name. Thus, an index pointer can be deconstructed into a FileID, PageID, and Slot# to map a value back to a table record location. Index pointers are typically the same as the internal DBMS row identifier pseudo-column.

DBMS Version	FileID	PageID	Slot#
SQLServer	Yes	Yes	Yes
Oracle	Yes	Yes	Yes
ApacheDerby	No	Yes	Yes
PostgreSQL	No	Yes	Yes
Firebird	No	Yes	Yes
DB2	No	Yes	Yes
MySQL	No	Yes*	No

*The pointer references the second level of an IOT.

Table 1: Pointer Deconstruction.

Figure 7 demonstrates how index values are mapped back to the table records through our generalized pointer deconstruction. For each index value(A), the pointer stores a PageID(B) and Slot#(C). The pointer PageID(B) corresponds to the page identifier(D) in the table page header. The pointer Slot#(C) corresponds to the row directory address(E) in the table page. For example, the pointer for 'Austin' stores PageID = 8 and Slot# = 12. To find the record, the table page with identifier = 8 is found and the 12th row directory address is used to locate the record (68, 'Alice', 'Austin') within the page.

Figure 7: An example of mapping index values to a record.

Index Organized Tables. While MySQL was the only evaluated DBMS that created IOTs by default, IOTs are commonly used in other DBMSes under different names (e.g., IOT in Oracle, Included Columns in SQL Server) so we incorporated their pointer deconstruction. The pointer for a secondary index built on an IOT is made of a PageID that references a page one level above the IOT B-Tree leaf page, and the primary key value. The PageID for the IOT leaf page can then be retrieved from the pointer stored in the second level of the B-Tree. After performing this additional IOT B-Tree access, we can associate every secondary index value with a PageID and a primary key value, where the PageID references an IOT leaf page and the primary key value replaces the Slot#. Figure 8 illustrates how a secondary index value can be mapped back to an IOT record. We have the same index on *City* and the same records from Figure 7. However, the records are now stored in an IOT, and we now have a B-Tree page one level above the IOT leaf pages. The *City* index values(A) now store the PageID for IOT B-Tree page(B) and the primary key values(C) as the pointer. The IOT B-Tree page stores primary key values(F) and leaf PageIDs(G) as the pointer. For example, the pointer for 'Austin' stores PageID 20 and the primary key 68. This directs us to the IOT B-Tree page with PageID 20 and the value-pointer pair (57, 8). The IOT B-Tree pointer tells us 'Austin' is in the leaf page with PageID 8 and the primary key value 68.

Figure 8: Mapping index values to an IOT record example.

8 VERIFYING INDEX INTEGRITY

It is plausible for an adversary to tamper with the relevant index values in an attempt to conceal evidence of file tampering. In this section, we address several types of index tampering, and how to detect such activity.

8.1 B-Tree Integrity Verification

If the attacker changes a value, adds a record, or wipes a record from a table, he may also perform a complimentary operation in the index. For example, 'Dan' was changed to 'Jane' in a table record could also be similarly modified in the index leaf node.

Interestingly, this type of activity creates inconsistencies in the index B-Tree that do not arise in the table. We consider the case where an index value is changed in-place and the case where index value was erased (and possibly reinserted into the correct position in the B-Tree). If the index value was changed in-place, it would appear out-of-order in the leaf of the B-Tree. If the index value was erased, it creates an uncharacteristic blank space between values within the leaf page, which *never* occurs naturally.

8.2 The Neighboring Value Problem

An index value may sometimes be altered without violating the correct ordering of the B-Tree. For example, in Figure 9 'Dan' is changed to 'Dog' preserving a correct value ordering of the Name index. This example shows how a table and an index can be altered without producing an inconsistency.

We build a function-based index that stores the hash value of column(s) to thwart tampering that involves neighboring range values. The values in hash-index will have a different ordering than the values in the secondary index so a neighboring value can occur in one, but not both. Figure 9 shows an example of how a hash index can be used to detect index tampering the involves neighboring values. In both the table and the Name index, the value was changed to 'Dog.' Changing the value in the Name index preserved the correct ordering. However, changing the value in the hash-index would result in an incorrect ordering since the values are organized differently. Function-based indexes are supported by many major DBMSes (e.g., IBM DB2, Oracle, and PostgreSQL); a computed column can be used for DBMSes that do not support function-based indexes (e.g., MySQL and Microsoft SQL Server).

Figure 9: Preventing the neighboring value problem.

8.3 SQL Index Rebuild

Although we assume that the attacker does not have privileges to rebuild an index through SQL, the index may nevertheless be rebuilt as part of routine maintenance. If an index is rebuilt post tampering, the reconstruction of the index will eliminate any inconsistencies (extraneous or erased data) between the table and the index because indexes will be built anew using the *current* table state. However, when an object is rebuilt, a new object is created and artifacts (discarded pages) from the old object are left behind in storage. Many of the pages from the old index are likely to be overwritten, but some pages are going to persist in storage following the rebuild [30].

Pages left behind from an index rebuild can serve as separate evidence to detect tampering. The old index version (or the parts recovered) can be treated as a separate index (I_{t-1}) from the newly rebuilt version (I_t). While the old index version does not

contain a complete set of values due to having been partially overwritten, it can still be used to detect tampering. This would be applicable when auditing is not performed at regular intervals relative to the frequency of index rebuilds.

8.4 Manual Index Rebuild

In order to deceive DBStorage Auditor, an attacker would have to completely rewrite the entire index (or at least several different pages in it). While such operation is possible, performing it successfully poses several major challenges. We emphasize that typical security solutions are designed to greatly increase the level of difficulty to perform an attack, rather than create an absolute defense.

Section 5 discussed cached dirty page problem when physically modifying a page. Moreover, dirty index pages can introduce additional complications. First, a given index page is more likely to have a dirty version cached compared to a table page. An index page is not only modified when the indexed column is updated, but the index pointer must also be updated if an update causes a record to be written to a new location. Furthermore, index pages store significantly more values than table pages, increasing their chance to be modified. Second, as the index changes, the database may reorganize the B-Tree structure (e.g., page split). As parts of the index are rebuilt, pages are likely to be written to new locations in a file. We note that the physical order of a B-Tree does not reflect the logical order of the B-Tree. Third, the attacker may have to discover the physical location of other connected index pages (i.e., just finding the page with needed value is insufficient, several parts of the B-Tree would need to be reconstructed). Index leaf pages point to the next logical page in the B-Tree and sometimes to the previous page as well. This means that if a logically adjacent page is rebuilt and written to a new location, then a modified index page would need to reflect that change. Therefore, the attacker would need to be aware of all internal B-Tree structure changes to guarantee a successful manual index rebuild. Finally, if a function-based index storing a hash value exists, we assume that an SA would not have knowledge of this function. Therefore, inconsistencies would still arise in any attempts to manually rewrite the index.

9 INDEX SORTING

When tables and indexes are carved, the data is extracted based on the physical location within the files. Therefore, the relationship between the ordering of the carved table records compared to the index values is random, with a possible exception of a clustered index (it is common for a clustered index to be manually updated, such as PostgreSQL with VACUUM command). Assuming that the index can not be fully loaded into RAM, expensive random seeks must be performed to map index values to table records. In this section we propose a method to reorder the index to make the process of matching index values and table records scalable.

As demonstrated in Section 7, index pointers correspond to the physical position of the table records. Therefore, sorting the index values by the pointers produces the same ordering for index values and table records. Carved table records and index values are then read sequentially, similar to a merge join process.

For an index that is too large to fit into memory, sorting the index pointers can be a costly operation. If we assume that N table pages will be read into memory when detecting table tampering (Section 10), then index values need to be sorted across every N pages, but values do not need to be sorted within N pages.

We call each set of index values that belong in N table pages a **bucket**. We perform approximate sorting by re-ordering index values across buckets but not within buckets.

For each index bucket, we record the minimum and maximum table page identifier. If an index value is in the range of page identifiers for a bucket, the page identifier, slot number, and index value are stored in that bucket. When table pages are read for table tampering detection, the relevant bucket(s) are read into memory using the table page identifier and the index bucket minimum and maximum values.

Figure 10 shows an example of an index that is approximately sorted on the pointer. For each value in the index, there is a pointer that contains a PageID and a Slot#. We first create a set of buckets where each bucket contains 1000 PageIDs. We read the carved index data, and assign a value to the appropriate bucket using the pointer. For example, the first and second index values 'Alex' and 'Bob' belong in bucket #2 because their PageIDs, 2000 and 1002 are between the minimum and maximum PageID range for the bucket. We then store the PageID, Slot#, and Value in the bucket. 'Carl' has a PageID 5 so that value belongs in bucket #1. Bucket #2 demonstrates that PageIDs do not need to be sorted within the bucket. Furthermore, we see that PageID 2000 in bucket #2 has two values. This can occur as a result of legitimate SQL operations that create stale index values.

Carved Index			Approximately Sorted Index				
Value	Pointer		Bucket #	PageID Min/Max	PageID	Slot #	Value
Alex	2000	1	1	1 - 1000	5	33	Carl
Bob	1002	2	2	1001 - 2000	2000	1	Alex
Carl	5	33			1002	2	Bob
Dan	4400	12			1001	1	Joe
Jane	3050	20				2	Pat
Joe	1001	1	3	2001 - 3000	None		
Kate	1002	1	4	3001 - 4000	3050	20	Jane
Pat	1001	2	5	4001 - 5000	4400	12	Dan
Sam	2000	1					

Figure 10: An approximately sorted index example.

Our current implementation does not use the FileID even when it is stored in the pointer. We assume that each table is stored in a single file, and that the user has directed DBStorage Auditor to the relevant table and index files. DBMS-specific system tables would allow us to connect FileID to the information on target table and index files.

Index Organized Tables. Approximately sorting secondary indexes for index organized tables (IOT) is a slightly different process. When an IOT is used, the secondary index pointer is made up of a PageID that references a second level B-Tree page and the primary key value instead of a PageID that references the table and a Slot#. To sort the secondary index values, the second level BTree pages from the primary key is used to retrieve the table PageIDs for each value. Furthermore, the primary key value is now used in place of the Slot#.

The cost of approximate sorting is dependent on the amount of available memory. A bucket must fit into memory. Fewer buckets results in quicker bucket assignment for values, but buckets will be larger requiring more memory. In Section 11.2 we provide costs of approximately sorting an index.

10 DETECTING TABLE TAMPERING

In Section 5 we discussed how database files, specifically tables, are vulnerable to tampering. We propose using the validated indexes (Section 8) to verify the integrity of table records in storage. Earlier in this paper, we classified data tampering that

involves changing a value or adding records as extraneous data, and we classified data tampering that involves wiping records as erased data. In this section we present and discuss algorithms to detect both extraneous and erased data.

10.1 Extraneous Data Detection

Extraneous data is a record or a value that has been added to a table through file tampering. Since extraneous data is not added using the DBMS, it is not reflected in the indexes. Therefore, if a record does not have *any* corresponding index pointer, then the entire record is suspected of having been added through file tampering. Any table with a primary key can be tested because an index is automatically created for a primary key constraint. Similarly, if a table value does not match an index value with the corresponding pointer, then the value is assumed to have been modified through file tampering. This validation test does require that an index exist on the column(s). We use the carved data from Section 7 and an approximately sorted index (Section 9) that was not been subject to tampering (Section 8).

Algorithm 1 describes how to detect extraneous data. First, we read N table pages at a time for evaluation; we then scan the approximately sorted index buckets for the relevant table page identifiers and read the index pages from the relevant bucket(s). For every record in the N table pages, we find the corresponding index pointer. If an index pointer does not exist, this record is added to a list of likely extraneous data. If an index pointer does exist for a record, the indexed column is compared to the index value(s) for that pointer (there may be more than one index value per pointer for legitimate reasons). If the table value is not in the set of index values, then this value is added to a list of likely extraneous data. This is evidence of a value that has been changed. After all table pages have been read and all records evaluated, the resulting extraneous data list is returned to the user.

Algorithm 1 Extraneous Data Detection

```

1:  $Table \leftarrow$  carved table data: PageIDs, Slot #s, and Records.
2:  $N \leftarrow$  the number of table pages to be read.
3:  $SortedIndex \leftarrow$  the approximately sorted index (Section 9).
4:  $Flag \leftarrow$  an empty list to store extraneous data.
5: for each  $NPages \in Table$  do
6:    $MinPID \leftarrow$  the minimum page ID from  $NPages$ .
7:    $MaxPID \leftarrow$  the maximum page ID from  $NPages$ .
8:    $Indexes \leftarrow$  an empty list to store index pages.
9:   for each  $Bucket \in SortedIndex$  do
10:    if  $(MinPID \in Bucket) \vee (MaxPID \in Bucket) \vee$ 
       $(MinPID < Bucket \wedge MaxPID > Bucket)$  then
11:       $Indexes.append(Bucket)$ 
12:    for each  $Rec \in NPages$  do
13:       $RecPtr \leftarrow Rec.PageID.Slot\#$ 
14:      if  $RecPtr \in Indexes.PageID.Slot\#$  then
15:        if  $Rec.Val \notin Indexes.PageID.Slot\#.Vals$  then
16:           $Flag.append(['ModVal', RecPtr, Rec, Val])$ 
17:        else
18:           $Flag.append(['HiddenRecord', RecPtr, Rec])$ 
19: return  $Flag$ 

```

10.2 Erased Data Detection

Erased data is data explicitly wiped from table storage through file tampering. Deleted records are likely to be overwritten by new records over time as the DBMS runs. However, a deleted

record will never be overwritten by something that is not another record of the same structure. Therefore, if an index value points to an area in storage that does not contain a proper record (including metadata), then record wiping is suspected. We are not concerned with matching the specific index value since this is done in Algorithm 1, but rather that a pointer must reference an area in storage that resembles a record.

Algorithm 2 describes how to detect erased data. First, we read each bucket from the approximately sorted index. When a bucket is read, the table pages with the relevant page identifiers are also read. We iterate through each index value in the bucket. If the pointer for an index value does not match any record in the table pages, then the index value is appended to a list of erased data. After all index buckets have been evaluated, the list of erased data is returned to the user.

Algorithm 2 Erased Data Detection

```

1:  $Table \leftarrow$  carved table data: PageIDs, Slot #s, and Records.
2:  $SortedIndex \leftarrow$  the approximately sorted index (Section 9).
3:  $Flag \leftarrow$  an empty list to store erased data.
4: for each  $Bucket \in SortedIndex$  do
5:    $NPages \leftarrow$  pages from  $Table$  where  $PageID \in Bucket$ 
6:   for each  $IndexValue \in Bucket$  do
7:      $Ptr \leftarrow IndexValue.PageID.Slot\#$ 
8:     if  $Ptr \notin NPages$  then
9:        $Value \leftarrow$  the index value
10:       $Flag.append(['ErasedRecord', Ptr, Value])$ 
11: return  $Flag$ 

```

Adjacent Deleted Records. It is possible that multiple deleted records can exist adjacent to one another in a page. When this happens it is also possible the a single record could overwrite all of one record and part of another. For example, (1, 'Ed') and (2, 'Tom') are deleted records that are next to each other in storage. The inserted record (3, 'Karen') could overwrite all of (1, 'Ed') and part of (2, 'Tom'). This presents a problem because any old index value for (2, 'Tom') would now point to the middle of the inserted record, rather than to a full record. In this scenario, Algorithm 2 would return a false-positive for the index value from (2, 'Tom'). These false-positives can be eliminated by comparing these results to audit log entries. For example, if a delete command in the log could explain (2, 'Tom'), then this could be declared as not malicious. This functionality is not currently supported by DBStorageAuditor, and it would be explored in future work to achieve a more complete auditing system.

11 EXPERIMENTS

In this section, we present a set of experiments that evaluate the performance, accuracy, and limitations of DBStorageAuditor. Table 2 summarizes the experiments in this section.

MySQL 5.7, PostgreSQL 9.6, and Oracle 11g R2 DBMSes were used in these experiments. We believe these three RDBMSes are a good representative selection from the commonly used RDBMSes. Not only are they widely used commercial and open-source DBMSes, but they also represent the spectrum of different storage decisions across about ten DBMSes we have studied. For example, PostgreSQL does not support IOTs, Oracle offers an option to create IOTs, and MySQL automatically uses IOTs. The default page sizes for each DBMS were used: 8K for Oracle and PostgreSQL and 16K for MySQL. Data from the Star Schema Benchmark (SSBM) [16] was used to populate our DBMS instances. Table 3

#1	Forensic analysis (Sec 7) cost evaluation. DB files were carved at a rate of 1.2 MB/s. A checksum comparison can improve carving costs.
#2	Approximate sorting (Sec 9) cost evaluation. Fewer buckets improves runtime, but requires more memory.
#3	Algms 1 and 2 (Sec 10) cost evaluation. Both algorithms increase linearly with table size.
#4	DBStorageAuditor detection evaluation. Alg 1 detects an added record, Alg 1 detects a modified value only for an indexed column, and Alg 2 reconstructs erased data that was indexed.
#5	DBStorageAuditor detection limitations after an index rebuild (Sec 8). DBStorageAuditor can use the old version of an index depending on the DBMS.

Table 2: Summary of experiments.

can be used to reference table sizes used throughout this section. DBMS instances ran on servers with an Intel X3470 2.93 GHz processor and 8GB of RAM running Windows Server 2008 R2 Enterprise SP1 or CentOS 6.5.

Table	Scale	DB File Size(MB)	Values(M)
Lineorder	1	600	6
Lineorder	4	2400	24
Lineorder	14	8300	84
Supplier	1	<1	2K

Table 3: SSBM table sizes used through the experiments.

The different DBMS storage-altering operations that we are seeking to detect are discussed in Section 10. When modifying files, we re-calculated and updated the page checksum value for the PostgreSQL pages; in MySQL and Oracle we disabled the page checksum validation. Before modifying files, we first shutdown the DBMS instance.

11.1 Forensic Processing

The objective of this experiment is to evaluate the computational cost associated with the forensic processing component of DBStorageAuditor discussed in Section 7. In Part-A, we provide DBCarver runtimes against database files of various sizes from MySQL, Oracle, and PostgreSQL DBMSes. In Part-B, we repeat the same evaluation, further including a checksum re-computation.

Part-A. We created a series of database files for each DBMS to pass to DBCarver. We created three LINEORDER tables: Scale 1, 4, and 14. Each table was stored in a separate file. The PostgreSQL files were carved at an average rate of 1.0 MB/s, the MySQL files were carved at a rate of 1.2 MB/s, and the Oracle files were carved at a rate of 1.5 MB/s.

Part-B. We used the PostgreSQL LINEORDER Scale 4 table from Part-A to evaluate the checksum comparison we added to DBCarver. We modified pages that induced a checksum change for 1%, 5%, 10%, and 100% of the pages in the database file. The carving rate for each percent modification was 100% → 1MB/s, 10% → 9 MB/s, 5% → 18 MB/s, and 1% → 58 MB/s. The cost of forensic pre-processing is thus proportional to the number of modified pages rather than the total size of the DBMS storage.

11.2 Index Sorting

The objective of this experiment is to evaluate the costs associated with approximately sorting the index values on the pointers. The output produced by the forensic analysis is similar for all DBMSes

so this component of DBStorageAuditor is not tested for DBMS-specific features. In Part-A, we vary the size of bucket; in Part-B, we vary the size of the indexes.

Part-A. To evaluate approximate sorting with respect to bucket size, we used the carved output from PostgreSQL database files containing a LINEORDER Scale 4 table, a secondary index on LO_Revenue, and a secondary index on LO_Orderdate. Table 4 summarizes the performance results. As the number buckets decreases the time to sort the data decreases. However, a bucket must fit into memory, so increasing of bucket sizes is limited by available RAM.

Bucket Size (Pages)	Bucket Count	Orderdate (sec)	Revenue (sec)
5,000	63	1366	1380
10,000	32	1121	1131
50,000	7	932	945
100,000	4	909	926
200,000	2	903	918

Table 4: Index sorting costs with varying bucket sizes.

Part-B. To evaluate approximate sorting with respect to the size of an index, we used the carved output from PostgreSQL database files containing LINEORDER Scale 1, 4, and 14 tables and a secondary index on LO_Revenue for each table. Table 5 summarizes the results. If the bucket size is increased proportionally for the table size, the approximate sorting cost increases linearly.

Bucket Size (Pages)	Index sorting time (sec)		
	Scale 1	Scale 4	Scale 14
10,000	239	1131	6193
50,000	231	945	3797
100,000	n/a*	926	3486
200,000	n/a*	918	3357

*Bucket size is larger than the table.

Table 5: Approximate sorting costs for varying table sizes.

11.3 Tampering Detection Costs

The objective of this experiment is to evaluate the costs associated with of Algorithms 1 and 2. For this experiment we used the LINEORDER Scale 4 table. We used one index on the LO_Revenue and multiple indexes on the LO_Revenue and LO_Orderdate. We approximately sorted the index using buckets with 50K pages.

Part-A: Algorithm 1. To evaluate the costs associated with Algorithm 1, we used the output from two different secondary indexes (LO_Revenue and LO_Orderdate) on LINEORDER Scale 4 and one secondary index (LO_Revenue) on LINEORDER Scale 14. Table 6 summarizes the runtime results. The runtime for Algorithm 1 was the same for LO_Revenue and LO_Orderdate on LINEORDER Scale 4, and the cost increased linearly for LO_Revenue on LINEORDER Scale 14.

Table	Index	Part-A (sec)	Part-B (sec)
Scale 4	LO_Revenue	966	503
Scale 4	LO_Orderdate	961	476
Scale 14	LO_Revenue	3482	1773

Table 6: Algorithm 1 and 2 runtimes.

Part-B: Algorithm 2. We used the same tables in indexes from Part-A of this experiment to evaluate the costs associated with Algorithm 2. Table 6 summarizes the runtime results. Similar to Algorithm 1, the cost for Algorithm 2 was nearly the same for LO_Revenue and LO_Orderdate on LINEORDER Scale 4, and the cost increased linearly for LO_Revenue on LINEORDER Scale 14.

11.4 Detection Capabilities

The objective of this experiment is to demonstrate the file tampering activity that DBStorageAuditor is capable of detecting. For each part in this experiment, we simulate one defined type of malicious activity and explain how it was detected. We manually add records to the database file (Part-A), change values in the database file (Part-B), and erase records from the database file (Part-C). We present results only for PostgreSQL because we our results for Oracle and MySQL were very similar.

Setup. We created a LINEORDER Scale 4 table for a PostgreSQL DBMS. An index existed on the primary key (LO_Orderkey, LO_Linenum) and we created a secondary index for LO_Revenue and LO_Orderdate.

We also created a function-based index on LO_Revenue that used the 32-bit version of the MurmurHash2 hash function.

Part-A. We manually added 5 records (shown in Figure 11) to the file containing the LINEORDER table. We added a record to five different pages (with PageIDs 11, 12, 13, 14, and 15). Existing primary key values were included in each of the five records. For each of these records, all of the data was the same as the existing records with the same primary key except we used LO_Supkey -5 and LO_Revenue -100000.

Primary Key	LO_Supkey = -5	LO_Revenue = -100000
① 1011 108733 7417	-5 19960319 '3-MEDIUM' 0 49	7352695 20527439 10 -100000 90033 0 19960529 'AIR'
② 40011 38143 210370	-5 19931228 '1-URGENT' 0 26	3328936 3362225 0 -100000 76821 1 19940113 'RAIL'
③ 120011 2303 391486	-5 19970718 '4-NOT SPECI' 0 8	1261976 17693973 1 -100000 94648 1 19971011 'SHIP'
④ 1000011 102599 383999	-5 19941106 '3-MEDIUM' 0 14	2916172 2995491 4 -100000 124978 7 19950117 'SHIP'
⑤ 2000011 85157 130108	-5 19960903 '1-URGENT' 0 21	2390010 2413431 1 -100000 68286 2 19961005 'REG AIR'

Figure 11: Records added to the LINEORDER file.

The addition of these five records produced several interesting outcomes. First, these records bypassed the primary key constraint since they contained primary key values that previously existed in the table. The DBMS only checks constraints when executing API-based load commands, and it does not retroactively check the table for constraint violations. Adding the record to the file bypasses all official channels and is thus never checked for constraint violations. Second, these records also bypassed referential integrity since the LINEORDER table references the SUPPLIER table, and LO_Supkey -5 did not exist in the SUPPLIER. Similar to the primary key violation, the constraint violation was never caught by the DBMS. Finally, table access for the same query could produce different results because the indexes were not updated after we added these five records. For example, the two versions of the following query returns different results:

- Query 1 → 34600180980

```
SELECT SUM(LO_Revenue) FROM Lineorder
WHERE LO_Orderdate = 19960319;
```
- Query 2 → 34600180980 - 100000

```
set enable_seqscan=true;
SELECT SUM(LO_Revenue) FROM Lineorder
WHERE LO_Orderdate = 19960319;
```

Query 1 uses the LO_Orderdate index to access the table while Query 2 uses a full table scan. Record #1 from Figure 11 was included in Query 2, but it was not included in Query 1.

Algorithm 1 successfully detected the fact that five new records do not have corresponding pointers in the primary key index, the two secondary indexes, and in the function-based index. Problem was flagged by a False value for the line 14 If condition resulting in the malicious records being added to the list of invalid data at line 18. Each existing index serves as an additional validation to detect table tampering – and the function-based makes sure that small incremental changes are not possible.

Part-B. Next, we changed LO_Revenue for all 41 records where the LO_Custkey 4321 and LO_Orderdate between 19930101 and 19931231. To simulate a neighboring value problem (a small change that does not violate index ordering), we changed the record with LO_Custkey 4321 and LO_Revenue 3271986 to 3271987 in both the table and the LO_Revenue index. For all other records we subtracted 100000 from LO_Revenue in the table.

Algorithm 1 reported that 40 records had an inconsistent value based on the LO_Revenue index and 41 records had an inconsistent value based on the function-based index on LO_Revenue. The difference of the one additional record was due to the neighboring value attack which regular index may fail to detect. These values were detected by a False value for the line 15 If condition resulting in the malicious values being added to the list of invalid data at line 16. We can conclude that the primary key and LO_Orderdate columns were not tampered with for these and all records since they were not included in the invalid data. However, we can not make any conclusion if any other of the non-indexed columns for these or any records were tampered.

Part-C. Next, we erased all 3085 records with the LO_Supkey 123 from the file. For data erasure, we explicitly overwrote the records and their metadata with the NULL ASCII character.

Algorithm 2 returned that primary key index, the two secondary indexes, and the function-based index each had 3085 values that did not point to a valid record structure. These were detected by a True value for the line 8 condition in Algorithm 2, resulting in malicious data being added to the list of invalid data at line 10. By combining the values for each pointer we reconstructed partial records containing the index columns to explain the missing data. However, the data for the non-indexed columns was unable to be reconstructed since it was not indexed.

11.5 Long-Term Detection

The objective of this experiment is to evaluate the artifacts produced by an index rebuild that can be used by DBStorageAuditor. We evaluate a different DBMS for each part of this experiment: Oracle in Part-A, MySQL in Part-B, and PostgreSQL in Part-C.

We performed the following steps for each DBMS. After each step, we copied the database file for analysis. Table 7 summarizes the results.

- T_0 : Started with the Supplier Scale1 (2K records) table and a secondary index on S_Name.
- T_1 : Erased/wiped all 829 records where S_Region equaled 'ASIA' or 'EUROPE'.
- T_2 : Rebuild the index. Each DBMS used a different index rebuild command:
 - Oracle: ALTER INDEX Supp_Name REBUILD ONLINE
 - MySQL: DROP and CREATE commands
 - PSQL: REINDEX TABLE Supplier

Part-A: Oracle. The index contained 1 root page and 9 leaf pages after creation at T_0 . No changes were made to the index after the table records were erased at T_1 . After the index rebuild at T_2 , the new index contained 1 root page and 5 leaf pages. All of

DBMS	T_0 (pgs)	T_1	T_2
Oracle	1 root, 9 leaf	no change	All index pages from the old index remained in DB storage.
MySQL	1 root, 5 leaf	no change	2 leaf pages from the old index remained in DB storage.
PSQL	1 root , 10 leaf	no change	None of the old index remained in DB storage.

Table 7: Index rebuild summary.

the pages from the original version at T_0 remained in the database file. The DBMS assigned a new ObjectID to the new version of the index so index pages between versions were easily distinguished. Since the entire version of index was found, it could be used by DBStorageAuditor. The old version of the index still contained pointers to the erased records, whereas the new version only contained pointers to active records in the table.

Part-B: MySQL. The index contained 1 root page and 5 leaf pages after creation at T_0 . No changes were made to the index after the table records were erased at T_1 . After the index rebuild at T_2 , the new index contained 1 root page and 3 leaf pages. 2 out of the 5 leaf pages from the original index remained in database storage. This demonstrates that the DBMS immediately reclaimed the pages from the dropped index. Since the new index version used less storage space, 2 pages from the old version remained in the file. In this scenario, a B-Tree could not be fully validated with only 2 leaf pages making them less useful as evidence for DBStorageAuditor. It is likely that copies of the index could be carved from a disk image due to activity such as writes that do not occur in place and paging files. DBStorageAuditor does not currently reconstruct entire B-Tree indexes from disk images. Future work will seek to reconstruct objects from disk images, which requires multiple versions of pages to be considered.

Part-C: PostgreSQL. The index contained 1 root page and 10 leaf pages after creation at T_0 . No changes were made to the index after the table records were erased at T_1 . After the index rebuild at T_2 , the new index contained 1 root page and 6 leaf pages. The new version of the index was assigned a new ObjectID and a separate file. All pages belonging to the old version of the index were disassociated with its file, and this storage was reclaimed by the file system. In this scenario, DBStorageAuditor can no longer detect that the records were erased. As discussed in Part-B, it is likely that the index could be carved from a disk image. This will be explored in future work since a logical timeline would need to be recreated to account for multiple page versions.

12 CONCLUSION

Database file tampering can be used to perform malicious operations while bypassing database security mechanisms (logging and access control) and constraints. We presented and evaluated DBStorageAuditor component that detects database file tampering. Our approach relies on a forensic inspection of database storage and identifies inconsistencies between tables and indexes.

Future work plans to expand upon this paper and work from [28] to create a complete database auditing framework. This future work would include creating a timeline of events and user attribution of storage artifacts. Our auditing framework relies on inherent characteristics of database storage that users, including privileged users, are incapable of controlling.

ABSTRACT

Repairing techniques for relational databases have leveraged integrity constraints to detect and then resolve errors in the data. User guidance has started to be employed in this setting to avoid a prohibitory exploration of the search space of solutions. In this paper, we present a user-guided repairing technique for Knowledge Bases (KBs) enabling updates suggested by the users to resolve errors. KBs exhibit more expressive constraints with respect to relational tables, such as tuple-generating dependencies (TGDs) and negative rules (a form of denial constraints). We consider TGDs and a notable subset of denial constraints, named contradiction detecting dependencies (CDDs). We propose user-guided polynomial-delay algorithms that ensure the repairing of the KB in the extreme cases of interaction among these two classes of constraints. To the best of our knowledge, such interaction is so far unexplored even in repairing methods for relational data. We prove the correctness of our algorithms and study their feasibility in practical settings. We conduct an extensive experimental study on synthetically generated KBs and a real-world inconsistent KB equipped with TGDs and CDDs. We show the practicality of our proposed interactive strategies by measuring the actual delay time and the number of questions required in our interactive framework.

1 INTRODUCTION

Integrity constraints have been used in relational databases to detect inconsistencies and thus repair error-prone data within tables. Notable classes of these constraints are represented by functional dependencies (FDs) and conditional functional dependencies (CFDs) that are both table-level constraints as they express conditions without or with predicates on entire relations. Denial constraints (DCs) [7] are more general first-order formulas that encompass FDs and CFDs and strike a balance between expressiveness and complexity. Denial constraints are, however, difficult to understand for end users and their intractability and prohibitive search space make them unattractive for repairing algorithms [3].

In this paper, we focus on a subset of denial constraints, which we call contradiction-detecting dependencies (CDDs) capturing contradictions in the data. CDDs correspond to denial constraints restricted to equality predicates in their respective bodies. They are used mainly to capture contradictions and disjointness between relations. They differ from other subfamilies of DCs such as keys, functional dependencies and equality-generating dependencies. Knowledge Bases (KBs) typically rely on the interaction of CDDs (also known as negative rules or negative constraints) with tuple-generating dependencies (also called existential rules) [5, 11]. The following example underlines the importance of CDDs.

Example 1.1. Figure 1 (a) shows our running example. Let \mathcal{F} contain the set of facts of a KB describing the prescriptions of patients at a hospital and Σ_C the set of CDDs. *Aspirin* is prescribed to *John* who is allergic to it, whereas *Mike* has an allergy against *Penicillin*. The CDD in Σ_C dictates that prescribing a drug to a person who has an allergy against it leads to a contradiction.

Several approaches to repair KBs exist, such as deletion-based repairing, which amounts to remove the inconsistencies in order to satisfy the constraints. However, the generated repairs are not compatible, as a consequence, choosing among them is not feasible for end-users, as shown by the following example.

Example 1.2. Following the deletion-based repairing approaches, one can either remove *prescribed(Aspirin, John)* or *hasAllergy(John, Aspirin)* as either one of them is false according to the CDD. The first one gives us the repair \mathcal{F}_1 that conveys the information that *Aspirin* is prescribed to *John*. Conversely, the second repair \mathcal{F}_2 would lead us to conclude that *John* has an allergy against *Aspirin*. Moreover, none of the above repairs preserves as much information as possible. The information about *John* having an allergy that could be against *Aspirin* or any other drugs is indeed lost in \mathcal{F}_1 whereas the information that *Aspirin* is prescribed to someone which could be *John* or someone else is also lost in \mathcal{F}_2 . This example also shows the impossibility for an end-user of making a choice between these two repairs.

An alternative to deletion-based repairing is given by update-based repairing [24, 28], which inspired our work. In update-based repairing, atomic values can be modified instead of removing entire facts from the knowledge base.

Example 1.3. By applying an update-based repairing to the above inconsistent knowledge base, we obtain the set of facts \mathcal{F}_3 (in which X_1 is a labeled null referring to an unknown allergy). Another possible repair is that *John* has an allergy against *Penicillin* rather than *Aspirin*. Or, *Penicillin* is prescribed to *John* rather than *Aspirin*. Clearly, all these update-based repairs preserve more facts than the deletion-based ones illustrated above.

Although being beneficial, update-based repairing suffers from the problem of choosing the positions to modify and the value to use in repairing. For instance, do we need to change *Aspirin* to *Penicillin* in *hasAllergy(John, Aspirin)* or *Aspirin* to a labeled null? Clearly, user intervention is compulsory in such a case in order to reach a repair that meets the user's requirements and his expertise about the domain.

The problem becomes more complex when CDDs and TGDs are considered as shown in Figure 1 (b). Besides the fact that \mathcal{F} already contains inconsistencies as illustrated in Figure 1 (a), we consider Σ_T and the new introduced atoms in \mathcal{F} and a new CDD in Σ_C' . In this KB, another inconsistency is raised due to the interaction between TGDs and CDDs corresponding to the fact that *John* was prescribed incompatible drugs, i.e. *Aspirin* and *Nsaids*. Such a contradiction can only be discovered after applying the TGD that results in deducing the fact *John* is prescribed *Nsaids*, because he has *Migraine* pain and *Nsaid* is a painkiller. In such a

$$\begin{aligned} \mathcal{F} &= \{prescribed(Aspirin, John), hasAllergy(John, Aspirin), hasAllergy(Mike, Penicillin)\} \\ \Sigma_C &= \{prescribed(X, Y), hasAllergy(Y, X) \rightarrow \perp\} \\ \mathcal{F}_1 &= \{prescribed(Aspirin, John), hasAllergy(Mike, Penicillin)\} \\ \mathcal{F}_2 &= \{hasAllergy(John, Aspirin), hasAllergy(Mike, Penicillin)\} \\ \mathcal{F}_3 &= \{prescribed(Aspirin, John), hasAllergy(John, X_1), hasAllergy(Mike, Penicillin)\} \end{aligned}$$

(a) An inconsistent knowledge base with only CDDs. \mathcal{F}_i are repairs.

$$\begin{aligned} \mathcal{F}' &= \mathcal{F} \cup \{hasPain(John, Migraine), isPainKillerFor(Nsaids, Migraine), incompatible(Aspirin, Nsaids)\} \\ \Sigma_T &= \{isPainKillerFor(X, Y), hasPain(Z, Y) \rightarrow prescribed(X, Z)\} \\ \Sigma_{C'} &= \Sigma_C \cup \{prescribed(X, Z), prescribed(X, Y), incompatible(Y, Z) \rightarrow \perp\} \end{aligned}$$

(b) An inconsistent knowledge base with CDDs and TGDs.

Figure 1: Examples on tuple-based repairing and update-based repairing.

case, after applying the rule in Σ_T , a new inconsistency has been introduced. Hence, the choice of which inconsistency to handle first and which atom to update is crucial. For instance, updating the atom $prescribed(Aspirin, John)$ will resolve automatically the new inconsistency without updating other atoms, whereas updating the atom $prescribed(Nsaids, John)$ will not. In addition, propagating back the changed positions in $prescribed(Nsaids, John)$ should be done in order to establish consistency.

In this paper, we present a user-guided update-based repairing framework that is capable of solving contradictions triggered by CDDs. We study the interaction of such rules with more classical tuple-generating dependencies (or, existential rules) in KB reasoning. The study of DCs in a relational setting has been extensively conducted in the literature as witnessed by several papers in the area [13, 24, 28]. We defer the discussion of the differences between our work and previous work to the next subsection. In this paper, we focus on the following problem statement, which substantially deviates from the objectives of previous work.

(URP) *Given a KB equipped with a set of TGDs and CDDs, the User-guided Repairing Problem is to compute, by means of user's update fixes, an error-free KB by addressing two main challenges: (i) minimizing user interactions and (ii) accounting for the interplay of TGDs and CDDs. If the user is an oracle, then the repair of the KB is also a u-repair, i.e. a repair with a minimal (w.r.t \subseteq) set of update fixes.*

Contributions. The main contributions of our paper are as follows:

(1) Update-based repairing: We introduce contradiction detection dependencies (CDDs) and we formalize update-based repairing in the presence of both CDDs and TGDs. We prove that repairability is guaranteed and can be checked in polynomial time.

(2) Update-based repairing with user interaction: We define an interactive framework letting the user repair the knowledge base and meet his requirements. We prove two interesting properties: (i) *soundness*, i.e. we show that the framework is sound, which means that for every dialogue with a user we can reach a consistent state of the knowledge base; (ii) *soundness w.r.t. an oracle*, i.e. we assume that the interaction is done with an oracle that has a specific repair in mind and we prove that the output of the dialogue with an oracle is exactly the repair of the oracle. We show that the dialogue algorithm has a polynomial delay in generating questions.¹

We present an extensive experimental study, devoted to confirm the polynomiality of delay time and showing the feasibility of our interactive approach in terms of number of questions and average number of conflicts per question in the knowledge bases. In our assessment, we contrast the two cases of only CDDs and

CDDs alongside with TGDs and we study the impact of the chase algorithm on the proposed interactive strategies in both cases.

Paper organization. The paper is organized as follows. In Section 2, we introduce the basic notions and definitions. In Section 3, we introduce the update-based repairing framework and the repairability of KBs. In Section 4, we formalize user intervention by means of the notion of inquiry and we prove the soundness and termination of an inquiry engaging the end-user. We also discuss the case in which the user is an oracle and prove that the inquiry has a polynomial delay time. In Section 5, we introduce different interactive strategies with the user. In Section 6, we present our experimental assessment. Finally, Section 7 concludes the paper.

1.1 Related Work

Rule-Based Repairing. Logical data cleaning has leveraged reasoning over more or less sophisticated classes of declarative dependencies [9, 14] in order to detect and repair error-prone values and tuples. A plethora of data quality constraints have been introduced to this purpose, ranging from classical functional dependencies and their approximate variants for relational tables [9, 27] to their counterparts in graph databases [17]. Denial constraints [7] are first-order formulas more expressive than functional dependencies and conditional functional dependencies. Comprehensive classes of graph constraints, including the expressive graph entity dependencies (encompassing denial constraints) have been presented in [16]. The detection problem [17] for these constraints consists in checking whether a given database (or a graph) contains no violations of the input set of constraints. While [16] focuses on the detection problem along with satisfiability and implication among constraints, our goal in this paper is to compute an update-based repair for a knowledge base with an interactive exploration of the search space of solutions. Our contradiction detecting dependencies are a subset of denial constraints, limited to equality as built-in predicate. While denial constraints have been already employed as data quality rules in the relational setting [13], their use in the realm of knowledge bases characterized by the schema-less nature of data and their combination with other KB constraints, such as TGDs, is not explored. CLAMS [18] investigates the use of DCs in data lakes, including RDF KBs, but it does not consider the TGDs and their interactions with DCs. With that being said, our approach goes with the same line of [13, 18] in reinforcing and endorsing a holistic view of repairing for knowledge bases by compiling the information coming from multiple violations in a structure called the Conflicts Hypergraph [13, 24]. Repairing a database [1, 7, 28] according to a set of constraints corresponds to bringing the database to its legal state, in which all the constraints are satisfied. Since many possible repairs for a given database may exist, one would tend to prefer the (minimal) one, which entails less modifications of the original database. Various notions

¹The delay between the asked questions is bounded by a polynomial.

of repairs have been used and many approaches have used insert and delete operations on the original database to make it reach its consistent state with respect to a given class of constraints. Such approaches may exhibit drawbacks in that the granularity of the operations performing the repairs is too coarse. Indeed, deletions and insertions are typically executed at the tuple level for relations, thus leading to discard possibly error-free values. Our work has been inspired by update-based repairing proposed in [10, 28] to allow value replacement on positional attributes in relational tuples. While [28] focused on consistent query answering for update repairs aiming at finding the answers of a query in the intersection of all possible repairs, our intent is to exploit user interactions in the update-based repairing process of an entire knowledge base. Repairing by value modification with functional dependencies and inclusion dependencies has been tackled in [10] with the aim of building minimal-cost repairs. Their algorithms are not directly applicable to KBs due the inherent difference of expressiveness of the constraints and the consequent interaction between tuple-generating dependencies and the CDDs. In addition, user intervention has not been considered in [10].

User-guided data cleaning. A fruitful line of work has led to the design of several data cleaning tools, such as Llunatic [19], GDR [29], Katara [14], Dance [4] and Falcon [21].

GDR [29] considers user-guided relational data repairing. CFDs are used to generate candidate updates for the tuples that are violating them. The user is presented with groups of updates and her feedback is fed into an active learning process that decides about the correctness of updates without user involvement. The convergence of updates in our method is ensured by the chase algorithm involving CDDs and TGDs on KBs.

Llunatic [19] is mapping and cleaning tool accepting user suggestions during the chase procedure with EGDs on relational instances. Llunatic also explores the interaction among several classes of constraints such as FDs, CFDs, editing rules and TGDs. To the best of our knowledge Llunatic cannot be directly applied to knowledge bases with constraints such as CDDs and TGDs.²

Falcon [21] relies on a set of SQL update queries instead of a set of input logical constraints to entail the repair of a relational database. A set of SQLU queries is inferred starting from one triggering input tuple-based update proposed by the non-expert user. Our approach is based on rule-based repairing of knowledge bases and on a tight interaction with the domain expert to perform data curation, not considered in the above system.

Dance [4] introduces a user-driven cleaning approach for relational tuples, by considering constraints similar to classical EGDs and TGDs. Dance proposes a set of suspicious tuples whose update can contribute to constraint resolution. However, neither they consider DCs or subset thereof employed in our framework nor they leverage their interaction with TGDs as in our approach.

Katara [14] is orthogonal to our work in that it leverages knowledge bases and guidance from crowdsourcing to fix the errors in RDBMS. Because of that, input KBs are assumed to be well curated, as opposed to the assumption undertaken in our paper.

2 PRELIMINARIES

In this section, we briefly recap the notions needed in our framework, namely the definition of a knowledge base and the corresponding constraints, along with the definition of conflicts.

²Benchmarks on LUBM in [6] have been performed on a relational representation of the LUBM ontology with vertical partitioning.

Constraints and KBs. A *tuple-generating dependency* (abbreviated TGD) is of the form $R : \forall \mathbf{x} \forall \mathbf{y} B(\mathbf{x}, \mathbf{y}) \rightarrow \exists \mathbf{z} H(\mathbf{y}, \mathbf{z})$, where \mathbf{x} and \mathbf{y} are sequences of variables, B and H are conjunctions of atoms, with $\text{vars}(B) = \mathbf{x} \cup \mathbf{y}$, and $\text{vars}(H) = \mathbf{y} \cup \mathbf{z}$. B and H are respectively called the *body* and the *head* of R . A *contradiction-detecting dependency* (abbreviated CDD) is of the form $N : \forall \mathbf{x} B(\mathbf{x}) \rightarrow \perp$ where B is a conjunction of atoms, with $\text{vars}(B) = \mathbf{x}$. The body B may have equalities but no inequalities [12]. Inequalities are not used as they lead to undecidability even for TGDs [20]. Notice that whereas CDDs are a subset of DCs (Denial Constraints), they are different from Keys, FDs and EGDs (subsets of DCs).

A dependency with an empty body B and a non-empty head H is called a *fact*. Therefore, a fact is a set of atoms with existential variables (i.e. labeled nulls). A knowledge base $\mathcal{K} = (\mathcal{F}, \Sigma_T, \Sigma_C)$ consists of a finite sets of facts, TGDs and CDDs, respectively. Reasoning with a knowledge base is done via the chase. A rule $R : B \rightarrow H$ is *applicable* to a fact F if there exists a homomorphism π from B to F . The *application of R to F w.r.t. π* produces a finite set of atoms (also called atomset) $\alpha(F, R, \pi) = F \cup \pi(\text{safe}(H))$, where $\text{safe}(H)$ is obtained from H by replacing existential variables with fresh variables. The application of all TGDs to a set of facts is called the chase. The result of the chase on \mathcal{F} is denoted as $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F})$ which produces an expanded set of facts \mathcal{F}^* . In this paper, we restrict ourselves to weakly-acyclic TGDs to avoid non-terminating chase sequences [15]. Let us consider the example in Figure 1 (b), on which we show the result of the chase.

Example 2.1. The result of the chase on the set of fact \mathcal{F}' is: $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F}') = \mathcal{F}' \cup \{\text{prescribed}(\text{Nsaid}, \text{John})\}$.

Query Answering. Given a set of facts \mathcal{F} , an answer to Q in $\mathcal{K} = (\mathcal{F}, \Sigma_T, \Sigma_C)$ is a tuple of constants (A_1, \dots, A_k) such that there exists a homomorphism π from Q to $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F})$, with $(A_1, \dots, A_k) = (\pi(x_1), \dots, \pi(x_k))$. We denote by $Q(\mathcal{F}, \Sigma_T)$ the set of all answers of Q over \mathcal{F} in presence of Σ_T .

Inconsistent knowledge bases and conflicts. A widely accepted assumption in KBs is that the set of TGDs is compatible with the set of CDDs, i.e. the union of the two sets is satisfiable [25]. A set of facts \mathcal{F} is inconsistent with respect to a set of TGDs Σ_T and CDDs Σ_C (or inconsistent for short) if and only if there exists a dependency $N \in \Sigma_C$ such that $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F}) \models \text{body}(N)$. A knowledge base $\mathcal{K} = (\mathcal{F}, \Sigma_T, \Sigma_C)$ is inconsistent if and only if there exists a set of facts $\mathcal{F}' \subseteq \mathcal{F}$ such that \mathcal{F}' is inconsistent. We use the alternative notation $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F}) \models \perp$ hereafter.

Example 2.2 (Example 2.1 Ct'd). The knowledge base $\mathcal{K} = (\mathcal{F}', \Sigma_T, \Sigma_C')$ is inconsistent because the bodies of the two CDDs are entailed from $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F}')$.

Inconsistency can also be characterized by conflicts.

Definition 2.3 (Conflict). Let $\mathcal{K} = (\mathcal{F}, \Sigma_T, \Sigma_C)$ be an inconsistent knowledge base. A conflict is defined as a tuple $X=(N, h)$ such that h is a homomorphism from $\text{body}(N)$ to $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F})$ such that $h(\text{body}(N)) \subseteq \mathcal{C}\ell_{\Sigma_T}(\mathcal{F})$.

Example 2.4. The knowledge base $\mathcal{K} = (\mathcal{F}', \Sigma_T, \Sigma_C')$ has two conflicts $X_1 = (N_1, h_1)$ and $X_2 = (N_2, h_2)$ defined as follows:

- $N_1 = \text{prescribed}(X, Y), \text{hasAllergy}(Y, X) \rightarrow \perp$.
- $h_1(X) = \text{Aspirin}, h_1(Y) = \text{John}$
- $N_2 = \text{prescribed}(X, Z), \text{prescribed}(Y, Z), \text{incompatible}(X, Y) \rightarrow \perp$.
- $h_2(X) = \text{Aspirin}, h_2(Y) = \text{Nsaid}$.

We denote by $\text{conflict}(\mathcal{K}, N)$ all the conflicts for a given constraint $N \in \Sigma_C$. The set of all conflicts of a given knowledge base is denoted as:

$$\text{allconflicts}(\mathcal{K}) = \bigcup_{N \in \Sigma_C} \text{conflict}(\mathcal{K}, N)$$

A knowledge base \mathcal{K} is consistent iff $\text{allconflicts}(\mathcal{K}) = \emptyset$.

In order for CDDs to be meaningful, we impose that CDDs contain atoms with join variables. This assumption is made to avoid for instance CDDs of the form $\text{prescribed}(X, Y) \rightarrow \perp$ in the above example. Such CDD is a schema constraint imposing that *prescribed* should be removed from the vocabulary of the KB.

3 UPDATE-BASED REPAIRING

In this section, we introduce the framework of update-based repairing for KBs. As opposed to deletion-based repairing, the granularity of update-based repairing is no longer an atom but instead a position that we need to update within a given atom. In what follows, we introduce the concept of a position and a fix on a position. Then, we proceed by giving the definition of a repair in such context, i.e. based on a minimal set of fixes needed to be applied in order to recover the consistency of a KB.

Given an atom $A = p(t_1, \dots, t_n)$, we denote by $\text{arity}(A) = n$ the arity of the predicate $\text{pred}(A) = p$. The tuple (A, i) such that $i \in [1, \text{arity}(A)]$ is called a position and *identifies* the position of the i -th argument of p . We denote by $\text{adom}(A, i, \mathcal{F})$ the active domain of the argument i of p in \mathcal{F} .

A position is a building block in update-based repairing as it gives access to the inner structure of an atom. For instance, $(A, 1)$ such that $A = \text{prescribed}(\text{Aspirin}, \text{John})$ is a position that refers to the first argument of A .

Given \mathcal{F} , the set of all positions of \mathcal{F} is defined as:

$$\text{pos}(\mathcal{F}) = \{(A, i) \mid A \in \mathcal{F} \text{ and } i \in [1, \text{arity}(A)]\}$$

The function $\text{value}_A^i(\mathcal{F})$ returns the value of the position (A, i) . Since existential variables can be present in atoms, $\text{value}_A^i(\mathcal{F})$ can be either an existentially quantified variable or a constant. The set of all values of a set of facts \mathcal{F} is defined as:

$$\text{vals}(\mathcal{F}) = \{\text{value}_A^i(\mathcal{F}) \mid (A, i) \in \text{pos}(\mathcal{F})\}.$$

A position fix specifies an update on a given atom in a given position.

Definition 3.1 (Position fix). A fix on a position (A, i) in \mathcal{F} is a triple (A, i, t) such that $t \in \text{adom}(A, i, \mathcal{F}) \setminus \text{value}_A^i(\mathcal{F})$ or $t = X_A^j$ is an existential variable that is uniquely attributed to (A, i) .

A fix on a position can specify a value that is within the active domain of the predicate p and different from the actual value. A fix can also specify an existential variable that refers to an unknown individual. Please note that such a variable is unique to the position in question and it is not used elsewhere in the knowledge base.

The *application* of a set of fixes \mathcal{P} on \mathcal{F} is defined as follows:

$$\text{apply}(\mathcal{F}, \mathcal{P}) = \{p(t'_1, \dots, t'_n) \mid A = p(t_1, \dots, t_n) \in \mathcal{F} \text{ and } \forall i \in \{1, \dots, n\} \text{ either } (A, i, t'_i) \in \mathcal{P} \text{ or } (A, i, t'_i) \notin \mathcal{P} \text{ and } t'_i = t_i\}$$

We consider only *valid* set of fixes which are set of fixes \mathcal{P} such that there exist no two fixes $(A, i, t), (A, i, t') \in \mathcal{P}$ and $t \neq t'$. The application of a set of fixes \mathcal{P} on a set of facts gives another set of facts called *the update* of \mathcal{F} by \mathcal{P} . It is clear that $|\mathcal{F}'| = |\mathcal{F}|$ and $\text{pos}(\mathcal{F}') = \text{pos}(\mathcal{F})$.

Example 3.2. The following is a set of fixes $\mathcal{P} = \{(A, 2, X_1), (A', 2, \text{Aspirin})\}$ such that:

- $A = \text{hasAllergy}(\text{John}, \text{Aspirin})$.
- $A' = \text{hasAllergy}(\text{Mike}, \text{Penicillin})$.

The update of \mathcal{F} by \mathcal{P} gives:

- $\mathcal{F}'_1 = \{\text{prescribed}(\text{Aspirin}, \text{John}), \text{hasAllergy}(\text{John}, X_1), \text{hasAllergy}(\text{Mike}, \text{Aspirin})\}$

The following set of fixes is not valid as it modifies the same position with different values:

- $\mathcal{P}' = \mathcal{P} \cup \{A, 2, \text{Penicillin}\}$

An important notion that will be used later is the reconstruction of a set of fixes \mathcal{P} given a set of facts \mathcal{F} and its update \mathcal{F}' . We define the function $\text{diff}(\mathcal{F}, \mathcal{F}')$ as follows:

$$\text{diff}(\mathcal{F}, \mathcal{F}') = \{(A, i, t'_i) \mid A = p(t_1, \dots, t_n) \in \mathcal{F}, A' = p(t'_1, \dots, t'_n) \in \mathcal{F}' \text{ and } \text{match}(A) = A' \text{ and } \exists j \in \{1, \dots, \text{arity}(A)\} \text{ such that } t'_j \neq t_j\}$$

Notice that the function $\text{match}(x)$ puts the atoms of \mathcal{F} and \mathcal{F}' in one-to-one correspondence. Such one-to-one correspondence exists because we know that \mathcal{F}' is an update of \mathcal{F} , therefore $|\mathcal{F}| = |\mathcal{F}'|$. $\text{match}(x)$ should satisfy the condition that $\text{match}(x) = y$ if and only if $x \in \mathcal{F}$ and $y \in \mathcal{F}'$ and $\text{pred}(x) = \text{pred}(y)$.

Example 3.3. Consider \mathcal{F} of Example 1.1 and its update \mathcal{F}' of Example 3.2, one can construct \mathcal{P} by defining $\text{match}(A_1) = A'_1$, $\text{match}(A_2) = A'_2$ and $\text{match}(A_3) = A'_3$ such that:

- $A_1 = \text{prescribed}(\text{Aspirin}, \text{John})$ and $A'_1 = \text{prescribed}(\text{Aspirin}, \text{John})$.
- $A_2 = \text{hasAllergy}(\text{John}, \text{Aspirin})$ and $A'_2 = \text{hasAllergy}(\text{John}, X_1)$.
- $A_3 = \text{hasAllergy}(\text{Mike}, \text{Penicillin})$ and $A'_3 = \text{hasAllergy}(\text{Mike}, \text{Aspirin})$.

Note that there may be finitely many one-to-one correspondences between two sets of facts.

The set of fixes \mathcal{P} gives a consistent update \mathcal{F}' . In fact, it is minimal in the sense that only what is necessary to recover consistency has been changed. In what follows, we introduce the notion of consistent fixes, repair fixes and update repair.

Definition 3.4 (c-fix and r-fix). Let \mathcal{K} be an inconsistent knowledge base, \mathcal{P} a set of fixes and $\mathcal{F}' = \text{apply}(\mathcal{F}, \mathcal{P})$ the update of \mathcal{F} by \mathcal{P} . \mathcal{P} is called consistent fixes (denoted c-fix) of \mathcal{K} iff $\mathcal{K} = (\mathcal{F}', \Sigma_T, \Sigma_C)$ is consistent. \mathcal{P} is called repair fixes (denoted r-fix) of \mathcal{K} iff \mathcal{P} is a c-fix and it contains no c-fix $\mathcal{P}' \subset \mathcal{P}$.

\mathcal{F}' is an update-repair if \mathcal{P} is an r-fix. A c-fix is a set of fixes that gives a consistent update, an r-fix is a set of fixes that gives a consistent update that is minimal with respect to the changes.

Example 3.5. \mathcal{P} is a c-fix and $\mathcal{P}_1 = \mathcal{P} \setminus \{(A', 2, \text{Aspirin})\}$ is an r-fix. However, $\mathcal{P}_2 = \mathcal{P} \setminus \{(A, 2, X_1)\}$ is not a c-fix.

The following is a u-repair produced by \mathcal{P}_1 :

$$\mathcal{F}'_1 = \{\text{prescribed}(\text{Aspirin}, \text{John}), \text{hasAllergy}(\text{John}, X_1), \text{hasAllergy}(\text{Mike}, \text{Penicillin})\}.$$

It is not hard to see that there exist finitely many r-fixes for a given set of facts \mathcal{F} because a position can take a finite set of values assuming that the active domain is finite.

After having defined the basic notions for update-based repairing, in what follows we introduce Π -repairability, a key concept in our framework. For a given knowledge base \mathcal{K} , we are interested in knowing whether there always exists a way to repair \mathcal{K} . In Example 1.1, the knowledge base is repairable because there exists an r-fix for \mathcal{F} . In fact, for an arbitrary inconsistent knowledge base \mathcal{K} , repairability is guaranteed as one can change all positions to fresh existential variables, and since such variables are unique to the positions no constraint will be triggered. This gives us a c-fix,

consequently an r-fix for \mathcal{K} . Π -repairability is a generalization of repairability where Π refers to those positions that are *immutable* or not allowed to be changed. This generalization helps us to know whether the KB is repairable when some positions are modified by the user and not allowed to be changed.

Definition 3.6 (Π -repairability). Let \mathcal{K} be an inconsistent knowledge base and $\Pi \subseteq \text{pos}(\mathcal{F})$ be a set of positions. We say that \mathcal{K} is Π -repairable if and only if there exists an r-fix \mathcal{P} of \mathcal{K} such that there exists no $(A, i, t) \in \mathcal{P}$ and $(A, i) \in \Pi$.

A knowledge base can be inconsistent but Π -repairable. In such case, Π -repairability indicates in a sense the possibility of finding a u-repair for \mathcal{K} if certain positions are fixed prior to the repairing process. If \mathcal{K} is not Π -repairable then \mathcal{K} has no u-repair whose corresponding r-fix \mathcal{P} changes the positions in $\text{pos}(\mathcal{F}) \setminus \Pi$.

As stated above, Π -repairability is a generalization of the concept of repairability. When all positions are immutable then Π -repairability reduces down to a consistency check. Formally, if $\Pi = \text{pos}(\mathcal{F})$ and \mathcal{K} is Π -repairable then \mathcal{K} is consistent.

Algorithm 1 for checking Π -repairability proceeds by changing all positions to fresh existential variables except those positions that belong to Π . Then, we check the consistency of this new knowledge base using $\text{CHECKCONSISTENCY}(\mathcal{K})$. In fact, the algorithm checks if fixing some positions with their corresponding values will result in fixing the violations of some CDDs. If this is the case, the knowledge base can never be repaired.

Example 3.7. Consider the following knowledge base \mathcal{K} with an empty Σ_T :

- $\mathcal{F} = \{p(a, b), q(b, d)\}$
- $\Sigma_C = \{p(X, Y), q(Y, Z) \rightarrow \perp\}$

If we take $\Pi = \emptyset$ then \mathcal{K} is Π -repairable. This is because the c-fix $\mathcal{P} = \{(p(a, b), 1, X_1), (p(a, b), 2, X_2), (q(b, d), 1, X_3), (q(b, d), 1, X_4)\}$ gives a consistent update. Consequently, \mathcal{P} is a c-fix. Necessarily, one can consider the r-fix $\mathcal{P}' = \{(p(a, b), 2, X_1)\} \subset \mathcal{P}$ which gives a u-repair. However, if $\Pi = \{(p(a, b), 2), (q(b, d), 1)\}$ then \mathcal{K} is not Π -repairable because regardless of the values that the other positions can take the dependency will always be violated. Note that the fact that Σ_T is empty does not change the situation, given that the consistency check function is generic.

Checking Π -repairability is easy from a computational perspective. Algorithm 1 does perform such check in a polynomial time. The function $\text{CHECKCONSISTENCY}(\mathcal{K})$ in Algorithm 1 evaluates on the body of every CDD $N \in \Sigma_C$ on $\text{Cl}_{\Sigma_T}(\mathcal{F})$ and checks whether the query has an answer. If this is the case, \mathcal{K} is inconsistent, otherwise it proceeds until no CDD is left to be evaluated, where the knowledge base achieves consistency. Clearly, the function $\Pi\text{-REP}(\mathcal{K})$ runs in linear time of the size of $\text{pos}(\mathcal{F})$ plus the computational overload of the function $\text{CHECKCONSISTENCY}(\mathcal{K})$. This gives a polynomial data complexity as evaluating boolean conjunctive queries is polynomial in data complexity even in presence of weakly-acyclic TGDs [12, 22].

We now need to prove that the algorithm is sound, i.e. if the knowledge base is Π -repairable then the algorithm produces true as an output, otherwise false.

PROPOSITION 3.8. \mathcal{K} is Π -repairable iff $\Pi\text{-rep}(\mathcal{K}, \Pi) = \text{true}$.

PROOF. (\Rightarrow): suppose that \mathcal{K} is Π -repairable and $\Pi\text{-REP}(\mathcal{K}, \Pi)$ returns false. The former implies that there exists an r-fix \mathcal{P}' of \mathcal{K} such that $\mathcal{F}'' = \text{apply}(\mathcal{F}, \mathcal{P}')$ is the u-repair of \mathcal{F} By \mathcal{P}' . The latter implies that $\mathcal{K}' = (\mathcal{F}', \Sigma_T, \Sigma_C)$ in line 5 is inconsistent, thus there exists a conflict $\mathcal{X} = (N, h)$ in \mathcal{K}' . Since there

exists a homomorphism from $\text{body}(N)$ to \mathcal{F}' , we now show that $\mathcal{K}'' = (\mathcal{F}'', \Sigma_T, \Sigma_C)$ is necessarily inconsistent by constructing a homomorphism g from \mathcal{F}' to \mathcal{F}'' i.e. \mathcal{X} would also be a conflict in \mathcal{K}'' , thus \mathcal{K}'' is inconsistent.

Recall that \mathcal{P}' is the set of fixes that assigns to every position $(A, i) \in \text{pos}(\mathcal{F})$, $(A, i) \notin \Pi$ a unique existential variable X_A^i . Let $\mathcal{P}'' = \text{diff}(\mathcal{F}', \mathcal{F}'')$, we define the homomorphism $g : A \mapsto B$ such that $A = \{X_A^i \mid (A, i, X_A^i) \in \mathcal{P}'\}$, $B = \{t \mid (A, i, t) \in \mathcal{P}''\}$, and $g(X_A^i) = t$ such that $(A, i, t) \in \mathcal{P}''$. Since there exists a homomorphism from $\text{body}(N)$ to \mathcal{F}' , and from \mathcal{F}' to \mathcal{F}'' then there exists necessarily a homomorphism from $\text{body}(N)$ to \mathcal{F}'' . Hence, \mathcal{K}'' is inconsistent.

(\Leftarrow): it is trivial, if \mathcal{K}' is consistent then \mathcal{P} is a c-fix of \mathcal{K} such that $\nexists(A, i, t) \in \mathcal{P}$, (A, i) . By definition, $\exists \mathcal{P}' \subseteq \mathcal{P}$ such that \mathcal{P}' is an r-fix of \mathcal{K} . \square

Algorithm 1 Π -repairability

```

1: function  $\Pi\text{-REP}(\mathcal{K}, \Pi)$ 
2:    $\Pi' \leftarrow \text{pos}(\mathcal{F}) \setminus \Pi$ 
3:    $\mathcal{P} \leftarrow \{(A, i, t) \mid (A, i) \in \Pi' \text{ and } t = X_A^i\}$ 
4:    $\mathcal{F}' \leftarrow \text{apply}(\mathcal{F}, \mathcal{P})$ 
5:    $\mathcal{K}' \leftarrow (\mathcal{F}', \Sigma_T, \Sigma_C)$ 
   return  $\text{CHECKCONSISTENCY}(\mathcal{K}')$ 
6: end function

```

We have introduced so far the key concepts of our framework. Nevertheless, as already mentioned in the introduction, update-based repairing is unfeasible in practice because there are no guidelines on (1) how to choose the positions among those possible, and (2) who provides the corresponding fixes. Our positioning here is that update-based repairing should go hand in hand with user intervention. In the next section, we introduce our interactive framework serving this purpose.

4 USER INTERVENTION

The key idea behind user intervention is that the user may have a repair in mind, which corresponds to how the knowledge base should turn to be consistent. Obviously, it is impossible for a user to manually repair the KB. In this section, we propose a framework of *inquiry dialogue* that takes a place between the knowledge base and the user. The basic idea is that the knowledge base asks questions about some fixes and the user chooses which one is true until he reaches a consistent knowledge base or, alternatively, a u-repair under some conditions.

Definition 4.1 (*Inquiry*). Given an inconsistent knowledge base \mathcal{K} and a possibly empty set of positions Π . A **question** has the form $\phi = \{f_1, \dots, f_n\}$ such that f_k is a fix. An **answer** to ϕ is a fix $f_k \in \phi$. Given a conflict $\mathcal{X} = (N, h)$ in \mathcal{K} , a question $\phi = \{f_1, \dots, f_n\}$ is said to be **sound** if and only if for every fix $f_k = (A, i, t) \in \phi$ where $\Pi' = \Pi \cup \{(A, i)\}$, $\mathcal{K} = (\text{apply}(\mathcal{F}, \{f\}), \Sigma_T, \Sigma_C)$ is Π' -repairable. An **inquiry** over \mathcal{K} is a finite sequence of pair of sound questions and answers $\Omega_{\mathcal{K}} = ((\phi_1, f_1), \dots, (\phi_n, f_n))$ such that $f_i \in \phi_i$.

A question ϕ is a set of fixes, whereas an answer is a fix that the user chooses from ϕ . In the framework, questions are sound if, once answered, will not render the knowledge base unrepairable. These questions are crucial to guide the user.³

Example 4.2. Consider the knowledge base of Example 1.1 and the following sound question:

³Hereafter, every question is meant to be sound.

- $\phi = \{(A, 1, X_1), (A, 2, X_2), (A', 1, \text{Mike}), (A', 1, X_3), (A', 2, \text{Penicillin}), (A', 2, X_4)\}$ such that:
 - $A = \text{prescribed}(\text{Aspirin}, \text{John})$ and,
 - $A' = \text{hasAllergy}(\text{John}, \text{Aspirin})$.

An inquiry is a sequence of tuples of question and answer. In what follows we show how a sound question can be generated and how an inquiry with a user takes place.

Algorithm 2 generates a sound question from a given conflict \mathcal{X} . The choice of a conflict being the starting point of a question is evident. In fact, fixing those atoms that are parts of some conflicts necessarily solves inconsistencies. The algorithm in line 4 generates all positions of the atoms of the conflict \mathcal{X} , then for each position (A, i) that does not belong to Π , we generate all possible fixes in lines 6-7. The fixes change the value of the position (A, i) to other values in the active domain different than the actual value and to an existential variable uniquely attributed to (A, i) . Next in line 10, we enter in a filtering step where each fix is omitted if it renders the knowledge base not Π -repairable. Then it returns just ϕ . The following lemma proves that Algorithm 2 always gives a non-empty question which is necessarily sound.

LEMMA 4.3. *Given an inconsistent knowledge base \mathcal{K} and a set of positions Π such that \mathcal{K} is Π -repairable. Given a conflict $\mathcal{X} = (N, h)$, then $\text{soundquestion}(\mathcal{K}, \Pi, \mathcal{X}) \neq \emptyset$ and $\text{soundquestion}(\mathcal{K}, \Pi, \mathcal{X})$ outputs a sound question.*

PROOF. First, if $\Pi = \text{pos}(\mathcal{F})$ then \mathcal{K} is consistent (Π -repairability reduces down to consistency in this case), therefore there will be no conflict \mathcal{X} in \mathcal{K} . Assume that $\Pi \subset \text{pos}(\mathcal{F})$, then $\text{SOUNDQUESTION}(\mathcal{K}, \Pi, \mathcal{X}) = \emptyset$ if and only if: (1) In Line 5, $\Pi' \subseteq \Pi$, or, (2) In Line 8, $val = \emptyset$ for each position $(A, i) \in P$, or, (3) In Line 16, every fix is removed from ϕ .

For (1), suppose it is the case. We know that \mathcal{K} is Π -repairable, therefore there exists an r-fix \mathcal{P} of \mathcal{K} such that there exists no $(A, i, t) \in \mathcal{P}$ and $(A, i) \in \Pi$. Let $\mathcal{F}' = \text{apply}(\mathcal{F}, \mathcal{P})$ be the update repair of \mathcal{F} by \mathcal{P} . We know that $h(\text{body}(N)) \subseteq \mathcal{F}$, and $\forall A \in h(\text{body}(N))$ and for every $j \in [1, \text{arity}(A)]$, $(A, i) \notin \mathcal{P}$ for some t because $(A, i) \in \Pi'$. Therefore, $h(\text{body}(N)) \subseteq \mathcal{F}'$, which means that $\mathcal{X} = (N, h)$ is a conflict in $\mathcal{K} = (\mathcal{F}', \Sigma_T, \Sigma_C)$, consequently \mathcal{K}' is inconsistent and \mathcal{F}' is not a u-repair, thus \mathcal{P} is not r-fix, which contradicts the fact that \mathcal{K} is Π -repairable. For (2), it cannot be the case because val can always hold $\{X_A^i\}$. For (3), it is clear at each iteration the fix $f_k = (A, i, X_A^i)$ is in ϕ and will not be removed because if \mathcal{K}' is Π -repairable then $\mathcal{K}' = (\text{apply}(\mathcal{F}, f_k), \Sigma_T, \Sigma_C)$ is also Π' -repairable where $\Pi' = \Pi \cup \{(A, i)\}$.

The fact that $\text{SOUNDQUESTION}(\mathcal{K}, \Pi, \mathcal{X})$ returns a sound question is quite straightforward since if $\text{SOUNDQUESTION}(\mathcal{K}, \Pi, \mathcal{X}) \neq \emptyset$, the Algorithm in line 14 drops any answer that does not lead to a Π -repairable knowledge base. \square

This lemma tells us that if \mathcal{K} is Π -repairable, we can always find a sound question. This relies on the intuition that \mathcal{K} is Π -repairable, i.e. there necessarily exists some fixes that can be applied to render the knowledge base consistent.

Engaging the user in an inquiry needs to guarantee that the knowledge base is eventually repaired the way the user want it to be. However, such goal may never be accomplished if the inquiry cannot ensure that the resulting knowledge base is consistent. Algorithm 3 is the principled procedure that undertakes an inquiry dialogue with the user. The key idea is that we keep asking questions until there is no conflict left in the knowledge base. When

the user chooses a fix (A, i, t) from ϕ , the position (A, i) becomes *immutable* to prevent modifying the value again. The algorithm terminates and produces a consistent knowledge base.

Algorithm 2 Generate sound question

```

1: function SOUNDQUESTION( $\mathcal{K}, \Pi, \mathcal{X}$ )
2:    $\mathcal{X} = (N, h)$ 
3:    $\phi \leftarrow \emptyset$ 
4:    $\Pi' \leftarrow \{(A, i) \mid A \in h(\text{body}(N)) \text{ and } i \in [1, \text{arity}(A)]\}$ 
5:   for each  $(A, j) \in \Pi' \setminus \Pi$  do
6:      $val \leftarrow \text{adom}(A, i, \mathcal{F}) \setminus \{\text{value}_A^i(\mathcal{F})\}$ 
7:      $val \leftarrow val \cup \{X_A^i\}$ 
8:      $\phi \leftarrow \phi \cup \{(A, i, t) \mid t \in val\}$ 
9:   end for
10:  for each  $f_k = (A, i, t) \in \phi$  do
11:     $\Pi_{tmp} \leftarrow \Pi \cup \{(A, i)\}$ 
12:     $\mathcal{K}' \leftarrow (\text{apply}(\mathcal{F}, f), \Sigma_T, \Sigma_C)$ 
13:    if  $\Pi\text{-REP}(\mathcal{K}', \Pi_{tmp}) = \text{false}$  then
14:       $\phi \leftarrow \phi \setminus (A, i, t)$ 
15:    end if
16:  end for
17:  return  $\phi$ 

```

Algorithm 3 Inquiry with a user

```

1: function INQUIRY( $\mathcal{K}, \Pi$ )
2:    $\mathcal{K}' \leftarrow \mathcal{K}$ 
3:    $\Pi' \leftarrow \Pi$ 
4:   while  $\text{allconflicts}(\mathcal{K}') \neq \emptyset$  do
5:     Pick a conflict  $\mathcal{X} \in \text{allconflicts}(\mathcal{K}')$ 
6:      $\phi \leftarrow \text{SOUNDQUESTION}(\mathcal{K}, \Pi', \mathcal{X})$ 
7:      $f \leftarrow \text{ASKUSER}(\phi)$ 
8:      $\mathcal{K}' \leftarrow (\text{apply}(\mathcal{F}, f), \Sigma_T, \Sigma_C)$ 
9:      $\Pi' \leftarrow \Pi' \cup \{(A, i) \mid f = (A, i, t)\}$ 
10:    Recompute  $\text{allconflicts}(\mathcal{K}')$ 
11:  end while
12:  return  $\mathcal{K}'$ 

```

PROPOSITION 4.4 (SOUNDNESS AND TERMINATION). *Given an inconsistent knowledge base \mathcal{K} and a set of positions Π . Then, $\text{inquiry}(\mathcal{K}, \Pi)$ returns a consistent KB \mathcal{K} in a finite time.*

PROOF. Let $\mathcal{K}'_i, \Pi'_i, \phi_i, f_i$ be the knowledge base \mathcal{K}' , the set of positions Π' , the sound question ϕ and the chosen fix f at the beginning of the while loop at round i .

Round 1: $\mathcal{K}'_1 = \mathcal{K}$ is inconsistent and Π'_1 -repairable such that $\Pi'_1 = \Pi$.

Round i : \mathcal{K}'_i is either consistent, therefore $\text{allconflicts}(\mathcal{K}') = \emptyset$ and Algorithm 3 terminates, or inconsistent. However, we know that it is Π_i -repairable because $\mathcal{F}'_i = \text{apply}(\mathcal{F}'_{i-1}, \{f_i\})$ such that $f_i \in \phi_i$ and ϕ_i is a sound question. Let this round be the one in which $|\text{pos}(\mathcal{F}'_i)| - |\Pi'_i| = 1$. This means that at line 6 $\text{SOUNDQUESTION}(\mathcal{K}, \Pi, \mathcal{X}) \neq \emptyset$ and when the user chooses a fix in line 7, it is clear that at line 11 \mathcal{K}'_i is Π'_i -repairable with $\Pi'_i = \text{pos}(\mathcal{F}'_i)$. It is obvious that \mathcal{K}'_i is consistent hence $\text{allconflicts}(\mathcal{K}') = \emptyset$. \square

In what follows, we investigate the complexity of Algorithm 2.

PROPOSITION 4.5. *In the worst-case, Algorithm 2 runs in $O(d \times (|\text{pos}(\mathcal{F})| + C_{\Pi\text{-rep}}))$ with d being the size of the largest active domain in \mathcal{K} and $C_{\Pi\text{-rep}}$ being the worst-case complexity of Π -repairability algorithm.*

PROOF. The worst-case corresponds to $\Pi = \emptyset$ and $h(\text{body}(N)) = \mathcal{F}$, i.e. the whole set of facts is a conflict. In this case, the loop at line 5 will iterate over all positions, i.e. $\text{pos}(\mathcal{F})$. The loop at line 8 depends on d . The additional loop at line 10 performs d iterations.

We assume that the instruction at line 12 runs in constant time. Then, the function $\Pi\text{-REP}(\mathcal{K}', \Pi'_{tmp})$ is called d times. \square

The ultimate and most desirable goal of the inquiry is to arrive at the user's repair. A well-founded framework is the one that meets such requirement. However, this depends on how the user answers the questions, his background knowledge and so on. Therefore, some assumptions have to be made. In the next section, we consider a special case, i.e. when the user is *an oracle*.

4.1 The Oracle

In this section, we discuss the case in which interaction takes place with an oracle O . The oracle corresponds to a u-repair \mathcal{F}_O with an associated answering mechanism. The oracle draws its answers from \mathcal{F}_O as follows: given a question ϕ , f_i is an oracle answer if and only if $f_i \in \text{diff}(\mathcal{F}, \mathcal{F}_O)$. In case of multiple answers from the oracle, O non-deterministically chooses one of them. Note that not all the sets of fixes in $\text{diff}(\mathcal{F}, \mathcal{F}_O)$ are necessarily r-fixes. There may exist finitely many set of fixes, even though we assume that if a given r-fix \mathcal{P}_O is chosen by O , we name it an oracle r-fix. Note that such r-fix always exists as shown hereafter.

PROPOSITION 4.6. *Let \mathcal{F}' be a u-repair of \mathcal{F} . Then, there exists a one-to-one correspondence $\text{match}(x)$ such that $\text{diff}(\mathcal{F}, \mathcal{F}')$ is an r-fix.*

The proof is straightforward as there may exist exponentially many $\text{match}(x)$ that make all possible one-to-one correspondences. One of them must necessarily correspond to the real match because $|\mathcal{F}| = |\mathcal{F}'|$ and \mathcal{F}' is homomorphic to \mathcal{F} .

It turns out that when interacting with the oracle, the oracle is capable of answering every question asked by Algorithm 3.

LEMMA 4.7. *Given a consistent knowledge base \mathcal{K} , a possibly empty set of positions Π , an oracle O and its chosen r-fix \mathcal{P}_O . Every question ϕ_i generated in $\text{inquiry}(\mathcal{K}, \Pi)$ contains at least a fix f_i such that f_i is in \mathcal{P}_O .*

PROOF. If there exists a sound question ϕ_i generated by $\text{INQUIRY}(\mathcal{K}, \Pi)$ at an iteration i such that $\phi_i \cap \mathcal{P}_O = \emptyset$ then there exists $f \in \mathcal{P}_O$ such that $\mathcal{K} = (\text{apply}(\mathcal{F}, \{f\}), \Sigma_T, \Sigma_C)$ is not Π'_i -repairable. Therefore, \mathcal{K} has no u-repair. This contradicts the fact that \mathcal{F}_O is a u-repair. \square

This lemma gives us the most important result, by stating that when the inquiry ends, the resulting knowledge base is in fact the oracle's u-repair \mathcal{F}_O .

PROPOSITION 4.8 (SOUNDNESS W.R.T O). *Let $\mathcal{K}' = (\mathcal{F}', \Sigma_T, \Sigma_C)$ be the knowledge base returned by $\text{inquiry}(\mathcal{K}, \Pi)$ with an oracle O as the user. Then, \mathcal{F}' is the oracle's repair \mathcal{F}_O .*

PROOF. Since every question ϕ_i contains at least a fix $f \in \mathcal{P}_O$ then O will definitely choose a fix $f \in \mathcal{P}_O$. After answering by f , every next question ϕ_{i+1} will not contain f because once a fix is applied it will never be proposed again. However, by Lemma 4.7, ϕ_{i+1} will definitely contain a fix f' such that $f' \in \mathcal{P}_O \setminus \{f\}$. Hence, O will choose it until choosing all fixes in \mathcal{P}_O . We can see that in fact we are applying \mathcal{P}_O on \mathcal{F} one fix at a time. We know that \mathcal{P}_O is an r-fix, thus in other words we are constructing a u-repair identical to \mathcal{F}_O . Therefore, $\mathcal{F}' = \mathcal{F}_O$. \square

Let us give an example of an inquiry with an oracle.

Example 4.9 (Inquiry with oracle). Consider the knowledge base of Figure 1 (b) and the oracle repair \mathcal{F}_O :

$$\mathcal{F}_O = \begin{cases} \text{prescribed}(\text{Aspirin}, \text{John}) & \text{hasAllergy}(\text{Mike}, \text{Aspirin}) \\ \text{hasAllergy}(\text{Mike}, \text{Penicillin}) & \text{hasPain}(\text{Mike}, \text{Migraine}) \\ \text{isPainKillerFor}(\text{Nsaid}, \text{Migraine}) \\ \text{incompatible}(\text{Aspirin}, \text{Nsaid}) \end{cases}$$

The inquiry is as follows:

- (1) KB: which fix is true from the following set?
 - $\{\text{prescribed}(\text{Aspirin}, \text{John}), 1, t \mid t \in \{X_1, \text{Nsaid}\}\} \cup$
 - $\{\text{prescribed}(\text{Aspirin}, \text{John}), 2, t \mid t \in \{X_2, \text{Mike}\}\} \cup$
 - $\{\text{hasAllergy}(\text{John}, \text{Aspirin}), 1, t \mid t \in \{X_3, \text{Mike}\}\} \cup$
 - $\{\text{hasAllergy}(\text{John}, \text{Aspirin}), 2, t \mid t \in \{X_4, \text{Penicillin}\}\}$
- (2) O : the fix $(\text{hasAllergy}(\text{John}, \text{Aspirin}), 1, \text{Mike})$ is true.
- (3) KB: which fix is true from the following set?
 - $\{\text{incompatible}(\text{Aspirin}, \text{Nsaid}), 1, X_5\} \cup$
 - $\{\text{incompatible}(\text{Aspirin}, \text{Nsaid}), 2, X_6\} \cup$
 - $\{\text{prescribed}(\text{Aspirin}, \text{John}), 1, t \mid t \in \{X_7, \text{Nsaid}\}\} \cup$
 - $\{\text{prescribed}(\text{Aspirin}, \text{John}), 2, X_8\} \cup$
 - $\{\text{hasPain}(\text{John}, \text{Migraine}), 1, X_9\} \cup$
 - $\{\text{hasPain}(\text{John}, \text{Migraine}), 2, X_{10}\} \cup$
 - $\{\text{isPainKillerFor}(\text{Nsaid}, \text{Migraine}), 1, X_{11}\} \cup$
 - $\{\text{isPainKillerFor}(\text{Nsaid}, \text{Migraine}), 2, X_{12}\}$
- (4) O : the fix $(\text{hasPain}(\text{John}, \text{Migraine}), 1, \text{Mike})$ is true.

The knowledge base asks a question on a possible set of fixes. Then, the oracle chooses among them a fix that belongs to its r-fix. As one can notice after applying the fixes provided by the oracle in 2 and 4, the resulting knowledge base is indeed consistent and its set of facts equals \mathcal{F}_O . Notice that for instance the fix $f = (\text{incompatible}(\text{Aspirin}, \text{Nsaid}), 1, X_5)$ has no proposed value other than the existential variable because the active domain is empty. An additional comment is in order. The size of the questions grows polynomially (and not exponentially) in the size of the conflicts and in the size of the active domain. As a consequence, presenting these questions to the user is an implementation concern that can benefit from advanced HCI techniques [8] and is beyond the scope of this paper.

When interacting with an oracle, Algorithm 1 performs as many iterations as the number of conflicts in the knowledge base. However, the number of iterations corresponds to the size of the oracle's r-fix, denoted as r_O^{num} . This is the case because the oracle at each step answers with a fix $f \in \mathcal{P}_O$ until all fixes in \mathcal{P}_O are used. Given a set of empty positions Π and a Π -repairable inconsistent knowledge base $\mathcal{K} = (\mathcal{F}, \Sigma_T, \Sigma_C)$, then $r_O^{\text{num}} \leq |\text{pos}(\mathcal{F})|$. Therefore, the number of iterations is linear in the size of \mathcal{F} . However, the algorithm is dominated by the complexity of $\text{SOUNDQUESTION}(\mathcal{K}, \Pi', X)$ at line 6 and the computation of all conflicts. In fact, a conflict is the result of evaluating the body of a CDD, thus leading to a polynomial data complexity of boolean conjunctive query (for weakly-acyclic TGDs).

PROPOSITION 4.10. *Let C_{query} be the data complexity of evaluating a conjunctive query on a set of facts \mathcal{F} , in presence of a set of weakly-acyclic TGDs Σ_T . C_{soundq} be the complexity of soundquestion (Proposition 4.5) then the complexity of Algorithm 1 is $O(|\text{pos}(\mathcal{F})| \times (|\Sigma_C| \times C_{\text{query}} + C_{\text{soundq}}))$.*

The above result gives us a polynomial delay algorithm.

COROLLARY 4.11. *Algorithm 3 takes a polynomial delay between questions.*

A polynomial delay algorithm is an algorithm in which the time between the output of the solutions is bounded by a polynomial function of the input size in the worst case [23]. In between questions, we perform query evaluation which costs $|\Sigma_C| \times C_{\text{query}}$ and the computation of a sound question which costs C_{soundq} . Therefore, the user will not have to wait from one question to the next more than an amount of time that is polynomially bounded.

5 QUESTIONING STRATEGIES

The goal of a strategy is to minimize the number of questions to be asked to the user in order to arrive at a consistent knowledge base. In this section, we present four strategies improving one on another. We introduce: the baseline strategy called *random*; another strategy, called *opti-join*, that improves over *random* by considering the so-called join positions; another variant of *opti-join* called *opti-prop* that uses propagation, and finally a fourth strategy, called *opti-mcd* that improves over *opti-join*.

First, let us define the lower and upper bounds of the number of questions for each strategy. It is obvious that the maximum number of questions is equal to $|\text{pos}(\mathcal{F})|$. This case corresponds to a knowledge base in which every position needs to be changed to recover consistency. The minimum number of questions is clearly zero if the knowledge base is consistent.

The functions $\Pi\text{-REP}(\mathcal{K}, \Pi)$ of Π -repairability and $\text{CHECKCONSISTENCY}(\mathcal{K}')$ in Algorithm 1 and $\text{recompute_allconflicts}(\mathcal{K}')$ in Algorithm 3 shown in Section 4 are used in all the strategies. In the following, we detail Algorithm 4 where we propose an optimized version of these functions.

CHECKCONSISTENCY-OPT(\mathcal{K}'): the most naive approach for consistency check is to compute the chase on \mathcal{F} to get $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F})$ then to check whether there exists a CDD whose body evaluates to true in $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F})$, as implemented in $\text{CHECKCONSISTENCY}(\mathcal{K}')$. The optimized version $\text{CHECKCONSISTENCY-OPT}(\mathcal{K}')$ considers CDDs and TGDs such that \perp is seen as unary predicate (i.e. a constant). If, during the chase, the constant \perp is produced then the knowledge base is inconsistent. This is quite fruitful as it helps to stop consistency check as early as possible.

$\Pi\text{-REPOPT}(\mathcal{K}, \Pi)$: we can easily observe that if a knowledge base \mathcal{K} is Π -repairable and some positions have been fixed using a set of values \mathcal{V} then in the case in which a new fix f arrives with value v (constant or fresh existential variable), the knowledge base stays Π -repairable if $v \notin \mathcal{V}$. This is quite intuitive because if the fixed positions do not trigger any CDDs, the new value will not trigger any CDDs since all atoms have different values. If the value is already used, we proceed to the optimized consistency check $\text{CHECKCONSISTENCY-OPT}(\mathcal{K}')$. This is the optimized Π -repairability check of $\Pi\text{-REP}(\mathcal{K}, \Pi)$.

Let us now turn to the optimization of $\text{allconflicts}(\mathcal{K}')$. Let $\text{allconflicts}_{\text{naive}}(\mathcal{K}')$ be defined as the set of all naive conflicts. A naive conflict $X = (N, h)$ is defined as a conflict in the sense of Definition 2.3 except that h is a homomorphism from $\text{body}(N)$ to \mathcal{F} such that $h(\text{body}(N)) \subseteq \mathcal{F}$ and $\mathcal{C}\ell_{\Sigma_T}(\mathcal{F}) \models \perp$. These conflicts are computed on \mathcal{F} without applying the chase. It is clear that if $\text{allconflicts}_{\text{naive}}(\mathcal{K}') = \emptyset$, \mathcal{K} is not necessarily consistent as there is the possibility of having conflicts that will appear after applying the chase like the conflict X_2 in Example 2.4. However, we observed that resolving naive conflicts at first can eliminate other conflicts that are discovered after applying the chase. For instance in Example 2.4, if we resolve the conflict X_2 by updating the atom $\text{prescribed}(\text{Aspirin}, \text{John})$ on the first position, this will resolve the conflict that can be detected using the second CDD after applying the TGD. Therefore, our strategies are *two-phases* strategies. In the first phase, naive conflicts are resolved, while in the second phase, if the KB is still inconsistent, new conflicts are discovered and resolved during the chase. In what follows, we provide an optimization of conflicts computation.

UPDATECONFLICTS(\mathcal{K}'): we compute the initial set of naive conflicts over \mathcal{K} and keep them in a set C_{naive} . Then C_{naive} is

updated as follows. If the user provides a fix $f = (A, i, t)$ which results in a new set of facts \mathcal{F}' , then we remove all conflicts that are related to A from C_{naive} . Next, we define a subset $\Sigma_C^A \subseteq \Sigma_C$ that is related to A as follows: a CDD $N \in \Sigma_C^A$ iff $\exists A' \in \text{body}(N)$ and a homomorphism h such that $h(A') = A$. Finally, C_{naive} is updated by evaluating the body of each CDD $N \in \Sigma_C^A$ over the new set of facts \mathcal{F}' . In this optimization, instead of recomputing all conflicts, we are limiting the computation to the modified atom which is more efficient than evaluating all CDDs on \mathcal{F}' .

Once we have defined the above optimizations, we turn our attention to our proposed strategies, namely *random*, *opti-join*, *opti-prop* and *opti-mcd*. Algorithms 4 & 5 are parametrized, thus we can easily plug in the above optimizations. The main code of each strategy is Algorithm 4 which calls the functions $\text{GENERATEQUESTION}(\mathcal{K}, \Pi', \mathcal{X})$ and $\text{GENERATEQUESTION-CHASE}(\mathcal{K}, \Pi', \mathcal{X})$. These functions are implemented differently for each strategy. In addition, these functions make use of $\text{SOUNDQUESTION}(\mathcal{K}, \Pi', \mathcal{X})$ for which the function $\text{RETRIEVE-POSITIONS}(\mathcal{X}, \mathcal{K})$ changes from a strategy to another. For space reasons, in the following we report a concise description of each strategy. Their implementation and effectiveness are discussed in the next section.

Random. This strategy selects randomly a conflict from C_{naive} before asking a question about all positions. More precisely, $\text{GENERATEQUESTION}(\mathcal{K}, \Pi', \mathcal{X})$ randomly picks a conflict from C_{naive} and calls $\text{SOUNDQUESTION}(\mathcal{K}, \Pi', \mathcal{X})$. Then, $\text{RETRIEVE-POSITIONS}(\mathcal{X}, \mathcal{K})$ for each atom in $h(\text{body}(N))$, generates all positions (A, i) and proceed normally in $\text{SOUNDQUESTION}(\mathcal{K}, \Pi', \mathcal{X})$. While applying the chase if a violation of a CDD is detected, $\text{GENERATEQUESTION-CHASE}(\mathcal{K}, \Pi', \mathcal{X})$ gets all facts in \mathcal{F} that contribute to its violation, then generates all positions from this set and returns it as a question using $\text{SOUNDQUESTION}(\mathcal{K}, \Pi', \mathcal{X})$.

Opti-join. This strategy improves over *random* on $\text{RETRIEVE-POSITIONS}(\mathcal{X}, \mathcal{K})$ where only join positions are generated. Given a conflict $X = (N, h)$, a position (A, i) is a join position if and only if the variable at the position i in A' is a join variable in the CDD N such that $h(A') = A$. For instance, consider the example of Figure 1(b) the position $(\text{prescribed}(\text{Aspirin}, \text{John}), 1)$ is a join position because the variable X in $A' = \text{prescribed}(X, Y)$ is a join variable in the second CDD. Clearly, this strategy generates smaller questions and most notably avoid asking unnecessary questions. Consider the knowledge base \mathcal{K} without TGDs:
 $\mathcal{F} = \{\text{isUrgent}(\text{Mike}, a, 145), \text{isDeferredTo}(\text{Mike}, 12/10/2015)\}$.
 $\Sigma_C = \{\text{isUrgent}(X, Y, Z), \text{isDeferredTo}(X, W) \rightarrow \perp\}$.

Here the position $(\text{isDeferredTo}(\text{Mike}, "12/10/2015"), 2)$ is not a join position. However, the position $(\text{isUrgent}(\text{Mike}, a, 145), 1)$ is a join position. Join positions are pivotal in order to resolve conflicts, since changing non-join positions does not affect the homomorphisms and does not resolve conflicts.

Opti-prop. This strategy behaves the same as *opti-join* except that a propagation technique is used. By definition if the user chooses a fix $f = (\text{isUrgent}(\text{Mike}, a, 145), 1, X_1)$ from a question ϕ produced from a conflict X , then every position generated from X (except the chosen one in f) is added to Π if and only if it is not involved in any other conflict X' . This is quite intuitive because when the user chooses a fix f from a question ϕ , he is implicitly indicating that they are non-erroneous. However, if some of these positions participate in other conflicts then it is possible that they are erroneous, thus they will not be added to Π .

Opti-mcd. This strategy is an improvement over *opti-join*, it is based on the so-called Conflict Hypergraph (CH) [13, 24] where $\text{GENERATEQUESTION}(\mathcal{K}, \Pi', \mathcal{X})$ and $\text{GENERATEQUESTION-CHA}$

$SE(\mathcal{K}, \Pi', \mathcal{X})$ compute the **Maximally ContainD** position in all computed conflicts. Each position p is attributed a rank that indicates the number of conflicts containing p . The question is generated on the position that has the maximum rank. If more than one position are attributed the same maximum rank, one is picked randomly. Using CH, the maximally contained position p corresponds to the vertex of maximum degree. Obviously, this strategy can avoid asking unnecessary questions by looking ahead and choosing the position that resolves as many conflicts as possible.

15:    end if
16:  end for
17:  return  $\phi$ 

```

6 EXPERIMENTAL STUDY

Our experimental assessment is devoted to study two major features of our user-guided repairing framework: (i) *effectiveness*: investigates to what extent the framework is efficient in helping the user repair the knowledge base with minimal effort, in terms of average number of asked questions per strategy and average number of conflicts per question, and (ii) *delay time*: the efficiency of our framework when it comes to maintaining a reasonable delay time between each asked question. By a reasonable delay time we intend a delay less than 1 to 2 seconds as discussed in [26].

Experimental setup. We have implemented our framework using Java 1.8 on a 2.40GHz 4-core, 16Gb laptop running Windows 7.

We have used GRAAL⁴ as a chase engine. Each experiment has been repeated a number of times, as indicated in the individual plots (after discarding the cold start). As there are no existing datasets or benchmarks equipped with the rich set of constraints we consider in this paper, we rely on synthetically generated knowledge bases and corresponding constraints. We also employ a real-world knowledge base on Durum Wheat from [2]. This knowledge base has been constructed manually from documents and reports, which led to have notable inconsistencies. Moreover, the attached constraints (including TGDs and CDDs) have been validated by experts. Such a KB turned to be suitable for our experiments as it fits the assumption that the set of facts is dirty and the set of constraints is reliable.⁵

Synthetic KBs. The synthetic knowledge bases were generated by tuning some input parameters. We first generate a *vocabulary* of the knowledge base, i.e. predicate, variable, and constant spaces by allowing also n-ary relations. Each predicate is assigned a random arity from 2 to 10 following a uniform probability distribution. A given number of CDDs are generated over the vocabulary by parameterizing the number of atoms s involved in the CDDs and the percentage $v\%$ of atoms positions corresponding to join variables such that $s \in [5, 10]$ and $v\% \in [10\%, 100\%]$. TGDs are generated following the same procedure as CDDs. To make the knowledge base meaningful, links between TGDs and CDDs are made so that some TGDs may introduce facts that will violate the CDDs. A *depth* $d_{\mathcal{K}}$ for a given knowledge base \mathcal{K} is defined as how many TGDs applications are needed to violate a CDD. A conflict depth $d_{\mathcal{K}} = 2$ means for each CDD we need the application of two distinct TGDs so that the CDD is violated. Inconsistent KBs are generated as follows, for a given facts size $n_{\mathcal{F}}$ and an *inconsistency ratio* r_{inc} ⁶, we keep generating sets of atoms that violate the CDDs until we reach r_{inc} . Then, we pad the set of facts \mathcal{F} with atoms that are not involved in any conflicts. We add two indicators of the structure of conflicts in the KB, namely “Avg # atoms per overlap” and “Avg scope”. The first embodies the average number of atoms in each overlap, an overlap being the intersection between at least two conflicts. The avg scope indicates for each conflict how many conflicts are overlapping with it, this number being averaged over the total number of conflicts.

The Durum Wheat KBs. The real-world Durum Wheat knowledge base in our experiments has been augmented with new domain-specific TGDs and CDDs. The table in Figure 2 presents the different characteristic of the knowledge bases and an example of facts, a TGD and a CDD. Please note that ChaseSize (#atoms) refers to the size of the facts after applying the chase. We made two versions of the knowledge base of increasing size of CDDs, i.e. Durum Wheat v1 and Durum Wheat v2. Notice that the number of conflicts increases from v1 to v2 while inconsistency ratio stays the same. This is due to the fact that the conflicts newly discovered by the added constraints in v2 involve the same number of atoms.

We have simulated the end-user via an algorithm that randomly chooses a valid fix from the proposed fixes following a uniform probability distribution. Considering other kinds of distributions and, in particular, choosing the most appropriate probability distribution that can simulate all the user’s choices is not trivial and falls under user modeling, which is beyond the scope of our paper.

⁴<http://graphik-team.github.io/graal/>.

⁵Notice that we could not use popular knowledge bases such as YAGO, DBPedia and LUBM because of their limited expressiveness on the vocabulary (only binary relations) and lack of TGDs and CDDs.

⁶Number of atoms involved in at least one conflict divided by $n_{\mathcal{F}}$.

Analysis of Durum Wheat KBs. We measure the average number of asked questions for each strategy in order to gauge the effectiveness of our approach on our real-world dataset. Figure 2 (a) and (b) show the results for all the considered strategies. We can observe that *opti-mcd* is outperforming the other strategies on Durum Wheat v1 with an average of 14.18 questions asked. This difference is also observed on Durum Wheat v2 in Figure (a) where *opti-mcd* outperforms other strategies with an average of 29.36 questions asked. The reason why *opti-mcd* is the winning strategy is due to the fact that this strategy is actually capable of exploiting the overlapping among conflicts which is given by the indicator *avg scope*. In this case, the value of such indicator is 8 meaning that in the best case, roughly speaking, each question can solve 8.1 (or 7.1 for V2) conflicts. This is under the assumption that the conflicts are overlapping on the same atoms. Regarding the difference with the other strategies, the results show that the strategies (other than *opti-mcd*) tend to behave the same as they do not exploit such a property. In addition, notice that *opti-join* and *opti-prop* are very close to random strategy. This is due to the fact that the percentage of join positions in conflicts is close to 90%. This makes the probability of choosing a join position with random strategy very high. Moreover, the increase in the average number of asked questions in all strategies in v2 is explained by the fact that v2 has slightly more conflicts than v1.

Another perspective that gives a better illustration of the effectiveness of our interactive strategies is the average number of resolved conflicts per question in Figures (c) and (d). The former is computed as total nr. of conflicts/total nr. of questions (per strategy). Again, we can observe that the *opti-mcd* strategy handles more conflicts per question on average and proves to be the most effective strategy compared to the others.

Analysis of Synthetic KBs. We now analyze the effectiveness where the average number of asked questions is measured for each strategy on synthetically generated KBs. For the first experiment described in Figure 3, we generated a knowledge base with only CDDs and no TGDs. Then, we increased the inconsistency ratio by increments of 5% while keeping the size of the knowledge base fixed (see the table in Figure 3 for characteristics). The results show a good performance of *opti-mcd*, while *opti-join* and *opti-prop* behave similarly. The random strategy performs the worst among them. This result in fact confirms the observation already made on the Durum Wheat knowledge base about overlapping conflicts. In this experiment, we notice a larger gap between *opti-join* and *opti-prop* strategies on one side and random strategy on the other side. Since the percentage of join positions in conflicts is very low in the generated atoms (under to 30%), it is less likely that the random strategy would randomly choose a join position. The average number of resolved conflicts per question is shown in Figure 3 (b) where one can see the performance of each strategy.

We should highlight that the baseline strategy (*random*) in the two experiments is performing quite well as it still asks less questions than the number of conflicts. This is quite natural as the conflicts are in fact overlapping (as confirmed by the two indicators, *avg # atoms per overlap* and *avg scope*) hence many conflicts are resolved via the resolution of other conflicts. However, there is a huge gap between the performance of the baseline strategy and those of the more optimized strategies.

The second experiment aims at studying the convergence of each strategy. Figure 4 (a) is done on an inconsistent knowledge base with CDDs and no TGDs. We can observe that as the strategies proceed with questioning, they exhibit different speeds in getting toward a full resolution of the conflicts. While *opti-mcd*

is faster than all the other strategies, *opti-join* and *opti-prop* are quite similar with a small difference on the number of asked questions. Figure 4 (b) is done on a fixed inconsistent knowledge base with both CDDs and TGDs. We can observe that each strategy hits the lowest number of conflicts at a point (close to 0) then it starts slightly fluctuating until convergence. The rapid descending phase corresponds to the process of handling only CDDs that are directly violated by the initial set of facts without taking into account the TGDs. Once the TGDs are triggered and the chase starts, it interleaves TGDs with CDDs, leading to up and down fluctuations corresponding to new conflicts introduced by TGDs and resolution of conflicts with CDDs, respectively. Continuous lines between fluctuations correspond to stagnation, in which neither the questions are resolving conflicts nor triggering TGDs and CDDs brings new conflicts. The strategies *opti-mcd*, *opti-join* and *opti-prop* behave quite similarly with a notable difference in the convergence speed, bringing *opti-mcd* to be the fastest.

The next experiment is devoted to measure the delay time between questions for synthetic KBs. Note that the delay time for all previous experiments was very reasonable (less than 0.2 seconds) for both synthetic and Durum Wheat knowledge bases.

Figure 5 shows three different measures of the delay time using *opti-mcd* in all experiments. The delay time for the other strategies had a similar trend and is omitted for space reasons.

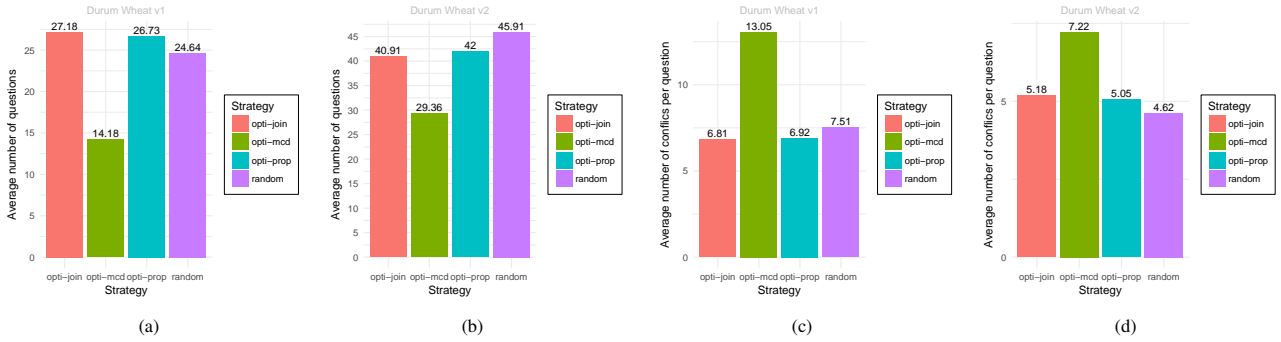

The goal of the experiment whose results are reported in Figure 5 (a) is to investigate whether increasing inconsistency (from 20% to 80%) would affect the delay time. We can observe that the inconsistency ratio is rather independent from the delay time. This is quite interesting as regardless of the inconsistency degree of the knowledge base, interactivity is guaranteed with the user in a very reasonable time (average is less than 0.25 sec). Some outliers are highlighted in the boxplot, however they stay within the limits of reasonable delay time (less than 0.8 sec).

In the next experiment (Figure 5 (b)), we employed a KB of increasing size (up to 20%, 40% and 60%), respectively while keeping the inconsistency ratio fixed to 30%. The delay time grows as the size of the knowledge base grows. Moreover, the boxplot shows that the variance of delay time increases as the size of the KB increases. This result shows that our method needs a piecemeal application of interactive repairing and can always be applied to small portions of the KB.

In the next experiment, we have chosen a worst-case scenario in which we have a fully inconsistent KB, corresponding to inconsistency ratio of 100%, and we vary the depth (from d_1 to d_4) of the dependencies involved (both TGDs and CDDs). For all depth d_i we have $\#CDD(d_i) = 150$, and $\#TGDs(d_1) = 50$, $\#TGDs(d_2) = 100$, $\#TGDs(d_3) = 150$, $\#TGDs(d_4) = 200$. We have already shown in the experiment of Figure 5 (a) that increasing the inconsistency ratio does not affect the delay time. We observe that the delay time increases with depth, in fact the larger the depth the more time the chase takes while repairing. Notice that the chase is involved in computing Π -repairability and consistency check. Overall, the delay time is kept low for all depths and less than 2 seconds.

7 CONCLUSION AND FUTURE WORK

In this paper, we have presented a novel user-guided repairing technique for knowledge bases, leveraging updates and interplay of dependencies (TGDs and CDDs). Several extensions can be thought of, such as formalization of user modeling to represent several classes of users (from domain experts to non-experts), and learning from provided user choices in the questioning strategies.

KB	Size (#atoms)	ChaseSize (#atoms)	Conflicts	Avg # atoms per overlap	Avg scope	#Repetitions
DURUM WHEAT V1	567	1075	185	1.42	8.1	10
DURUM WHEAT V2	567	1075	212	1.41	7.8	10
KB	#TGDs	#CDDs	Inconsistency ratio	Avg # atoms per conflict		
DURUM WHEAT V1	269	27	14% (79 atoms)	3		
DURUM WHEAT V2	269	100	14% (79 atoms)	2		

Durum Wheat KB	Content
\mathcal{F}	<i>hasPrecedent(soil2, vacoparis), sorghum(vacoparis), soil(soil2).</i> soil2 has a precedent vacoparis of type sorghum.
Σ_T	<i>isCultivatedOn(X1, X2), durum_wheat(X1), soil(X2) \rightarrow hasPrecedent(X2, X3), soybean(X3)</i> if a durum wheat is cultivated on a soil then the precedent on this soil is soybean.
Σ_C	<i>isAtGrowingStage(X, Z), isPerformedOn(X1, X), tillering_begins(Z), durum_wheat(X), fertilization(X1) $\rightarrow \perp$</i> it is forbidden (or impossible) to apply a fertilization on a durum wheat if it is in the beginning of the tillering growth stage.

Figure 2: Average number of questions per strategy on the Durum Wheat knowledge bases.

(a) Fixed size KB (1005 atoms) with increasing inconsistency ratio. CDDs and no TGDs.

(b) Average conflicts per question of (a).

KB	Size (#atoms)	ChaseSize (#atoms)	Conflicts	Avg # atoms per overlap	Avg scope	#Repetitions
“05%”	1005	1005	56	1.45	9.8	6
“10%”	1005	1005	135	1.57	12.8	6
“16%”	1005	1005	304	1.68	33.9	6
“20%”	1005	1005	356	1.65	30.5	6
“25%”	1005	1005	304	1.67	34.5	6
“30%”	1005	1005	496	1.66	31.6	6

Figure 3: Average number of questions per strategy on synthetic knowledge bases. The percentage on the axes represent inconsistency ratio.

We also believe that more challenges may arise in extending this work to full-fledged denial constraints and arbitrary (non weakly acyclic) TGDs.

ABSTRACT

Training deep learning models has received tremendous research interest recently. In particular, there has been intensive research on reducing the *communication cost* of training when using multiple computational devices, through reducing the precision of the underlying data representation. Naturally, such methods induce system trade-offs—lowering communication precision could decrease communication overheads and improve scalability; but, on the other hand, it can also reduce the accuracy of training. In this paper, we study this trade-off space, and ask: *Can low-precision communication consistently improve the end-to-end performance of training modern neural networks, with no accuracy loss?*

From the performance point of view, the answer to this question may appear deceptively easy: compressing communication through low precision should help when the ratio between communication and computation is high. However, this answer is less straightforward when we try to generalize this principle across various neural network architectures (e.g., AlexNet vs. ResNet), number of GPUs (e.g., 2 vs. 8 GPUs), machine configurations (e.g., EC2 instances vs. NVIDIA DGX-1), communication primitives (e.g., MPI vs. NCCL), and even different GPU architectures (e.g., Kepler vs. Pascal). Currently, it is not clear how a realistic realization of all these factors maps to the speed up provided by low-precision communication. In this paper, we conduct an empirical study to answer this question and report the insights.

1 INTRODUCTION

The system tradeoffs induced by training deep neural networks seem to be an endless discussion [9, 11, 15, 19, 24, 34, 46]. One reason for this sophistication is the level of diversity involved. At the algorithmic level, there are synchronous, asynchronous, and hybrid approaches. At the workload level, different neural networks have different computation and data movement patterns. At the architecture level, different computation devices, such as CPUs, GPUs, and FPGAs offer sharply different tradeoffs. Making matters worse, these are not pure performance tradeoffs, which one could tackle with performance modeling. Instead, different point in the tradeoff space has different *accuracy* of the trained model, a property that is very difficult to predict, and for which has there currently exists little theoretical understanding [49].

A Data Management Angle. From a data management perspective, these trade-offs provide an opportunity to build a *automatic optimizers* for deep learning tasks. Just as with previous optimizers that our community has been building [6, 8], the understanding of the tradeoff is often the prerequisite. Given the limited current theoretical understanding of deep learning, such modeling is inevitably empirical for the immediate future. Therefore, we believe that there is timely necessity for a set of empirical, fair, comparison to reveal the tradeoffs behind building and optimizing deep learning systems.

In this paper, we present an in-depth empirical study which focuses on a *subspace* of the whole tradeoff, that is, the tradeoff introduced by *the precision of communication when training deep neural networks with a synchronous multi-GPUs system*.

Low Precision Deep Learning. An emerging topic in deep learning systems is lowering the precision of data representation throughout the whole system [5, 14, 18, 20, 23, 33, 36, 50, 51]. There has been recent success in representing *all* data movements involved in training a neural network with as little as 1-bit per dimension while still getting the same accuracy for *some, but not all, networks* [36]. However, none of these work depict a full tradeoff space — they either focus on extreme cases (e.g., 1-bit) with significant loss of accuracy and do not discuss the impact of adding more bits, or only focus on algorithmic aspects, without a well-implemented system. In this paper, we conduct an empirical study to understand the impact of lower precision of data representation both on the training accuracy and the speed.

System Artefact. A fair empirical study calls for a system that achieves optimized performance for each configuration in the above space. Surprisingly, such a system does not exist off-the-shelf: if we just take CNTK or TensorFlow, the performance of many configurations is not as optimized as they could be. Thus, we decide to start from CNTK but conduct intensive performance optimization to ensure the fairness of our study. We first developed a system prototype optimized for low-precision machine learning. In this paper, we report an array of system optimizations that leads to up to 3.5× speed up over CNTK, which allows us to understand the tradeoff as fair as possible.

Summary of Contribution 1: Experimental Study. We consider the task of training deep neural networks on a single system with multiple GPUs, in a setting where all these GPUs communicate in a synchronous manner [24, 34]. In this setting, our first contribution is a study of the impact of *varying the number of bits to communicate between these devices from 1bit to 32bits*. Our study contains the following axes in the tradeoff space:

The tradeoff space we studied contains a full cross products the above axes (whenever possible); for each configuration, we vary the precision of data communication and measure (1) end-to-end performance (seconds), (2) convergence speed (#iterations), (3) speed per iteration (seconds), and (4) accuracy (%).

To fully depict this tradeoff, our study used more than 1400 machine hours on Amazon EC2's recently released 16-GPU instance and more than 20 machine hours on NVIDIA DGX-1. These give us an overview of how recent hardware and software have impact on the importance of low precision communication. This is so far the most comprehensive study of the impact of low-precision communication to deep learning. The system insights we get go significantly beyond those of previous work.

Summary of Contribution 2: Insights. Our study not only reveals insights beyond those of previous work, but also provides the first comparable quantitative evaluation of the results scattered in previous work that was original evaluated on different platforms and settings. We now briefly summarize these insights.

1. Does low-precision always hurt accuracy?

No. Across all datasets and models that we evaluated, we found parameter settings under which low-precision variants are able to achieve the same accuracy as full precision. Specifically, on all networks we evaluated, when quantizing communication using the 1bitSGD algorithm, a low-precision system is able to achieve the same accuracy (within 0.2%) as a full precision run. Using QSGD usually requires slightly higher precision: using 4-bit gradients always preserves the same accuracy (within 0.1%), while the 8-bit variant always matches or even *improves* final accuracy (within 0.5%). We note a few caveats regarding this result:

- (1) Different layers have different sensitivity to quantization: for convolutional neural networks, the convolutional layers require more bits than the fully connected layers.
- (2) Quantizing too aggressively can lead to significant accuracy loss: we identify scenarios where 2bit QSGD can no longer train to state-of-the-art precision.

2. Does low-precision always help performance?

Not always. The answer to this question depends on several factors. We postpone a detailed discussion to Section 5.2.

- (1) The most surprising result regarding performance regards the impact of the communication primitives used. When we replace MPI with the NCCL, a restricted set of communication primitives optimized by NVIDIA for GPU-to-GPU communication, 32bit full precision becomes much faster than MPI. Consequently, the speedup we can obtain with low-precision communication is also limited. In fact, on most networks, the performance improvement we get when using 8GPUs and NCLL is almost negligible; only for one network (VGG), we only get up to 1.4× speedup.
- (2) With slower MPI (which can be seen as a proxy for a slower interconnect), the tradeoff becomes more significant. One key factor is the ratio between computation

(time to calculate the gradient) and communication (time to communicate the gradient). For networks with a large number of parameters such as AlexNet, we observe up to 4× speedup using low-precision communication; For networks with small model, we observe almost no speedup.

- (3) The number of GPUs also plays a role. Naturally, when the number of GPUs increases, the necessity of using low-precision communication increases.

3. Is using extremely low precision ever helpful?

Rarely. We observe a trend of “diminishing returns” when lowering the precision of gradient to extreme cases such as a single bit, while such compression can lead to accuracy loss. Examining the time cost of a dataset iteration, even with MPI, using 1-bit rarely outperforms using 4-bit on our benchmarks. Through simulation, we can project a communication-to-computation regime where extreme low precision would have significant impact, but none of the existing networks fall into that regime.

4. Have the current programming models unleashed the full potential of low-precision machine learning?

No. NCCL hardcodes the reduction semantics with 32-bit full precision, and only offers a limited set of binary operations. Hence, there are currently no easy ways to use the NCCL primitives to support low-precision reduction efficiently. We conduct a simulation which implies that a version of NCCL with low-precision support could lead to a low-precision system that is up to 1.4× faster than our current prototype. MPI is also cumbersome to use in the context of low precision, although its richer semantics allow us to implement efficient variants of quantized methods.

5. Do we really need 16 GPUs on a single instance?

Rarely when training a single model. Amazon EC2 provides a single instance with 16 GPUs: p2.16xlarge, whose price is 2× higher than a p2.8xlarge 8-GPU instance, and currently stands at \$14/hour. We only find few scenarios where the speedup achieved with 16 GPUs versus 8 would justify the cost doubling.

Limitations. Our study has the following limitations.

The first is that our study assumes that the user has *zero error-tolerance*. That is, we focus on scenarios where the user wishes to obtain a model with the same accuracy as one trained at full precision, but wishes to save time (and money) on training by using quantized methods. If the user could tolerate higher errors (e.g., 10% accuracy loss), the results of our study might change, as we should be able to use more aggressive low-precision schemes.

The second limitation is that our study only considers the communication overhead when exchanging gradients across devices. Other potential benefits of using low-precision data representation is to speed up computation (each register can hold more numbers). We do not consider these, as the current GPU platform does not yet provide enough flexibility (e.g., 4-bit computation). A related limitation is that we only focus on GPU platforms. The current work is part of a larger ongoing study examining computation-to-communication trade-offs across CPU, GPU, XEON PHI, and FPGA; however, these other platforms are currently out of the scope of a single paper.

The third is that our study focuses on the speed of *training*, which is currently the most computationally-intensive aspect of neural networks. When the objective changes, e.g., energy efficiency, or speed of inference, the results might also change.

The fourth limitation is that we build our artefact starting from a specific platform, Microsoft CNTK. However, we expect similar observations to hold in the context of other deep learning systems, such as TensorFlow. All these systems use the same computational substrate (NVIDIA CUDA and cuDNN libraries [10]), and the semantics of the allreduce-based gradient exchange are similar across all synchronous systems. However, we do not wade into an in-depth quantitative analysis to support this claim. In the future, we plan to extend our study to a variety of systems, but this is out of the scope of this single paper.

The last limitation is that our study makes inherent assumptions of how different hyperparameters are tuned, e.g., learning rate and batch size. Although we believe our protocol of hyperparameters is reasonable and fair, it is also true that we did not fully explore all possible combinations of these hyperparameters, as the cost would increase significantly: by a rough estimate, an exhaustive search of the hyperparameter space would cost more than \$1M on EC2.

Reproducibility. All of our experiments can be reproduced using a virtual machine available on EC2: `i-0a7a0521e93c329d9`. Our variant of CNTK is available under `github.com/ZipML/CNTK`.

Overview. The rest of this paper is organized as follows. We introduce the background material in Section 2 and describe our system prototype in Section 3. We describe our experiment setup in Section 4 and analyze our results in Section 5. We provide more discussion in Section 5.4 and survey related work in Section 7.

2 PRELIMINARIES

We present background for our study. We first describe the stochastic gradient descent (SGD) algorithm and the synchronous parallel version of it which is the focus of our study. We then describe two low-precision SGD algorithms and discuss two different communication primitives based on MPI and NCCL.

2.1 Stochastic Gradient Descent

Stochastic gradient descent (SGD) is the workhorse algorithm in training deep learning models. SGD is developed for a more general class of optimization problems: Let $f : \mathcal{R}^n \rightarrow \mathcal{R}$, it solves $\min_{\mathbf{x}} f(\mathbf{x})$. The assumption of SGD is that we have access to the *stochastic gradients* of this function. We denote the stochastic gradient by \tilde{g} which satisfies $E[\tilde{g}(\mathbf{x})] = \nabla f(\mathbf{x})$. SGD will converge towards the minimum by iterating the following procedure

$$\mathbf{x}_{t+1} = \mathbf{x}_t - \eta_t \tilde{g}(\mathbf{x}_t),$$

where \mathbf{x}_t is the current state of the model, and η_t , also called the *step-size* or *learning rate* is a hyperparameter.

In the machine learning setting, we are given i.i.d. data points X_1, \dots, X_m generated from an unknown distribution D , and a loss function $\ell(X, \theta)$, which measures the loss of the model θ at data point X . We wish to find a model θ^* which minimizes $f(\theta) = E_{X \sim D}[\ell(X, \theta)]$, the expected loss to the data. Since for each i , the function $\nabla \ell(X_i, \theta)$ is a stochastic gradient for f , we can use SGD to find θ^* . This captures neural network training.

Synchronous Parallel SGD. In this paper, we focus on synchronous *data-parallel* SGD, modeling multi-GPU systems in which each GPU has a complete copy of the model. GPUs proceed in synchronous steps, and communicate using direct messages. Each of the K processors maintains a local copy of the model \mathbf{x} , of dimension n . The algorithm is described in Algorithm 1.

Each processor aggregates the value of \mathbf{x} , then obtains random gradient updates for each component of \mathbf{x} , then communicates

Data: Stochastic gradients

Data: Local copy of the parameter vector \mathbf{x}

```

1 for each iteration  $t$  do
2   Let  $\tilde{g}_t^i$  be an independent stochastic gradient ;
3    $M^i \leftarrow \text{Encode}(\tilde{g}_t^i(\mathbf{x}))$  //encode gradients ;
4   broadcast  $M^i$  to all peers;
5   for each peer  $\ell$  do
6     receive  $M^\ell$  from peer  $\ell$ ;
7      $\tilde{g}^\ell \leftarrow \text{Decode}(M^\ell)$  //decode gradients ;
8   end
9 end

```

Algorithm 1: Synchronous Data-Parallel SGD Algorithm.

Data: Gradient vector \mathbf{v} to be quantized

Data: Error ϵ from the previous round

```

1  $\mathbf{v} \leftarrow \mathbf{v} + \epsilon$  //add error from previous round ;
2 for each component  $i$  do
3    $q_i \leftarrow \text{avg}_+$  if  $v_i \geq 0$ ,  $\text{avg}_-$  otherwise;
4    $\epsilon_i \leftarrow v_i - q_i$ ;
5 end
6 return  $\mathbf{q}$ 

```

Algorithm 2: 1bitSGD procedure.

these updates to all other nodes, and finally aggregates the received updates and applies them to its local model. We have added *encoding* and *decoding* steps for the gradients before and after send/receive in lines 1 and 7. In the following, we assume the above pattern. Whenever describing a communication-efficient variant of SGD, we only specify the *encode/decode* functions. Note that these encoding process is often *lossy* that only recover an *approximate* gradient.

When the encoding and decoding steps are trivial (i.e., no encoding/decoding), we refer to this algorithm as *full-precision (parallel) SGD*. In this case, at each processor, if \mathbf{x}_t was the value of \mathbf{x} that the processors held before iteration t , then the updated value of \mathbf{x} by the end of this iteration is $\mathbf{x}_{t+1} = \mathbf{x}_t - (\eta_t/K) \sum_{\ell=1}^K \tilde{g}^\ell(\mathbf{x}_t)$, where each \tilde{g}^ℓ is a stochastic gradient. The speedup comes from the fact that all the updates are computed in parallel.

2.2 One-Bit Stochastic Gradient Descent

We describe the 1bitSGD quantization scheme, introduced by Seide et al. [39]. We denote the quantization function by $Q^{1b}(\mathbf{v})$, mapping a vector \mathbf{v} to its quantized version. The procedure first splits the vector \mathbf{v} into its positive and negative components, respectively, and computes the average over positive values, which we denote by avg_+ , and the average over negative values, which we denote by avg_- . Then,

$$Q_i^{1b}(\mathbf{v}) = \begin{cases} \text{avg}_+ & \text{if } v_i \geq 0 ; \\ \text{avg}_- & \text{otherwise.} \end{cases}$$

Simply put, the procedure replaces each component with the average corresponding to its respective sign. Critically, the procedure also maintains an error correction vector ϵ , associated to the model. In each iteration, the error from the previous iteration is *added* to the current value, before the value is quantized. This *error correction* step is critical to preserve accuracy [39]. The resulting algorithm works as Algorithm 2, which can be used as the Encode function of standard SGD (Algorithm 1).

2.3 SGD with Stochastic Quantization

We present the QSGD stochastic quantization scheme, following the description from the original paper [5]. We denote the quantization function by $Q_s(\mathbf{v})$, where $s \geq 1$ is a tuning parameter, corresponding to the number of “quantization levels”. Intuitively, s will define uniformly distributed levels between 0 and 1, to which each real value is quantized such that: 1) the value is preserved in expectation, and 2) minimal variance is introduced.

Given a non-zero vector $\mathbf{v} \in \mathcal{R}^n$, $Q_s(\mathbf{v})$ is defined as

$$Q_s(v_i) = \|\mathbf{v}\|_2 \cdot \text{sgn}v_i \cdot \xi_i(\mathbf{v}, s), \quad (1)$$

where $\xi_i(\mathbf{v}, s)$ ’s are independent random variables defined as follows. Let $0 \leq \ell < s$ be an integer such that $|v_i|/\|\mathbf{v}\|_2 \in [\ell/s, (\ell+1)/s]$. That is, $[\ell/s, (\ell+1)/s]$ is the quantization interval corresponding to $|v_i|/\|\mathbf{v}\|_2$. Then

$$\xi_i(\mathbf{v}, s) = \begin{cases} \ell/s & \text{with probability } 1 - p\left(\frac{|v_i|}{\|\mathbf{v}\|_2}, s\right); \\ (\ell+1)/s & \text{otherwise.} \end{cases}$$

Here, $p(a, s) = as - \ell$ for any $a \in [0, 1]$. If $\mathbf{v} = \mathbf{0}$, then we define $Q(\mathbf{v}, s) = \mathbf{0}$. The quantization distribution $\xi_i(\mathbf{v}, s)$ is defined to have minimal variance over distributions with support $\{0, 1/s, \dots, 1\}$. Its expectation satisfies $E[Q_s(v_i)] = v_i$. The quantizer is an unbiased estimator of the original gradient, thus ensures convergence [5, 14].

The above algorithm assumes quantization levels are uniformly distributed. There are algorithms in which quantization levels are distributed to further minimize variance, and they can, in some cases, significantly improve accuracy for model compression [50]. We implemented this for gradient but does not observe significant improvement.

2.4 Communication Primitives

The major communication bottleneck in the parallel SGD algorithm is in line 4 of Algorithm 1, where the gradient is broadcast to all other machines. Since the operation just needs to collectively add all gradients and produce the output at each node, this can be implemented using a standard instance of the `allreduce` operator, the optimized version of which has been studied for decades [32]. This operation can be implemented differently in standard CNTK: via a `reduce-and-broadcast` pattern implemented on top of MPI, which is the default in CNTK, and via NVIDIA’s NCCL extensions, which provide an `allreduce-sum` operation implementation.

2.4.1 MPI Reduce-and-Broadcast. The first aggregation algorithm is an MPI implementation of the classic `reduce-and-broadcast` pattern. More precisely, given a set of K nodes, the model of dimension n is split into n/K consecutive ranges, where the i th processor is logically assigned range $i[n/K]$. At the end of each processing batch, each processor has a full set of gradients, and the goal of the procedure is to aggregate (sum) all these gradients so that each processor has the same global gradient value at the end of the procedure.

The first step in the aggregation process is that a processor sends each range in its current gradient to the corresponding processor. Thus, each processor sums up the values for its assigned range locally. In the final step, each processor broadcasts its aggregated range to all other processors. Note that, in the actual implementation, the gradients may be transmitted in quantized form. (That is, we add quantization and un-quantization steps before communication, and after the message is received.) This does not affect the pattern.

2.4.2 NCCL Accumulation. NCCL [7] (pronounced “Nickel”) is an open-source communication library provided by NVIDIA, that is designed to provide efficient multi-GPU collective operations in a topology-aware way. In particular, NCCL provides a `sum` collective operation, which can be used to implement gradient aggregation. Internally, NCCL works by building a system-aware communication efficient ring topology, on top of which the collective operation is applied in a step-by-step manner. To minimize the memory impact of storing multiple copies, NCCL splits large data buffers into small slices (4-16KB), and uses efficient peer-to-peer access to push data between GPUs. NCCL currently supports several collective types (e.g., `all-gather`, `all-reduce`, `broadcast`) and a few binary operations (e.g., `sum`, `product`).

3 SYSTEM DESCRIPTION

We implemented our system on top of the Microsoft Cognitive Toolkit (CNTK) [3], version 2.0 beta 9. Our code is released both as open-source and as a docker instance at github.com/ZipML/CNTK. We first provide a brief technical overview of CNTK, and then focus on the additions brought by our artefact.

3.1 CNTK

The Microsoft Cognitive Toolkit (CNTK) is a computational platform optimized for deep learning. One general principle behind CNTK is that neural network operations are described by a directed computation graph, in which leaf nodes represent input values or network parameters, and internal nodes represent matrix operations on their children. CNTK supports and implements several popular network architecture types, such as feed-forward DNNs, convolutional nets (CNNs), and recurrent networks (RNNs/LSTMs). To train such networks, CNTK implements stochastic gradient descent (SGD) with automatic differentiation. CNTK supports parallelization across multiple GPUs and servers, with efficient MPI-based communication.

CNTK provides MPI-based GPU-to-GPU communication, and implements a CUDA-optimized version of the 1bit-SGD algorithm [39], as presented in Section 2.2. CNTK is optimized for usage with multi-server multi-GPU systems. CNTK exports APIs for C++, Python and C#/.NET. Additionally, CNTK specifies and implements a BrainScript scripting language, which can be used to define models such as neural networks, as well as to train and evaluate models without employing any lower-level programming languages. CNTK comes with many preinstalled scripts for training state-of-the-art models for different tasks, of which one of the most documented is image classification. Furthermore, it offers a number of pre-trained state-of-the-art models.

3.2 Low-Precision Support

CNTK implements 1bitSGD, which is used by default in multi-GPU environments with SGD. We now describe CNTK’s 1bitSGD implementation. Low-precision communication between GPUs is implemented using MPI `reduce-and-broadcast`.

3.2.1 Data Representation and 1bitSGD. CNTK stores the computation intensive data (model and minibatch samples) in the GPU memory, to ensure fast access and to avoid expensive data copying between host (main) and device (GPU) memory. In synchronized SGD, after every GPU is finished with the computation of gradients using backpropagation for its batch of samples, GPUs collectively aggregate gradients, so that each is left with a coherent copy of the model.

Gradients are stored using a matrix datatype in GPU memory. Aggregation is performed using the MPI Reduce-and-Broadcast technique described above. Sending gradient matrices is done separately for each gradient. To reduce communication, each GPU performs quantization and un-quantization on each message sent/received.

Quantization is done over columns. That is, the gradient is divided into columns, and each column is quantized separately. Thus, each quantized column is represented by two numbers avg_+ and avg_- , as well as an array of bits of size equal to number of elements in the column. That array of bits is represented as an integer array, where 8 quantized values, each consisting of 1 bit, are packed into 1 byte of memory. For instance, if there are n rows in a gradient matrix, then the quantized column is represented by two floating-point numbers and $\lceil n/8 \rceil$ bytes of memory.

In order for GPU memory to be aligned, if single-precision float-point numbers are used for calculations in a network, then avg_+ and avg_- are represented as a float data type, and n bits are packed in $\lceil n/32 \rceil$ C++ unsigned integers. If double-precision float-point numbers are used, avg_+ and avg_- are doubles and n bits are packed inside $\lceil n/64 \rceil$ C++ unsigned long long integers.

The quantization of a column is divided into 2 phases. The first phase launches GPU threads in order to calculate the numbers avg_+ and avg_- , where the number of threads is tuned for performance. The second phase uses calculated numbers avg_+ and avg_- to quantize values and pack bits into integers. For each integer in the quantized array, a new GPU thread is launched, which means that each thread in second phase quantizes exactly 32 or 64 elements of a column, depending on the precision employed. All of a gradient’s columns are quantized in parallel on the GPU. To optimize the performance, the *double buffering* technique is used, by which, while some gradients are being quantized, gradients that are finished with quantization are already being sent. That way communication overlaps with computation and GPU and CPU resources are maximally used. The current CNTK implementation uses MPI to exchange data between GPUs. Because of that, an additional transfer of the gradient between GPU device memory and host memory is required.

3.2.2 QSGD Implementation. In order to implement the QSGD quantization technique, we started from the 1bitSGD implementation. We re-wrote the quantization function, such that it follows the algorithm in Section 2.3. As in a case of 1bitSGD, we pack quantized values in integers, but we stored only one additional floating point number (for scaling) instead of two. The algorithm works such that the number of bits used for quantization is specified as $gBits$, and each gradient matrix values are quantize into an integer range with a specified number of bits. We implemented two different quantization methods, which differ in terms of the distribution of quantization levels. The first method follows faithfully the described algorithm: we use one out of $gBits$ bits to store the sign, and the rest of the bits is used for the quantized value. A second approach was to divide the interval $[-\|\mathbf{v}\|_2, \|\mathbf{v}\|_2]$ into $2^{gBits} - 1$ intervals of equal size, where the quantization levels are the endpoints of those intervals.

Since the dimensions of the gradient matrix could be large, and the variance introduced by quantization depends on the dimension, we implemented a variant which splits the vector into *buckets* of consecutive scalar values, where each bucket is quantized independently. The bucket size will be tuned for accuracy.

Dataset	# Training samples	# Validation samples	Size	# classes	Task
ImageNet	1.3M	50k	145GB	1000	Image
CIFAR-10	50k	10k	1GB	100	Image
AN4	948	130	64MB	NA	Speech

Figure 1: Statistics of datasets.

	p2.8xlarge	32	8 × K80	8 × 8.73	\$7.2
	p2.16xlarge	64	16 × K80	16 × 8.73	\$14.4
DGX1		2 × 16	8 × P100	8 × 10.6	\$50 (Nimbix)

Figure 2: Statistics of machines

Importantly, the whole matrix is reshaped such that each column has a specified number of elements, where we always try to place consecutive elements from the same column in original matrix in the same bucket. Using this bucketing approach, we are able to control quantization variance and get significant accuracy improvements.

We also implemented possibility to specify how the scaling factor for a vector is done. Currently, we support normalization by 2-norm and maximal element of a vector (infinity norm). The former is useful if we wish to obtain sparse quantized vectors, while the latter introduces smaller variance. In our experiments, normalizing by the maximal element gave better results in terms of accuracy, since more information is preserved. We used the NVIDIA cuRAND library with a different seed for each thread to generate random numbers.

Additional improvement was not to quantize matrices with small number of elements compared to total number of learning parameters in the model, since for those matrices we lose time by setting GPU threads and quantizing. We use full precision pipeline to send those matrices. We choose a threshold for small matrices in such way so we always quantize more than 99% of all parameters.

Reshaped 1bitSGD. We noted that some of the design choices made in the CNTK implementation of 1BitSGD can adversely affect the performance of this algorithm. For objects without dynamic dimensions, the first tensor dimension is the “row,” while the other dimensions are flattened onto “columns.” The CNTK implementation of 1BitSGD always quantizes *per column*.

Practically, on networks with many convolutional layers, this can lead to the following performance artefact: quantization is often applied to a column of very small dimension (1–3), which is computationally expensive, and leads to practically no communication reduction. (At the same time, this artefact leads to practically no accuracy loss for this version of the algorithm, since the gradients are almost unchanged.) Given this artefact, the standard implementation of 1BitSGD can be slower than even the full-precision version on heavily convolutional networks such as ResNet and Inception.

We correct this issue by always reshaping tensors with a reshaping technique applied in QSGD. We observe up to 4× speedup compared with the original CNTK implementation. In all experiments we will denote this version of 1bitSGD with 1bitSGD*.

4 EXPERIMENTAL SETUP

4.1 DataSets

We test various quantization techniques on two types of tasks: image classification, and automated speech recognition.

Task	Network	Dataset	Params.	# epochs to run	Initial Learning Rate
Image	AlexNet	ImageNet	62M	112	0.07
	BN-Inception	ImageNet	11M	300	3.6
	ResNet50	ImageNet	25M	120	1

LSTM	16	16	NA	NA	NA

Figure 4: Batch sizes used for each network and # GPUs. See Section 4.4 for the tuning protocol that results in these choices.

ImageNet. The ILSRVC 2015 dataset [37] (ImageNet) consists of 1.3 million images, each labelled into one of 1000 categories (classes), which cover a wide variety of objects, animals, scenes, or geometric concepts. To evaluate our models, we consider a standard scenario where validation set that consists of 100K images is used. The classifier has to predict either a single label (top-1) or five labels (top-5); an image is considered to be correct if at least one of the outputs matches the ground truth.

CIFAR-10. We also consider the small-scale CIFAR-10 object classification dataset [26]. The training set consists of 50,000 32×32 images. Images are labelled into 10 categories. The classifier has to output a single label (top-1); an image is considered to be correct if the prediction matches the ground truth.

AN4. For speech recognition, we use the CMU Alphanumeric (AN4) dataset [2]. AN4 consists of recordings of subjects spelling out their census data (name, address), as well as randomly generated sequences. It contains 948 training utterances, and 130 test utterances, sampled at 16 kHz, with 16-bit linear sampling.

4.2 Networks

We conducted our experiments on state-of-the-art networks for image classification and speech recognition.

For image classification we tested all the winning entries from the ImageNet competition from 2012 to 2015: AlexNet, VGG, BN-Inception, and ResNet. These architectures are state-of-the-art for this task. For experiments with VGG we used an instance with 19 layers, called VGG19. We performed experiments on the ImageNet dataset using ResNet networks with 50 and 152 layers (called ResNet50 and ResNet152), and used an instance of ResNet110 for the CIFAR10 dataset. All of these networks have different properties and different types of layers. BN-Inception is optimized for low number of parameters in network, whereas ResNet is built entirely of convolutional layers. For automated speech recognition we used a network that consists of 3 long short-term memory (LSTM) components. In all experiments we used architectures built and optimized by CNTK. More details about each network are in Figure 3.

4.3 Machines

For experiments, we used Amazon AWS EC2 P2 instances, designed for high-performance computing using GPUs. Instances we used are p2.xlarge with 1 GPU, p2.x8large with 8 GPUs on a single machine and p2.x16large with 16 GPUs on a single machine. The above instances have Nvidia Tesla K80 GPUs, based on the Kepler architecture. These GPUs support GPUDirect, which enables peer-to-peer GPU communication without using CPU.

Another machine we used is DGX1 that consists of 8×P100 GPUs. These GPUs are based on Pascal architecture and have NVlink high-bandwidth interconnection between GPUs. This results in highly-optimized GPU communication. The DGX machine also benefits from a customized interconnect, which provides high throughput and low latency.

4.4 Tuning and Experimental Protocol

We used nvidia-docker to conduct our experiments. One complicating factor of benchmarking deep learning systems is a large set of hyperparameters one needs to tune to conduct fair comparison. In this paper, we use the following tuning protocol.

Batch Size. The principle behind our hyperparameters tuning protocol is to always start from CNTK’s default hyperparameters, which have already been optimized by the CNTK developers for a specific network. For each configuration that we run, if CNTK does not run with the default hyperparameter setting, we vary the hyperparameter until it runs. For example, with the default batch size and 1GPU, CNTK cannot run ResNet because the whole batch does not fit in memory. In this case, we decrease the batch size until CNTK runs. Figure 4 shows the batch sizes we used.

Learning Rate. We always use the default learning rate, which is fine tuned by CNTK for 32-bit full precision. We use an SGD optimizer with default momentum (0.9 for most architectures). Note that, because we focus on synchronous communication, the number of GPUs has negligible impact on the convergence rate and final quality given a fixed value of the learning rate and momentum. This has been observed previously, in e.g. [24].

Bucket Size. QSGD and 1bitSGD with reshaped matrices introduce new hyperparameters, such as bucket size and normalization scaling factor. We picked these parameters that optimize for accuracy on these networks. We used QSGD 2bit with bucket size 128, QSGD 4bit and 8bit with bucket sizes 512, and QSGD 16bit with bucket size 8192. Also, for our version of 1bitSGD with reshaped matrices we tried multiple bucket sizes and used bucket size 64 for all performance and scalability numbers.

NCCL Simulation. CNTK uses NCCL only for full-precision data parallel SGD. When trying to twist it for low-precision, we find that its sum primitive only supports full precision and therefore, cannot be used for low-precision communication (as scaling factors cannot be taken into account). Thus, we implement a version where we simulated gradient aggregation with NCCL calls—we send the same number of bits using NCCL as we would if NCCL would have had support for low-precision. In the NCCL experiments, we use this simulated version to compare the performance of different low-precision setups.

5 ANALYSIS

We now analyze the experiment results and discuss the insights.

5.1 Accuracy

Does low-precision always hurt accuracy?

Figure 5: Accuracy results for various networks and datasets. Cyan = 32bit.

In the first set of experiments, we study the impact of training deep neural networks with low precision communication on the training accuracy. For each network and data set, we vary the precision and report the test accuracy¹ for each epoch. Figure 5 illustrates the result for AlexNet, ResNet50 and ResNet152 on ImageNet, ResNet110 on CIFAR, and an LSTM network on AN4.

Accuracy: Positives. There always exist settings of parameters for which quantized variants converge to the same or better final accuracy, compared to the full-precision version. For ResNet50/ImageNet, the full precision variant converges to 59.90% top-5 accuracy, whereas 1bitSGD converges to 60.31% accuracy. Similarly, QSGD with 4bit and 8bit quantization converge to 60.37% and 60.05% final accuracy, respectively. The accuracy improvement, of up to 0.47% is statistically significant. The reason for this small, but statistically significant, accuracy gain is not clear. We suspect it is caused by similar reasons with recent work observing that adding noise during the training process can improve accuracy [35]. Additional experiments show that, for this dataset, quantization also improves *training loss* (see Figure 5e), which is perhaps surprising. It is not clear what is the definitive reason of this behavior.

Accuracy: Negatives. It is also important to note that quantizing too aggressively can lead to significant accuracy loss. For example, QSGD where gradient values are quantized to two bits (levels 0, 1, and -1) has accuracy loss of at least 1 percentage point, consistently across image classification datasets. We note that this is not the case for non-convolutional networks (LSTMs), which appear to be able to handle quantization to very low precision. This finding is consistent with the theory [5, 50]: aggressive quantization increases the variance of the convergence process, and as such, the theory predicts that one would have to run for more iterations in order to converge to the same quality results.

Convergence Rate. Another aspect of accuracy is the *convergence rate*, i.e., how many epoches do the system need to converge to the same accuracy. We observe that 8bit bit QSGD with 512 bucket size is always enough, on all data sets considered, to guarantee effectively the same convergence rate. For 1bitSGD, we note that the reshaped variant requires relatively small bucket size (64) to converge to the same target accuracy. Even so, we note that the convergence rate of 1bitSGD (i.e., training error versus epoch) is lower per epoch compared to that of the full precision variant, but the best accuracy achieved across at the end of the training process is comparable for the two processes.

Impact of Layer Types. We also find *convolutional layers* are more “sensitive” to the noise induced by quantization. This phenomenon becomes apparent when we study the accuracy of two variants: (1) only quantize convolutional layers, and (2) quantize all layers. For example, on AlexNet, we can compare the accuracy of 1bitSGD with reshaping, which quantizes all layers, with the accuracy of standard 1bitSGD, which effectively does not quantize convolutional layers, as previously discussed. We observe that the reshaped variant has end accuracy that is lower; a closer examination of the loss-per-epoch graph shows that the reshaped version has consistently lower accuracy throughout the training process, although it almost catches up in terms of final accuracy across all epochs. The accuracy difference is starker (1 accuracy point) if we examine reshaped 1bitSGD with 512 bucket size.

Impact of Bucket Size. Another factor that has impact on the training accuracy is the bucket size of quantization, an additional parameter which we implemented for reshaped 1bitSGD and QSGD, and tuned for accuracy. For QSGD, this parameter can be used to directly throttle the added variance of the quantization process, at the cost of extra communication (since we need to send an extra floating-point number per each bucket). We observed that this can make a significant difference in terms of accuracy. For instance, on AlexNet / ImageNet, 4bit QSGD with 8192 bucket size has end accuracy that is $> 0.6\%$ inferior to the full-precision variant. Adjusting the bucket size to 512 allows it to *improve* accuracy over the full precision variant.

Further Lowering Accuracy. We also experimented with variants of QSGD with even lower communication overhead (such as 1-bit per location, or two-norm normalization). These variants are theoretically justified, in that they will eventually converge to a local optimum, at the cost of additional running time. However, in our experiments, these variants did not provide good accuracy results when run for the same number of epochs as the full precision version. These accuracy results are therefore omitted.

Discussion. One final observation we make is the impressive accuracy of the 1bitSGD error-correction techniques. It is worth emphasizing that this technique only sends the *signs* of the components, plus two scaling factors. On large-scale image classification datasets, it only loses relatively small amounts of accuracy ($< 0.3\%$). It is interesting future work to develop the theoretical foundation of its convergence and correctness, which is still an open question [39].

5.2 Performance

Does low-precision always help performance?

We now study the impact of low-precision training on end-to-end training time. We measure the time per iteration for the

¹We also conduct similar experiments for training accuracy. We leave the result to the full version as it does not change any claims.

Figure 6: Performance: Amazon EC2 Instance with MPI. QN = QSGD with N bits. 1b = 1bitSGD, 1b* = 1bitSGD with reshaping.

full-precision version (32bit), the standard CNTK implementation of 1bitSGD, our variant with reshaping and 64 bucket size (whose parameters are chosen so as to guarantee no accuracy loss), and QSGD with 2, 4 and 8-bit precision. (As observed, 512 bucket size guarantees state-of-the-art accuracy across all networks for the QSGD 4bit and 8bit variants. Even lowering the bucket size down to 32 for 2bit QSGD does not recover the full precision accuracy.) We break down the epoch time into communication time (bottom of each bar), and computation time (top of each bar, which also includes time spent compressing and uncompressing gradients). Figure 6 and Figure 7 show the result on the 16GPU Amazon instance, and Figure 8 and Figure 9 show the results on the 8GPU NVIDIA DGX-1. (Recall that DGX-1 machine has newer Pascal GPUs, as well as a faster, custom interconnect.)

Slow Inter-connections with Slow Primitives. We start with a setting that favors low precision communication the most — Amazon instances have 16 GPUs and all communications are conducted over MPI/PCIe. Figure 6 illustrates the result of using MPI as the communication primitives. We see that, in this setting, using low-precision communication significantly improves the performance — with 8GPUs on VGG network, the speedup of using 2-bit / 4-bit precision is almost 3× compared with using 32-bit full precision. On 16GPUs, the speedup is of > 5×.

This speedup does not hold across all network types, as these networks have different ratio between communication and computation: there are communication-dominated networks (such as

AlexNet and VGG), and computation-dominated networks (such as BN-Inception and ResNet50). ResNet152 balances these two.

Impact on Communication Overhead. We observe that on all networks, lowering the precision of communication significantly decreases the communication time. On AlexNet, the reduction in communication time with 4-bit quantization is almost 5×. For other networks, we observe similar speedups.

Impact on End-to-end Performance. As the computation time stays the same across different precision settings, the end-to-end performance speedup is smaller than our amount of savings we have in communication. For example, on AlexNet, the 5× speedup on communication results in 2× speedup overall. For computation-dominating network such as BN-Inception, we get only 1.3× speedup when lowering the precision by 16×.

Extremely Low Precision. This “diminishing returns” phenomenon implies that, even on machines with slow connection and slow communication, we rarely observe a case where using 1-2bit precision resulting in significant performance benefit as using 8-bits and 4-bits. In practice, this suggests that it may be reasonable to only lower the precision up to 8-bit gradients, since that going even lower does not really provide significant performance benefit on the model sizes we trained.

Precision versus Bucket Size. We observe that in many cases 1bitSGD is actually slower than 2bit QSGD. This is because, to preserve accuracy, we have to significantly decrease bucket size

Figure 10: Speed of using MPI on Amazon EC2 instance.

for the reshaped 1bitSGD algorithm. This renders it both more expensive in terms of communication, and increases the computational complexity of the GPU encoding/decoding operations.

Slow Inter-connections with Fast Primitives. Another way to implement the communication is to use NCCL instead of MPI. In our experiment, for the primitives we used in training, NCCL provides significantly faster communication. The reasons are two-fold: NCCL provides faster messaging, but also less memory overhead. Figure 7 shows the result of using NCCL on EC2.

Implementation Notes. We note the following caveats when using NCCL. First, NCCL does not currently support more than 8 GPUs, and we therefore only report numbers on up to 8 GPUs. Second, the current allreduce primitive in NCCL does not support low-precision and therefore all low-precision numbers of

Figure 11: Speed of using NCCL on Amazon EC2 instance.

Figure 7 are simulated by using the NCCL allreduce primitive to send the same amount of data that would be sent in a low-precision implementation using NCCL. (The rest of the algorithm remains the same; in this case, the GPUs will converge at a lower rate or could diverge, but this is irrelevant for the experiment.)

NCCL vs. MPI. We draw the reader’s attention to the performance difference between MPI (Figure 6) and NCCL (Figure 7). It is clear that the MPI implementation is slower than the NCCL – the computation time stays the same but the communication time differs significantly. One result we found especially surprising is that NCCL with full precision can be faster than MPI with low precision. Thus, on systems where NCCL is available, the fastest approach may be simply to run full precision with NCCL.

Super-Linear Scaling. The attentive reader may have noticed that, for the VGG19 network, the scaling is super-linear at 8GPUs. This phenomenon appears to be an artifact due to the minibatch size: at 8 GPUs, the batch for VGG19 consists of just 16 images, which the K80 GPUs are able to process in less than half of the time needed to process batches of 32 images. We were able to reproduce this behaviour on a single GPU with the same batch size, and we speculate that it may be due to better caching and less data movement at smaller sample size.

End-to-end Performance. Since NCCL could be modified to supports a low-precision allreduce in the future, we might be able to take advantage of low-precision communication to get even faster systems. As illustrated in Figure 7, on communication-dominated networks such as VGG, we get up to 1.5× speedup with 4-bit or 8-bit precision NCCL. This end-to-end speedup is

Figure 12: Scalability: Amazon EC2 Instance with MPI.

Figure 13: Scalability: Amazon EC2 Instance with NCCL.

Figure 14: Scalability: NVIDIA DGX-1 with MPI.

Figure 15: Scalability: NVIDIA DGX-1 with NCCL.

considerably lower than what we got in the MPI implementation, due to the balanced communication-to-computation ratio.

Fast Interconnect with Slow/Fast Primitives. On NVIDIA DGX-1, all GPUs are connected by a custom interconnect, which is significantly faster than PCIe. Further, the GPU is about 40% faster than in the Amazon instances. In this case, we observe similar results as the Amazon instances – when using slow primitives such as MPI, we get significant speedup by lowering the precision of communication, sometimes by up to 5× (VGG). However, with NCCL, the achievable speedup is again limited significantly. In fact, with NCCL, on VGG, we get up only 1.6× speedup when using 4-bits precision and relatively minor speedups for other networks and precision levels. It is interesting to note by examining the scalability graphs that the low precision brings the implementations close to linear scalability.

5.3 Scalability

Do we really need 16 GPUs on a single instance?

We now study scalability: how does the performance change with respect to the number GPUs we use? We define scalability as the number of samples per second in a certain configuration, divided by the number of samples per second processed by a single GPU for a training epoch. Figure 12-15 shows the result.

Scalability of Full Precision. We see that, using 32-bit full precision is able to scale, to some extent. For computation-dominated networks, 32-bit full precision is able to scale up to 6× with MPI and 7× with NCCL on 8 GPUs. However, for communication dominated networks, 32-bit suffers. For example, for AlexNet, 32-bit full precision with MPI only achieves 2× scale up with 16 GPUs. Comparing NCCL with MPI, NCCL scales up better than MPI for 32-bit full precision – This is not surprising, as NCCL is more efficient in dealing with communications.

Impact of Low Precision Communication. We see that using low-precision quantized communication consistently improves the scalability over 32-bit for all experiments. When using MPI on Amazon instances, the scalability for AlexNet is improved from < 3× to 8× by using 1bitSGD. Networks such as ResNet152 scale almost *linearly* once quantization is applied even with MPI: with quantization, scalability at 16GPUs is 2×, and 5× without.

When using NCCL, the difference between quantized communication and full precision decreases significantly. As shown in Figure 13 and Figure 15, quantization only introduces at most 50% scale up compared with full precision. The only exception is for VGG, which has the most number of parameters, in which 32-bit saturated the memory bandwidth. On the other hand, on AlexNet, we note that 32bit NCCL is *faster* than the 4bit variant. This explanation for this perhaps surprising result is the following: the computational overhead of AlexNet is relatively low; 4bit quantization adds to it, since we need to compress and

Figure 16: Left: Price and accuracy of training different neural networks with different # epochs on Amazon EC2 with 8-bit and NCCL. Right: The performance improvement of using low-precision communication w.r.t. the communication and computation ratio.

de-compress the data. This overhead is not compensated by the reduction in communication for this network.

Impact on Reshaping. One optimization we did to improve OneBitSGD is reshaping. The scalability of the reshaped version of 1bitSGD is initially lower than the original on e.g. AlexNet, due to the higher computational cost of quantizing into buckets, but this cost is amortized at higher thread counts. We note however that overall the less computationally expensive QSGD variant may perform better, although it sends more data per iteration.

5.4 Discussion

Accuracy vs. Cost. The experimental results we get in this paper also allow us to understand a tradeoff between the model accuracy and the dollar cost of training. Such tradeoff could be useful for scenarios like the following: assume a user with a large dataset (e.g., ImageNet), wishing to train a large-scale neural network to full precision, but on a limited budget. What is the most cost-effective way to do so, assuming current Amazon pricing?

Figure 16 illustrates the results of the price and accuracy for training different networks to full accuracy, according to its published recipe (accuracy and # of epochs to convergence). We use the cheapest EC2 solution for each network, which we derive from the scalability graphs. We see that there is an almost monotonic correlation between \$ cost and accuracy – the more \$ the user spent, the higher the quality s/he can expect. On the other hand, it is also clear that there exists a diminishing return phenomenon – spending \$600 to switch from AlexNet to ResNet-50 bumps the accuracy by 15 percentage points, but another \$1500 to switch to ResNet-152 only gets 2 percentage points improvement. It would be interesting to study an automatic management system that is both budget-aware and error tolerance-aware.

MPI vs. NCCL. The answer to this question may be now obvious to the reader. While low-precision techniques can render the MPI implementation competitive, the gap in performance is clear, since the NCCL implementation is heavily optimized. One issue is that NCCL is currently not fully supported for large GPU deployments, such as multi-node or supercomputer setups. In these cases, an MPI-based implementation is necessary. An interesting topic for future work would be to add or improve MPI support for such reduction operations, as well as support for low-precision data representations.

1bitSGD vs QSGD. Given our experiments, there is no clear winner between the two quantized methods. However, it is worth noting that the 8bit QSGD variant provides stable accuracy and

performance for all the architectures we consider, and therefore may be a good entry-level compressor. Further, we note that QSGD wins in most of the head-to-head comparisons, albeit by small margins. The 1bitSGD algorithm communicates the least data of all the methods we tried, and can provide impressive accuracy results. Thus, in a setting where tuning is possible or minimal communication is necessary, 1bitSGD may be a good alternative. Unfortunately, there is no easy way of predicting whether a quantized method will achieve the target accuracy for a network without actually running it.

6 OUTLOOK

One general way to interpret our results is that the neural network training workloads we considered are currently *not communication-bottlenecked*. More precisely, either by using compressed communication, NCCL, or both, all the networks we considered can achieve significant speedup on multiple GPUs.

What would happen to scalability if we extrapolate the trend of increasing the model size? In particular, *in what model-size-to-GFLOPS regime would the scalability impact of quantization be significant?* These are the questions we address in Figure 16, where we examine the performance improvement (in terms of speedup) of the 8-bit quantized variant over the full-precision one, as we (artificially) increase model size for the AlexNet architecture, for the 8GPU NCCL version, on which we only noted minimal improvements using quantization. The experiment shows that, the performance improvement due to low-precision communication depends on a key factor, i.e., the ratio between communication and computation (MB/GFLOPS). As the MB/GFLOPS ratio increases, running time becomes driven by the cost of communication, and hence the speedup because of quantization is more apparent. Notice that the overall speedup will always be upper bounded by the difference in bandwidth usage, which is $4\times$.

Another trend is the increased computational power of GPUs, and the presence of increasingly many GPUs on a single machine. The first factor decreases the computational cost of networks, while the second increases the overall communication bandwidth of the workload. We can therefore speculate that these factors will bring quantized methods closer to the fore in terms of ways to reduce total running time, although it is also likely that the speed of communication between GPUs will improve in the future.

7 RELATED WORK

Changing the precision of data representation in machine learning systems has received tremendous interest recently [5, 13, 14, 16–18, 20, 23, 28, 29, 33, 36, 39, 45, 50, 51]. These works cover a whole spectrum of machine learning tasks, from training to inference, as well as models, from deep learning to linear models. This paper builds upon this prior art, but focuses on the system perspective, to understand to what extent these approaches help.

Low-Precision Deep Learning Training The research area closest to our work is *training* deep learning models with low precision [3, 5, 18, 23, 39]. Most algorithms use *quantizing* different data channels to lower the precision of the data representation.

One of the first references to recognize the performance impact of gradient communication when training large speech models was 1BitSGD [39]. This algorithm is inspired by delta-sigma modulation [38] for analog-to-digital conversion. In further work, variants of the same algorithm are benchmarked and refined on large-scale Amazon proprietary datasets by Strom [42]. The

1BitSGD algorithm is available by default in the Microsoft Cognitive Toolkit (CNTK) [3]. Another algorithm we consider is QSGD [5], based on the idea of *stochastically rounding* floating-point values to a small set of integer levels. For both algorithms, it is not clear how well they generalize to other deep learning models and what are their system tradeoffs; if fact, 1BitSGD is even observed to diverge in some large-scale experiments by the original authors. The goal of this paper is to provide such a fair and well-optimized system benchmark.

Recent work considered alternative quantization strategies. Aji and Heafield [4] proposed to *truncate* the gradients to only the top few percentage of components—sorted by magnitude—and to store the remaining components locally, in an accumulation vector. This enables *sparse* communication to be employed, and the authors show that extremely small densities (<0.5%) are sufficient for convergence for neural machine translation tasks. This scheme is promising, and can be theoretically justified by relating it to *asynchronous* SGD. However, we believe that this method requires further research to be widely applicable, for the following two reasons. First, in ImageNet experiments on the Inception architecture, we noticed that the density levels required for convergence to the same accuracy level as the full communication variant were large (>10%); due to the extra cost of transmitting indices, it is not clear that the reduction in communication is sufficient to ensure scalability on such tasks. Second, sparse communication is not efficiently supported by communication primitives such as NCCL or MPI.

Another approach to reduced communication is to *factorize* large network layers, and communicate the factors instead of large matrices [11, 47]. These methods are effective at reducing communication for fully-connected layers, but are less useful for conv layers, where weights are typically smaller than activations. As many modern architectures, e.g. ResNet, are almost entirely convolutional, this could limit the usefulness of this approach.

Distributed Machine Learning There is certainly no shortage of distributed systems for machine learning, and deep learning in particular, such as TensorFlow [1], CNTK [3], Theano [44], Torch [12], Caffe [25], and MXNet [9]. The database community has also been contributing to this list intensively, and examples include MLib [31] built upon Spark [48], KeystoneML [41], SystemML [8], and GraphLab [30]. However, only a few of these systems support low precision training. We hope our study helps clarify the system tradeoff introduced by low precision communication and that the insights can help to improve these systems.

EasyCommit: A Non-blocking Two-phase Commit Protocol

Suyash Gupta, Mohammad Sadoghi
 Exploratory Systems Lab
 Department of Computer Science
 University of California, Davis

ABSTRACT

Large scale distributed databases are designed to support commercial and cloud based applications. The minimal expectation from such systems is that they ensure consistency and reliability in case of node failures. The distributed database guarantees reliability through the use of atomic commitment protocols. Atomic commitment protocols help in ensuring that either all the changes of a transaction are applied or none of them exist. To ensure efficient commitment process, the database community has mainly used the two-phase commit (2PC) protocol. However, the 2PC protocol is blocking under multiple failures. This necessitated the development of the non-blocking, three-phase commit (3PC) protocol. However, the database community is still reluctant to use the 3PC protocol, as it acts as a scalability bottleneck in the design of efficient transaction processing systems. In this work, we present Easy Commit which leverages the best of both the worlds (2PC and 3PC), that is, non-blocking (like 3PC) and requires two phases (like 2PC). Easy Commit achieves these goals by ensuring two key observations: (i) first transmit and then commit, and (ii) message redundancy. We present the design of the Easy Commit protocol and prove that it guarantees both safety and liveness. We also present a detailed evaluation of EC protocol, and show that it is nearly as efficient as the 2PC protocol.

1 INTRODUCTION

Large scale distributed databases have been designed and deployed for handling commercial and cloud-based applications [11, 14–18, 35, 37, 46–48, 56, 57]. The common denominator across all these databases is the use of transactions. A transaction is a sequence of operations that either reads or modifies the data. In case of geo-scale distributed applications, the transactions are expected to act on data stored in distributed machines spanning vast geographical locations. These geo-scale applications require the transactions to adhere to ACID [22] transactional semantics, and ensure that the database state remains consistent. The database is also expected to respect the atomicity boundaries that is either all the changes persist or none of the changes take place. In fact atomicity acts as a contract and establishes trust among multiple communicating parties. However, it is a common knowledge [39] that the distributed systems undergo node failures. Recent failures [19, 38, 55] have shown that the distributed systems are still miles away from achieving undeterred availability. In fact there is a constant struggle in the community to decide the appropriate level of database consistency and availability, necessary for achieving maximum system performance. The use of strong consistency semantics such as serializability [6] and linearizability [30] ensures system correctness. However, these properties have a causal effect on the underlying parameters such

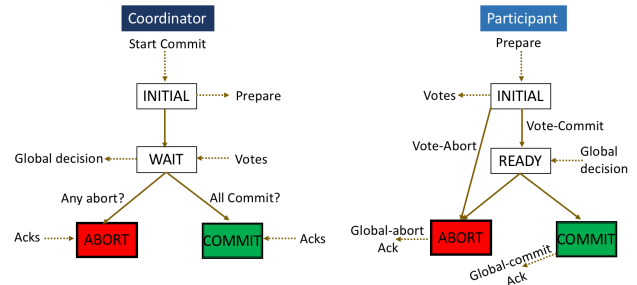

Figure 1: Two-Phase Commit Protocol

as latency and availability. Hence, a requirement for stronger consistency leads to a reduction in system availability.

There have been works that try to increase the database availability [2, 3]. But, more recently the distributed systems community has observed a shift in paradigm towards ensuring consistency. A large number of systems are moving towards providing strong consistency guarantees [15, 16, 18, 34, 41, 56]. Such a pragmatic shift has necessitated the use of agreement protocols such as Two-Phase Commit [21]. Commit protocols help in achieving the twin requirements of consistency and reliability in case of partitioned distributed databases. Prior research [9, 18, 42, 54, 56] has shown that data partitioning is an efficient approach to reduce contention and achieve high system throughput. However, a key point in hindsight is that the use of commit protocol should not be a cause for an increase in WAN communication latency in geo-scale distributed applications.

Transaction commit protocols help in reaching an agreement among the participating nodes when a transaction has to be committed or aborted. To initiate an agreement each participating node is asked to vote its decision on the operations on its transactional fragment. The participating nodes can decide to either commit or abort an ongoing transaction. In case of a node failure, the active participants take essential steps (run the termination protocol) to preserve database correctness.

One of the earliest and popular commitment protocol is the *two-phase commit* [21] (henceforth referred as 2PC) protocol. Figure 1 presents the state diagram [39, 52] representation of the 2PC protocol. This figure shows the set of possible states (and transitions) that a coordinating node¹ and the participating nodes follow, in response to a transaction commit request. We use solid lines to represent the state transitions and dotted lines to represent the inputs/outputs to the system. For instance, the coordinator starts the commit protocol on transaction completion, and requests all the participants to commence the same by transmitting *Prepare* messages. In case of multiple failures the two-phase commit protocol has been proved to be blocking [39, 51]. For example, if the coordinator and a participant fail, and if the remaining participants are in the READY state, then they cannot make progress (blocked!), as they are unaware about the state of the failed participant. This blocking characteristics

¹The coordinating node is the one which initiates the commit protocol, and in this work it is also the node which received the client request to execute the transaction.

of the 2PC protocol endangers database availability, and makes it unsuitable for use with the partitioned databases². The inherent shortcomings of the 2PC protocol led towards the design of resilient *three-phase commit* [50, 52] (henceforth referred as 3PC) protocol. The 3PC protocol introduces an additional PRE-COMMIT state between the READY and COMMIT states, which ensures that there is no direct transition between the non-committable and committable states. This simple modification makes the 3PC protocol non-blocking under node failures.

However, the 3PC protocol acts as the major performance suppressant in the design of efficient distributed databases. It can be easily observed that the addition of the PRE-COMMIT state leads to an extra phase of communication among the nodes. This violates the need of an efficient commit protocol for geo-scale systems. Hence, the design of a *hybrid* commit protocol, which leverages the best of both worlds (2PC and 3PC), is in order. We present the *Easy Commit* (a.k.a EC) protocol, which requires two phases of communication, and is non-blocking under node failures. We associate two key insights with the design of Easy Commit protocol that allow us to achieve the non-blocking characteristic in two phases. The first insight is to delay the commitment of updates to the database until the transmission of global decision to all the participating nodes, and the second insight is to induce message redundancy in the network. Easy Commit protocol introduces message redundancy by ensuring that each participating node forwards the global decision to all the other participants (including the coordinator). We now list down our contributions.

- We present the design of a new two-phase commit protocol and show it is non-blocking under node-failures.
- We also present an associated termination protocol, to be initiated by the active nodes, on failure of the coordinating node and/or participating nodes.
- We extend ExpoDB [45] framework to implement the EC protocol. Our implementation can be used seamlessly with various concurrency control algorithms by replacing 2PC protocol with EC protocol.
- We present a detailed evaluation of the EC protocol against the 2PC and 3PC protocol over two different OLTP benchmark suites: YCSB [10] and TPC-C [12], and scale the system upto 64 nodes, on the Microsoft Azure cloud.

The outline for rest of the paper is as follows: in Section 2, we motivate the need for EC protocol. In Section 3, we present design of the EC protocol. In Section 4, we present a discussion on assumptions associated with the design of commit protocols. In Section 5, we present the implementations of various commit protocols. In Section 6, we evaluate the performance of EC protocol against the 2PC and 3PC protocols. In Section 8, we present the related work, and conclude this work in Section 9.

2 MOTIVATION AND BACKGROUND

The state diagram representation for the two-phase commit protocol is presented in Figure 1. In 2PC protocol, the coordinator and participating nodes require at most two transitions to traverse from INITIAL state to the COMMIT or ABORT state. We use figure 3a to present the interaction between the coordinator and the participants, on a linear time scale. The 2PC commit protocol starts with the coordinator node transmitting a *Prepare* message

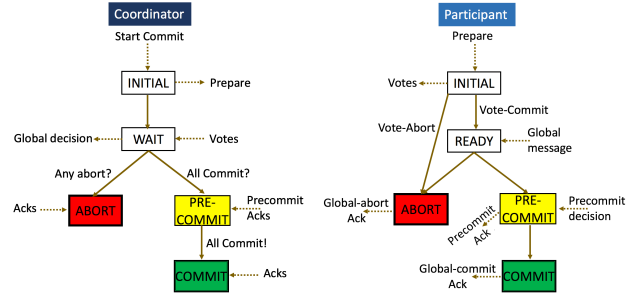

Figure 2: Three-Phase Commit Protocol

Figure 3: Commit Protocols Linearly Spanned

to each of the cohorts³ and adding a *begin_commit* entry in its log. When a cohort receives the *Prepare* message, it adds a *ready* entry in its log, sends its decision (*Vote-commit* or *Vote-abort*) to the coordinator. If a cohort decides to abort the transaction then it independently moves to the ABORT state, else it transitions to the READY state. The coordinator waits for the decision from all the cohorts. On receiving all the responses, it analyzes all the votes. If there is a *Vote-abort* decision, then the coordinator adds an *abort* entry in the log, transmits the *Global-Abort* message to all the cohorts and moves to the ABORT state. If all the votes are to commit, then the coordinator transmits the *Global-Commit* message to all the cohorts, and moves to COMMIT state, after adding a *commit* entry to log. The cohorts on receiving the coordinator decision move to the ABORT or COMMIT state, and add the *abort* or *commit* entry to the log, respectively. Finally, the cohorts acknowledge the global decision, which allows the coordinator to mark the completion of commit protocol.

²Partitioned database is the terminology used by the database community to refer to the shared-nothing distributed databases, and should not be intermixed with the term network partitioning.

³The term cohort refers to a participating node in the transaction commit process. We use these terms interchangeably.

The 2PC protocol has been proved to be blocking [39, 51] under multiple node failures. To illustrate this behavior let us consider a simple distributed database system with a coordinator C and three participants X , Y and Z . Now assume a snapshot of the system when C received *Vote-commit* from all the participants, and hence, it decides to send *Global-Commit* message to all the participants. However, say C fails after transmitting *Global-Commit* message to X , but before sending messages to Y and Z . The participant X on receiving the *Global-Commit* message, commits the transaction. Now, assume X fails after committing the transaction. On the other hand, nodes Y and Z would *timeout* due to no response from the coordinator, and would be blocked indefinitely, as they require node X to reach an agreement. They cannot make progress, as neither they have knowledge of the global decision nor they know the state of node X before failure. This situation can be prevented with the help of the three-phase commit protocol [50, 52].

Figure 2 presents the state transition diagram for the coordinator and cohort executing the three-phase commit protocol, while figure 3b expands the 3PC protocol on the linear time scale. In the first phase, the coordinator and the cohorts, perform the same set of actions as in the 2PC protocol. Once the coordinator checks all the votes, it decides whether to abort or commit the transaction. If the decision is to abort, the remaining set of actions performed by the coordinator (and the cohorts) are similar to the 2PC protocol. However, if the coordinator decides to commit the transaction, then it first transmits a *Prepare-to-Commit* message, and adds a *pre-commit* entry to the log. The cohorts on receiving the *Prepare-to-Commit* message, move to the PRE-COMMIT state, add a corresponding *pre-commit* entry to the log, and acknowledge the message reception to the coordinator. The coordinator then sends a *Global-Commit* message to all the cohorts, and the remaining set of actions are similar to the 2PC protocol.

The key difference between the 2PC and 3PC protocol is the PRE-COMMIT state, which makes the latter non-blocking. The design of 3PC protocol is based on the Skeen’s [50] design of a non-blocking commit. In his work Skeen laid down two fundamental properties for the design of a non-blocking commit protocol: (i) no state should be adjacent to both the ABORT and COMMIT states, and (ii) no non-committable⁴ state should be adjacent to the COMMIT state. These requirements motivated Skeen to introduce the notion of a new committable state (PRE-COMMIT) to the 2PC state transition diagram.

The existence of PRE-COMMIT state makes the 3PC protocol non-blocking. The aforementioned multi-node failure case does not indefinitely block the nodes Y and Z which are waiting in the READY state. The nodes Y and Z can make safe progress (by aborting the transaction) as they are assured that the node X could not have committed the transaction. Such a behavior is implied by the principle that no two nodes could be more than one state transition apart. The node X is guaranteed to be in one of the following states: INITIAL, READY, PRE-COMMIT and ABORT, at the time of failure. This indicates that node X could not have committed the transaction, as nodes Y and Z are still in the READY state (It is important note that in the 3PC protocol the coordinator sends the *Global-Commit* message after it transmits the *Prepare-to-commit* message to all the nodes.). Interestingly, if either of nodes Y or Z are in the PRE-COMMIT state then they can actually commit the transaction. However, it can be easily observed that the non-blocking characteristic of the 3PC protocol comes at an additional cost, an extra round of handshaking.

⁴INITIAL, READY and WAIT states are considered as non-committable states.

Figure 4: Easy Commit Protocol

3 EASY COMMIT

We now present the *Easy Commit (EC)* protocol. EC is a two-phase protocol, but unlike 2PC it exhibits non-blocking behavior. The EC protocol achieves these goals through two key insights: (i) first transmit and then commit, and (ii) message redundancy. In the second phase, Easy Commit ensures that each participating node forwards the coordinating node’s decision to all the other participants. To ensure non-blocking behavior, EC protocol also requires each node (coordinator and participants) to transmit the global decision to all the other nodes, before they commit. Hence, the commit step subsumes message transmission to all the nodes.

3.1 Commitment Protocol

We present the EC protocol state transition diagram, and the coordinator and participant algorithms in Figure 4 and Figure 5, respectively. The EC protocol is initiated by the coordinator node. It sends the *Prepare* message to each of the cohorts and moves to the READY state. When a cohort receives the *Prepare* message, it sends its decision to the coordinator, and moves to the READY state. On receiving the responses from each of the cohorts, the coordinator first transmits the global decision to all the participants, and then commits (or aborts) the transaction. Each of the cohorts, on receiving a response from the coordinator, first forward the global decision to all the participants (and the coordinator), and then commit (or abort) the transaction locally.

We introduce multiple entries to the log to facilitate recovery during node failures. Note: the EC protocol allows the coordinator to commit as soon as it has communicated the global decision to all the other nodes. This implies that the coordinator need not wait for the acknowledgments. When a node timeouts, while waiting for a message, it executes the *termination protocol*. Some of the noteworthy observations are:

- I. A participant node cannot make a direct transition from the INITIAL state to the ABORT state.
- II. The cohorts, irrespective of the global decision, always forward it to every participant.
- III. The cohorts need not wait for message from the coordinator, if they receive global decision from other participants.
- IV. There exists some hidden states (a.k.a TRANSMIT-A and TRANSMIT-C), only after which a node aborts or commits the transaction (cf. discussed in Section 3.2).

In Figure 3c, we also present the linear time scale model for the Easy Commit protocol. Here, in the second phase, we use solid lines to represent the global decision from the coordinator to the cohorts, and the dotted lines to represent message forwarding.

```

Send Prepare to all participants;
Add begin_commit to log;
Wait for (Vote-commit or Vote-abort) from all participants;
if timeout then
  Run Termination Protocol;
end if
if All messages are Vote-commit then
  Add global-commit-decision-reached in log;
  Send Global-commit to all participants;
  Commit the transaction;
  Add transaction-commit to log;
else
  Add global-abort-decision-reached in log;
  Send Global-abort to all participants;
  Abort the transaction;
  Add transaction-abort to log;
end if

```

(a) Coordinator's algorithm

```

Wait for Prepare from the coordinator;
if timeout then
  Run Termination Protocol;
end if
Send decision (Vote-commit or Vote-abort) to coordinator;
Add ready to log;
Wait for message from coordinator;
if timeout then
  Run Termination Protocol;
end if
if Coordinator decision is Global-commit then
  Add global-commit-received in log;
  Forward Global-commit to all nodes;
  Commit the transaction;
  Add transaction-commit to log;
else
  Add global-abort-received in log;
  Forward Global-abort to all nodes;
  Abort the transaction;
  Add transaction-abort to log;
end if

```

(b) Participant's algorithm

Figure 5: Easy Commit Algorithm.

3.2 Termination Protocol

We now consider the correctness of the EC algorithm under *node-failures*. We want to ensure that the EC protocol exhibits both liveness and safety properties. A commit protocol is said to be *safe* if there isn't any instant during the execution of the system under consideration when two or more nodes are in conflicting states (that is one node is in COMMIT state while other is in ABORT). A protocol is said to respect *liveness* if its execution causes none of the nodes to block.

During the execution of a commit protocol, each node waits for a message for a specific amount of time before it *times out*. When a node times out then it concludes loss of communication with the sender node, which in our case corresponds to failure of the sender node. A node is assumed to be blocked if it is unable to make progress on timeout. In case of such node failures, the active nodes execute the termination protocol to ensure system

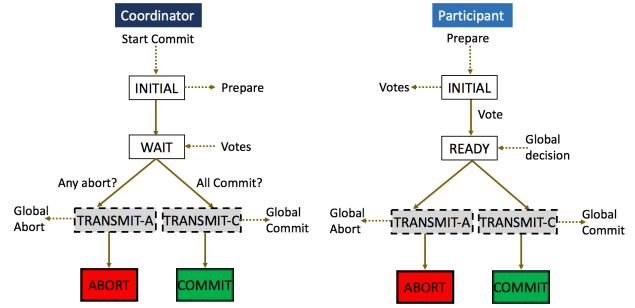

Figure 6: Logical expansion of Easy Commit Protocol.

makes progress. We illustrate the termination protocol by stating the actions taken by the coordinator and the participating nodes on timeout. The coordinator can timeout only in the WAIT state, while the cohorts can timeout in INITIAL and READY states.

- A. **Coordinator Timeout in WAIT state** – If the coordinator times out in this state, then it implies that the coordinator didn't receive the vote from one of the cohorts. Hence, the coordinator first adds a log entry for the *global-abort-decision-reached*, then transmits the *Global-abort* message to all the active participants, and finally aborts the transaction.
- B. **Cohort Timeout in INITIAL State** – If the cohort times out in this state, then it implies that it didn't receive the *Prepare* message from the coordinator. Hence, this cohort communicates with other active cohorts to reach a common decision.
- C. **Cohort Timeout in READY State** – If the cohort times out in this state, it implies that it didn't receive a *Global-Commit* (or *Global-Abort*) message from any node. Hence, it would consult the active participants to reach a decision common to all the participants.

Leader Election: In last two cases we force the cohorts to perform transactional commit or abort based on an agreement. This agreement requires selection of a new leader (or coordinator). The target of this leader is to ensure that all the active participants, follow the same decision that is commit (or abort) the transaction. The selected leader can be in the INITIAL or the WAIT state. It consults all the nodes if any of them has received a copy of the global decision. If none of the nodes know the global decision, then the leader first adds a log entry for the *global-abort-decision-reached*, then transmits the *Global-abort* message to all the active participants, and finally aborts the transaction.

To prove correctness of EC protocol, Figure 6 expands the state transition diagram. We introduce two intermediate hidden states (a.k.a TRANSMIT-A and TRANSMIT-C). All the nodes are oblivious to these states, and the purpose of these states is to ensure message redundancy in the network. As a consequence, we can categorize the states of the EC protocol under five heads:

- UNDECIDED – The state before reception of global decision (that is INITIAL, READY and WAIT states).
- TRANSMIT-A – The state on receiving the global abort.
- TRANSMIT-C – The state on receiving the global commit.
- ABORT – The state after transmitting *Global-Abort*.
- COMMIT – The state after transmitting *Global-Commit*.

Figure 7 illustrate whether two states can co-exist (Y) or they conflict (N). We derive this table on the basis of our observations: I - IV and cases A - C. We now have sufficient tools to prove the liveness and safety property of EC protocol.

	UNDECIDED	T-A	T-C	ABORT	COMMIT
UNDECIDED	Y	Y	Y	N	N
T-A	Y	Y	N	Y	N
T-C	Y	N	Y	N	Y
ABORT	N	Y	N	Y	N
COMMIT	N	N	Y	N	Y

Figure 7: Coexistent states in EC protocol (T-A refers to TRANSMIT-A and T-C refers to TRANSMIT-C).

THEOREM 3.1. *Easy Commit protocol is safe, that is in the presence of only node failures, for a specific transaction, two nodes cannot be in both Aborted and Committed states, at any instant.*

PROOF. Let us assume the case that two nodes p and q are in the conflicting states (say p voted to abort the transaction and q voted to commit). This would imply that one of them received *Global-Commit* message while the other received *Global-Abort*. From (II) and (III) we can deduce that p and q should transmit the global decision to each other, but as they are in different states, it implies a contradiction. Also, from (I) we have the guarantee that p could not have directly transitioned to the ABORT state. This implies p and q would have received message from some other node. But, then they should have received the same global decision.

Hence, we assume that either of the nodes p or q moved to a conflicting state and then failed. But, this violates property (IV) which states that a node needs to transmit its decision to all the other nodes before it can commit or abort the transaction. Also, once either of p or q fails, the rest of the system follows termination protocol (cases (A) to (C)), and reaches a safe state. It is important to see that the termination protocol is re-entrant. \square

THEOREM 3.2. *Easy Commit protocol is live that is in the presence of only node failures, it does not block.*

PROOF. The proof for this theorem is a corollary of Theorem 3.1. The termination protocol cases (A) to (C) provide the guarantee that the nodes do not block and can make progress, in case of a node failure. \square

3.3 Comparison with 2PC Protocol

We now draw out comparisons between the the 2PC and EC protocols. Although, EC protocol is non-blocking, but still 2PC protocol has a lower message complexity. EC protocol’s message complexity is $O(n^2)$, while the message complexity for 2PC $O(n)$.

To illustrate the non-blocking property of EC protocol, we now tackle the motivational example of multiple failures. For the sake of completeness we restate the example here. Let us assume a distributed system with coordinator C and participants X , Y and Z . We also assume that C decides to transmit *Global-Commit* message to all the nodes, and fails just after transmitting message to the participant X . Say, the node X also fails after receiving the message from C . Thus, nodes Y and Z neither received messages from C nor from node X . In this setting, the nodes Y and Z would eventually timeout, and run the termination protocol. From case (C) of termination protocol, it is evident that the nodes Y and Z would select a new leader among themselves, and would safely transit to the ABORT state.

3.4 Comparison with 3PC protocol

Although, EC protocol looks similar to 3PC protocol, but it is a stricter and an efficient variant to 3PC protocol. It introduces

the notion of a set of intermediate hidden states: TRANSMIT-A and TRANSMIT-C, which can be superimposed on the ABORT and COMMIT states, respectively. Also, in the EC protocol, the nodes do not expect any acknowledgements. So unlike the 3PC protocol, there are no inputs to the TRANSMIT-A, TRANSMIT-C, ABORT and COMMIT states. However, EC protocol has a higher message complexity than 3PC, which has a message complexity of $O(n)$.

4 DISCUSSION

Until now, all our discussion assumed existence of only node failures. In Section 3 we prove that EC protocol is non-blocking under node failures. We now discuss the behavior of the 2PC, 3PC and EC protocols under communication failures that is message delay and message loss. Later in this section we also study the degree to which these protocols support independent recovery.

4.1 Message Delay and Loss

We now analyze the characteristics of 2PC, 3PC and EC protocol, under unexpected delays in message transmission. Message delays represent an unprecedented lag in the communication network. The presence of message delays can cause a node to timeout and act as if a node failure has occurred. This node may receive a message pertaining transaction commitment or abort, after the decision has been made. It is interesting to note that 2PC and 3PC protocols are not safe under message delays [7, 39]. Prior works [26, 39] have shown that it is impossible to design a non-blocking commitment protocol for unbounded asynchronous networks with even a single failure.

We illustrate the nature of 3PC protocol under message delay, as it is trivial to show that 2PC protocol is unsafe under message delays. The 3PC protocol state diagram does not provide any intuition about the transitions that two nodes should perform when both of them are active but unable to communicate. In fact, partial communication or unprecedented delay in communication can easily hamper the database consistency.

Let us consider a simple configuration with a coordinator C and the participants X , Y and Z . Now assume that C receives *Vote-commit* message from all the cohorts, and, hence it decides to send the *Prepare-to-Commit* message to all the cohorts. However, it is possible that the system starts facing unanticipated delays on all the communication links with C at one end. We can also assume that the paths to node X are also facing severe delays. In such a situation, the coordinator would proceed to *globally commit* the transaction (as it has moved to the PRE-COMMIT state), while the nodes X , Y and Z would abort the transaction (as from their perspective the system has undergone multiple failures). This implies that the 3PC termination protocol is not sound under message delays, and similarly we can show that EC protocol is unsafe under message delays.

This situation can aggravate if the network undergoes message loss. Interestingly, message loss has been deemed to be true representation of the network partitioning [39]. Hence, no commit protocol is safe (or non-blocking) under message loss [7]. If the system is suffering from message loss then the participating nodes (and coordinator) would *timeout*, and would run the associated terminating protocol that could make nodes transit to conflicting states. Thus, we also conclude that 2PC, 3PC and EC protocols are unsafe under message loss.

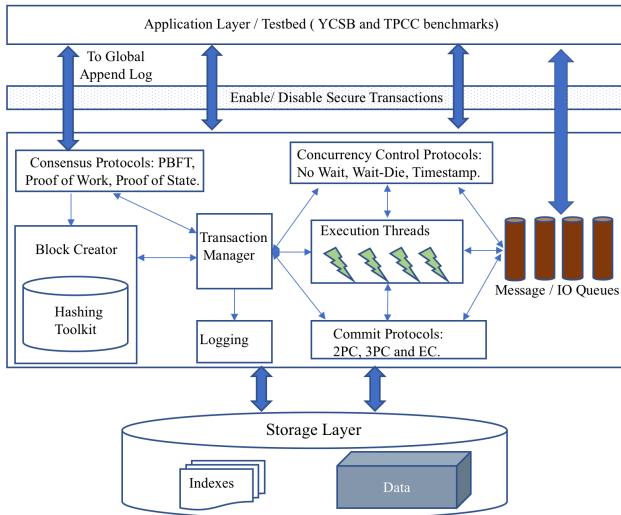

Figure 8: ExpoDB Framework - executed at each server process, hosted on a cloud node. Each server process receives a set of messages (from clients and other servers), and uses multiple threads to interact with various distributed database components.

4.2 Independent Recovery

Independent recovery is one of the desired properties from the nodes in a distributed system. An independent recovery protocol lays down a set of rules that help a failed node to terminate (commit or abort) the transaction which was executing at the time of its failure, without any help from other active participants. It is interesting to note that 2PC and 3PC protocols only support partial independent recovery [7, 39].

It is easy to present a case where the 3PC protocol lacks independent recovery. Consider a cohort in the READY state that votes to commit the transaction, and fails. On recovery this node needs to consult with the other nodes about the fate of the last transaction. This node cannot independently commit (or abort) the transaction, as it does not know the global decision, which could have been either commit or abort.

EC protocol supports independent recovery in following cases:

- (i) If a cohort fails before transmitting its vote, then on recovery it can simply abort the transaction.
- (ii) If the coordinator fails before transmitting the global decision then it aborts the transaction on recovery.
- (iii) If either coordinator or participant fail after transmitting the global decision and writing the log, then on recovery they can use this entry to reach the consistent state.

5 EASY COMMIT IMPLEMENTATION

We now present a discussion on our implementation of the Easy Commit (EC) protocol. We have implemented EC protocol in the ExpoDB platform [45]. ExpoDB is an in-memory, distributed transactional platform that incorporates and extends the Deneva [28] testbed. ExpoDB also offers secure transactional capability, and presents a flexible framework to study distributed ledger—blockchain [8, 43].

5.1 Architectural Overview

ExpoDB includes a lightweight layer for testing distributed protocols and design strategy. Figure 8 presents the block diagram

representation of the ExpoDB framework. It supports a client-server architecture, where each client or server process is hosted on one of the cloud nodes. To maintain inherent characteristics of a distributed system, we opt for a shared nothing architecture. Each partition is mapped to one server node.

A transaction is expressed as a stored procedure that contains both program logic and database queries, which read or modify the records. The clients and server processes communicate with each other using TCP/IP sockets. In practice, the client and server processes are hosted on different cloud nodes, and we maintain an equal number of client and server cloud instances.

Each client creates one or more transactions, and sends the transaction execution request to the server process. The server process in turn executes the transaction by accessing the local data and runs the transaction until further execution requires access to remote data. The server process then communicates with other server processes that have access to remote data (remote partitions), to continue the execution. Once, these processes return the result, the server process continues execution till completion. Next, it takes a decision to commit or abort the transaction (that is, executes the associated *commit protocol*).

In case a transaction has to be aborted then the coordinating server sends messages to the remote servers to rollback the changes. Such a transaction is resumed after an exponential back-off time. On successful completion of a transaction, the coordinating server process sends an acknowledgment to the client process, and performs necessary garbage collection.

5.2 Design of 2PC and 3PC

2PC: The 2PC protocol starts after the completion of the transaction execution. The read-only transactions and single partition transactions do not make use of the commit protocol. Hence, the commit protocol comes into play when the transaction is multi-partition and performs updates to the data-storage. The coordinating server sends a *Prepare* message to all the participating servers, and waits for their response. The participating servers respond with the *Vote-commit* message⁵. On receiving the *Vote-commit* message the coordinating server starts the final phase, and transmits the *Global-Commit* message to all the participants. Each participant on receiving the *Global-Commit* message commits the transaction, releases the local transactional resources, and responds with an acknowledgment for the coordinator. The coordinator waits on a counter for response from each participant and then commits the transaction, sends a response to the client node, and releases the associated transactional data-structures.

3PC: To gauge the performance of the EC protocol, we also implemented the three-phase commit protocol. The 3PC protocol implementation is a straightforward extension to the 2PC protocol. We add an extra PRE-COMMIT phase before the final phase. On receiving, all the *Vote-commit* messages, the coordinator sends the *Precommit* message to each participant. The participating nodes acknowledge the reception of the *Precommit* message from the coordinator. The coordinating server on receiving these acknowledgments, starts the finish phase.

5.3 Easy Commit Design

We now explain the design of Easy Commit protocol in the ExpoDB framework. The first phase (that is the INITIAL phase) is same for both the 2PC and the EC protocol. In the EC protocol,

⁵Without node failures, any transaction that reaches the prepare phase is assumed to successfully commit.

once the coordinator receives the *Vote-commit* message from all the nodes, it first sends the *Global-commit* message to each of the participating processes, and then commits the transaction. Next it, responds to the client with the transaction completion notification. When the participating nodes receive the *Global-Commit* message from the coordinator, they forward the *Global-Commit* message to all the other nodes (including the coordinator), and then commit the transaction.

Although, in the EC protocol the coordinator has a faster response rate to the client, but its throughput takes a slight dip due to additional, implementation enforced wait. It can be noted that we have not performed any cleanup tasks (such as releasing the transactional resources) yet. The cleanup of the transactional resources is performed once it is ensured that neither of those resources would be ever used, nor any messages associated with the transaction would be further received. Hence, we have to force all the nodes (both the coordinator and the participants) to poll the message queue, and wait till they have received the messages from each other node. Once all the messages are received, each node performs the cleanup.

To implement EC protocol we had to extend the message being transmitted with a new field which identifies all the participants of the transaction. This array contains the Id for each participant, and is updated by the coordinator (as only the coordinator has information about all the partitions) and transmitted as part of the *Global-Commit* message.

6 EVALUATION

In this section, we present a comprehensive evaluation of our novel Easy Commit protocol against 2PC and 3PC. As discussed in Section 5, we use the ExpoDB framework for implementing the EC protocol. For our experimentation, we adopt the evaluation scheme of Harding et al. [28].

To evaluate various commit protocols, we deploy the ExpoDB framework on the Microsoft Azure cloud. For running the client and server processes, we use upto 64 Standard_D8S_V3 instances, deployed in the US East region. Each Standard_D8S_V3 instance consists of 8 virtual CPU cores and 32GB of memory. For our experiments, we ensure a one-to-one mapping between the server (or client) process and the hosting Standard_D8S_V3 instance. On each server process, we allowed creation of 4 worker threads, each of which were attached to a dedicated core, and 8 I/O threads. At each server node, a load of 10000 open client connections is applied. For each experiment, we first initiated a warmup phase for 60 seconds, followed by 60 seconds of execution. The measured throughput does not include the transactions completed during warmup phase. If a transaction gets aborted then it is restarted again, only after a fixed time. To attenuate the noise in our readings, we average our results over three runs.

To evaluate the commit protocols, we use the NO_WAIT concurrency control algorithm. We use the NO_WAIT algorithm as: (i) it is the simplest algorithm, amongst all the concurrency control algorithms present in the ExpoDB framework, and (ii) has been proved to achieve high system throughput. It has to be noted that the use of underlying concurrency control algorithm is orthogonal to our approach. We present the design of a new commit protocol, and hence other concurrency control algorithms (except Calvin) available in the ExpoDB framework, can also employ EC protocol during the commit phase. We present a discussion on the different concurrency control algorithms, later in this section.

Figure 9: System throughput (transactions per second) on varying the skew factor (theta) for the 2PC, 3PC and EC protocols. These experiments run the YCSB benchmark. Number of server nodes are set to 16 and partitions per transaction are set to 2.

In NO_WAIT protocol, a transaction requesting access to a locked record is aborted. On aborting the transaction, all the locks held with this transaction are released, which allows other transactions waiting on these locks to progress. NO_WAIT algorithm prevents deadlock by aborting transactions in case of conflicts, and hence, has high abort rate. The simple design of NO_WAIT algorithm, and its ability to achieve high system throughput [28] motivated us to use it for concurrency control.

6.1 Benchmark Workloads

We test our experiments on two different benchmark suites: YCSB [10] and TPC-C [12]. We use YCSB benchmark to evaluate EC protocol on characteristics interesting to the OLTP database designers (Section 6.2 to Section 6.5), and use TPC-C to gauge the performance of EC protocol from the perspective of a real world application (Section 6.6 and Section 6.7).

YCSB – The Yahoo! Cloud Serving Benchmark consists of 11 columns (including a primary key) and 100B random characters. In our experiments we used a YCSB table of size 16 million records per partition. Hence, the size of our database was 16 GB per node. For all our experiments we ensured that each YCSB transaction accessed 10 records (we mention changes to this scheme explicitly). Each access to YCSB data followed the Zipfian distribution. Zipfian distribution tunes the access to hot records through the *skew factor* (theta). When theta is set to 0.1, the resulting distribution is uniform, while the theta value 0.9 corresponds to extremely skewed distribution. In our evaluation using YCSB data, we only executed multi-partition transactions, as single partition transactions do not require use of commit algorithms.

TPC-C – The TPC-C benchmark helps to evaluate system performance by modeling an application for warehouse order processing. It consists of a read-only, item table that is replicated at each server node while rest of the tables are partitioned using the warehouse ID. ExpoDB supports *Payment* and *NewOrder* transactions, which constitute 88% of the workload. Each transaction of *Payment* type accesses at most 2 partitions. These transaction first update the payment amounts for the local warehouse and district, and then update the customer data. The probability that a customer belongs to a remote warehouse is 0.15. In case of transactions of type *NewOrder*, first the transaction reads the local warehouse and district records and then modifies the district record. Next, it modifies item entries in the stock table. Only, 10% *NewOrder* transactions are multi-partition, as only 1% of the updates require remote access.

Figure 10: System throughput (transactions per second) on varying the number of partitions per transactions for the commit protocols. These experiments use YCSB benchmark. The number of server nodes are set to 16 and theta is set to 0.6.

6.2 Varying Skew factor (Theta)

We evaluate the system throughput by tuning the skew factor (theta), available in YCSB benchmarks, from 0.1 to 0.9. Figure 9 presents the statistics when the number of partitions per transaction are set to 2. In this experiment, we use 16 server nodes to analyze the effects induced by the three commit protocols.

A key takeaway from this plot is that, for $\theta \leq 0.7$ the system throughputs for EC and 2PC protocols are better than the system throughput for the 3PC protocol. On increasing the theta further the transactional access becomes highly skewed. This results in an increased contention between the transactions as they try to access (read or write) the same record. Hence, there is a significant reduction in the system throughput across various commit protocols. Thus, it can be observed that the magnitude of difference in the system throughputs for 2PC, 3PC and EC protocol is relatively insignificant. It is important to note that on highly skewed data, the gains due to the choice of underlying commit protocols are overshadowed by other system overheads (such as cleanup, transaction management and so on).

In the YCSB benchmark, for $\theta \leq 0.5$ the data access is uniform across the nodes, which implies that the client transactions access data on various partitions – low contention. Hence, each server node achieves nearly the same throughput. It can be observed that for all the three commit protocols the throughput is nearly constant (not same). We attribute the delta difference in the throughputs of the EC and 2PC protocols to the system induced overheads, network communication latency, and resource contention between the threads (for access to cpu and cache).

6.3 Varying Partitions per Transaction

We now measure the system throughput achieved by the three commit protocols on varying the number of partitions per transactions from 2 to 6. Figure 10 presents the throughput achieved on the YCSB benchmark, when theta is fixed to 0.6, and number of server nodes are set to 16. The number of operations accessed by each transaction are set to 16, and the transaction read-write ratio is maintained at 1 : 1.

It can be observed that on increasing the number of partitions per transaction there is a dip in the system throughput, across all of the commit protocols. On moving from 2 to 4 partitions there is an approximate decrease of 55%, while the reduction in system performance is around 25% from 4 partitions to 6 partitions, for the three commit protocols. As the number of partitions per transaction increase, the number of messages being exchanged in each round increases linearly for 2PC and 3PC, and quadratically for EC. Also, an increase in partitions imply the transactional

resources are held longer across multiple sites, which leads to throughput degradation for all the protocols. Note: in practice, the number of partitions per transaction are not more than four [12].

6.4 Varying Server Nodes

We study the effect of varying the number of server nodes (from 2 nodes to 32 nodes) on the system throughput and latency, for the 2PC, 3PC and EC protocols. In Figure 11 we set the number of partitions per transaction to 2 and plot graphs for the low contention ($\theta = 0.1$), medium contention ($\theta = 0.6$) and high contention ($\theta = 0.7$). In these experiments, we increase size of YCSB table in accordance to the increase in number of server nodes.

In Figure 11, we use the plots on the left to study the system throughput on varying the number of server nodes. It can be observed that as the contention (or skew factor) increases the system throughput decreases, and such a reduction is sharply evident on moving from $\theta = 0.6$ to $\theta = 0.7$. Another interesting observation is that the system throughput attained by the EC protocol is significantly greater than the throughput attained under 3PC protocol. The gains in system throughput are due to reduction of an extra phase which compensates for the extra messages communicated during the EC protocol.

In comparison to the 2PC protocol the system throughput under EC protocol is marginally lower at low contention and medium contention, and relatively same at high contention. These gains are the result of zero acknowledgment messages required by the coordinating node, in the commit phase, which helps EC protocol perform nearly as efficient as the 2PC protocol. This helps us to conclude that a database system using EC is as scalable as its counterpart employing 2PC.

6.4.1 Latency. In Figure 11, we use the plots on the right, to shows the 99 percentile system latency when one of the three commit protocols are employed by the system. We again vary the number of server nodes from 2 to 32. The 99 percentile latency is measured from the first commit to the final commit of a transaction. On increasing the number of server nodes there is a steep increase in latency for each commit protocol. The high latency values for 3PC protocol can be easily cited to the extra phase of communication.

6.4.2 Proportion of time consumed by various components: Figure 12 presents the time spent on various components of the distributed database system. We show the time distribution for the different degree of contention (θ). We categorize these measures under seven different heads.

Useful Work is the time spent by worker threads doing computation for read and write operations. **Txn Manager** is the time spent in maintaining transaction associated resources. **Index** is the time spent in transaction indexing. **Abort** is the time spent in cleaning up aborted transactions. **Idle** is the time worker thread spends when not performing any task. **Commit** is the time spent in executing the commit protocol. **Overhead** represents the time to fetch transaction table, transaction cleanup and releasing transaction table.

The key intuition from these plots is that as the contention (theta) increases there is an increase in time spent in abort. At low contention as most of the transactions are read-only, so the time spent in commit phase is least, and as contention increase, commit phase plays an important role in achieving high throughput from databases. Also, it can be observed at medium and high contention, worker threads executing 3PC protocol

(a) Low contention – (theta = 0.1).

(b) Medium contention – (theta = 0.6).

(c) High contention – (theta = 0.7).

Figure 11: System Throughput (transactions per second) and System Latency (in seconds), on varying the number of server nodes for the 2PC, 3PC and EC protocols. The measured latency is the 99-percentile latency, that is, latency from the first start to final commit of a transaction. For these experiments we use the YCSB benchmarks and set the number of partitions per transaction to 2.

are idle for the maximum time and perform the least amount of useful work, which indicates a decrease in system throughput under 3PC protocol due to an extra phase of communication.

6.5 Varying Transaction Write Percentage

We now vary the transactional write percentage, and draw out comparisons between the system throughput achieved by the Ex-poDB when employing one of the three commit protocols. These experiments are based on YCSB benchmark, and vary the percentage of write operations accessed by each transaction from 10 to 90. We set the skew factor to 0.6, number of server nodes to 16 and partitions per transaction to 2.

It can be seen that when only 10% of the operations are write then all the protocols achieve nearly the same system throughput. This is because most of the requests sent by the client consists of read-only transactions, and under read only transactions, the commit protocols are not executed. However, as the write percentage increases the gap between the system throughput achieved by 3PC protocol and the other two commit protocols increases. This indicates that 3PC protocol performs poorly when the underlying application consists of write intensive transactions.

In comparison to the 2PC protocol, EC protocol undergoes marginal reduction in throughput. As the number of write operations increase, the number of transactions undergoing the commit protocol also increase. We have already seen that under EC protocol (i) the amount of message communication is higher than the 2PC protocol, and (ii) each node needs to wait for additional *wait-time* before releasing the transactional resources. Some of these held resources include locks on data items, and it is easy to surmise that under EC protocol locks are held longer than the 2PC protocol. The increase in duration of locks being held also leads to an increased abort rate, which is another important factor for reduced system throughput.

6.6 Scalability of TPC-C Benchmarks

We now gauge the performance of the EC protocol with respect to a real-world application, that is using TPC-C benchmark. Figure 14 presents the characteristics of the 2PC, 3PC and EC protocols, under TPC-C benchmark, on varying the number of server nodes. It has to be noted that a major chunk of TPC-C transactions are single-partition, while most of the multi-partition transactions access only two partitions. Our evaluation scheme

Figure 12: Percentage of time spent by various database components, on executing the YCSB benchmark. We set the number of server nodes to 16 and partitions per transaction to 2.

Figure 13: System throughput (transactions per second) on varying the transaction write percentage for the 2PC, 3PC and EC protocols. These experiments use YCSB benchmark, and set the number of server nodes to 16 and partitions per transactions to 2.

sets 128 warehouses per server, and, hence a multi-partition can access two co-located partitions (that is on a single server).

Figure 14a represents the scalability of the *Payment* transactions for the three commit protocols. It is evident from this plot that as the number of server nodes increase, the system throughput increases for each commit protocol. However, there

(a) Payment Transaction

(b) NewOrder Transaction

Figure 14: System throughput on varying the number of server nodes, on the TPC-C benchmark. The number of warehouses per server are set to 128.

Figure 15: System throughput achieved by three different concurrency control algorithms. For experimentation, we use the TPC-C *Payment* transaction, and vary the number of server nodes to 16. The number of warehouses per server are set to 128. Here WDIE and TST refer to WAIT-DIE and TIMESTAMP, respectively.

is a performance bottleneck in case of 3PC protocol. In case of payment transactions as updates are performed at the home warehouse, which requires exclusive access, so there is an increase in the abort rate for the underlying concurrency control algorithm (in our case NO_WAIT). Now, as 3PC protocol requires an additional phase to commit the transaction, hence there is an increase in the abort rate. Interestingly, the throughput achieved by the EC protocol is approximately equal to the system throughput under 2PC protocol.

Figure 14b depicts the system throughput on executing TPC-C *NewOrder* transactions. The performance bottleneck is reduced for these transactions as there only 10 districts per warehouse, and hence, the commit protocols achieve comparatively higher throughput. Also, as there are only 10% multi-partition transactions, so all the protocols achieve nearly the same performance.

Figure 16: Comparison of throughput achieved by the system executing Calvin versus the system implementing the combination of No-Wait+EC protocol. In this experiment we use the TPC-C *Neworder* transaction, and vary the number of server nodes to 16. The number of warehouses per server are set to 128.

6.7 Concurrency Control

The presence of read/write data conflicts between transactional accesses necessitates the use of concurrency control algorithms by the database management system. The ExpoDB framework implements multiple state-of-the-art concurrency control algorithms. Although, in this work, we use NO_WAIT concurrency control algorithm, but EC protocol can be easily integrated to work alongside other concurrency control algorithms.

Figure 15 measures the system throughput for three different concurrency control algorithms. We use TPC-C *Payment* transactions for these experiments, and increase the number of server nodes upto 16. We also set the number of warehouses per server to 128. We compare the performance of EC protocol against the 2PC protocol, when the underlying concurrency control algorithm is WAIT-DIE [4], TIMESTAMP [4] and MVCC [5]. It is evident from these experiments that the EC protocol is able to achieve as high efficiency as the 2PC protocol, irrespective of the mechanism used for ensuring concurrency control.

We also analyze our commit protocol against an interesting deterministic concurrency control algorithm – *Calvin* [56]. *Calvin* is a deterministic algorithm that requires the prior knowledge of the read/write sets of the transaction before its execution. When the transaction’s read/write sets are not known, at prior, then *Calvin* causes some transactions to execute twice. Interestingly, in the second pass, if some records modify then the transaction is aborted and restarted again. Hence, prior works [28] have shown *Calvin* to perform poorly in such settings. Another strong critic against *Calvin* is that in case of failures, it requires a replica node that executes the same set of operations as the node responding to client query. This implies that Calvin is not suitable under failures for use with partitioned databases. Also, the requirement for replica node, reduces the system throughput.

Figure 16 presents a comparison of NO_WAIT algorithm (employing EC protocol) and Calvin. For this experiment we use the TPC-C *Neworder* transactions, and vary the number of server nodes from 2 to 16. These transactions are required to update the order number in their districts. Hence, the deterministic protocols such as Calvin suffer performance degradation.

7 OPTIMIZATIONS

In earlier sections, we presented a theoretical proof and an evaluation of Easy Commit protocol, which proved its relevance in the space of existing commit protocols. We now discuss some optimizations for the EC protocol.

An optimized version of the EC protocol would allow achieving further gains in comparison to both the 2PC and 3PC protocols. A simple approach is to reduce the number of messages

transmitted in the second phase. In the optimized protocol, each node only forwards messages to those nodes from which it has not received a *Global-Commit* or *Global-Abort* message. Another simple optimization is to ensure early cleanup, that is reduction of implementation enforced wait (refer Section 5.3). To achieve this, each node would maintain a lookup table, where an entry for each transaction is added, on receiving the first *Global-Commit* or *Global-Abort* message. The remaining messages, addressed to the same transaction, would be matched in the table and deleted. We would also need to periodically, flush some of the entries of the table, to reclaim memory. Interestingly, such an optimization would allow implementing a variant of EC protocol that does not require any “implicit” acknowledgments. Note a similar limited variant for 3PC protocol can be constructed where the coordinator does not wait for acknowledgments after sending the *Prepare-to-Commit* messages, and directly transmits *Global-Commit* message to all the cohorts. Our proposed optimized version is comparable to this 3PC variant.

8 RELATED WORK

The literature presents several interesting works [1, 23, 53] that suggest the use of *one phase commit* protocol. These works are strictly targeted at achieving performance, rather than consistency. Clearly, none of these works satisfy the non-blocking requirement, expected of a commit protocol.

Several variants to the 2PC protocol [20, 25, 29, 31, 33, 36, 40, 44, 49] have been proposed that aim at improving its performance. Presumed-commit and presumed-abort [36] work by reducing a single round of message transmission between the coordinator and the participants, when the transaction is to be committed or aborted, respectively. Gray and Reuter [25] present a series of optimizations for enhancing the 2PC protocol such as lazy commit, read-only commit and balancing the load by coordinator transfer. Group commit [20, 40] helps to reduce the commit overhead by committing a batch of transactions together. Samaras et al. [49] design several interesting optimizations to improve the performance of 2PC protocol. They present heuristics to reduce the overhead of logging, network contention and resource conflicts. Compared to all of these works, we present EC protocol, which is not only efficient, but also satisfies the non-blocking property.

Levy et al. [33] present an optimistic 2PC protocol that releases the locks held by a transaction once all the nodes agree to commit. In case a node decides to abort the transaction then to prevent violation of database atomicity, compensating transactions are issued to rollback the changes. Although their approach does not guarantee non-blocking behavior, but we believe the idea of optimistic resource release can be integrated with Easy Commit protocol to achieve further performance.

Boutros and Desai [44] present another variant to 2PC protocol which forces each node to send an additional message in case of a communication failure between the coordinator and the participant. Their approach is only susceptible to the cases where there is a message loss. However, their work does not resolve blocking under site failures and can be integrated with our work to achieve further resilience during message loss.

Haritsa [29] et al. improve the performance of the 2PC protocol, in the context of *real-time* distributed systems. Their protocol permits a conflicting transaction to access the non-committed data. This can lead to cascading aborts, and is not suitable for use with the traditional distributed databases. Our technique, on the other hand, is independent of the underlying concurrency control mechanism, and does not cause any special aborts.

Jiménez-Peris et al. [31] also allow their system to optimistically fetch the uncommitted data, thereby rendering the 2PC performance. However, their protocol is tailored for usage alongside strict two-phase locking, and assumes existence of an additional replica of each process. Our technique is not tailored to any specific concurrency control mechanism, and neither assumes existence of any extra process. Also, we believe these heuristics can be used alongside EC protocol, to render further benefits.

Reddy and Kitsuregawa [58] modify the 3PC protocol by introducing the notion of backup sites. With the help of backup sites they are able to achieve better performance than 3PC, but their approach blocks in case of multiple failures. Easy Commit is non-blocking and does not require any backup sites.

There also have been works [13, 27] that provide better performance bounds than the 3PC protocol if the number of failures are sufficiently less than the participants. Easy Commit does not bound the number of failures, and is nearly as efficient as 2PC.

Gray and Lamport [24] developed an interesting non-blocking version of 2PC protocol using Paxos [32]. Their approach shows that 2PC protocol is a variant of general consensus protocol. However, to ensure non-blocking property they require use of an extra set of acceptor nodes and in the worst case it can be shown that the number of messages transmitted in their approach is $O(n^2)$. Easy Commit is a hybrid between 2PC and 3PC protocol, which is nearly as efficient as former and non-blocking as latter. It also does not require the paxos consensus algorithm, and hence, no additional requirement of acceptor nodes.

9 CONCLUSIONS

We present a novel commit protocol – Easy Commit. Our design of Easy Commit, leverages the best of twin worlds (2PC and 3PC), it is non-blocking (like 3PC) and requires two phases (like 2PC). Easy Commit achieves these goals by ensuring two key observations: (i) first transmit and then commit, and (ii) message redundancy. We present the design of the Easy Commit protocol and prove that it guarantees both safety and liveness. We also present the associated termination protocol and state cases where Easy Commit can perform independent recovery. We perform a detailed evaluation of EC protocol on a 64 node cloud, and show that it is nearly as efficient as the 2PC protocol.

ABSTRACT

Graph pattern mining aims at identifying structures that appear frequently in large graphs, under the assumption that frequency signifies importance. Several measures of frequency have been proposed that respect the *apriori* property, essential for an efficient search of the patterns. This property states that the number of appearances of a pattern in a graph cannot be larger than the frequency of any of its sub-patterns. In real life, there are many graphs with weights on nodes and/or edges. For these graphs, it is fair that the importance (score) of a pattern is determined not only by the number of its appearances, but also by the weights on the nodes/edges of those appearances. Scoring functions based on the weights do not generally satisfy the *apriori* property, thus forcing many approaches to employ other, less efficient, pruning strategies to speed up the computation. The problem becomes even more challenging in the case of multiple weighting functions that assign different weights to the same nodes/edges. In this work, we provide efficient and effective techniques for mining patterns in multi-weight graphs. We devise both an exact and an approximate solution. The first is characterized by intelligent storage and computation of the pattern scores, while the second is based on the aggregation of similar weighting functions to allow scalability and avoid redundant computations. Both methods adopt a scoring function that respects the *apriori* property, and thus they can rely on effective pruning strategies. Extensive experiments under different parameter settings prove that the presence of edge weights and the choice of scoring function affect the patterns mined, and hence the quality of the results returned to the user. Finally, experiments on datasets of different sizes and increasing numbers of weighting functions show that, even when the performance of the exact algorithm degrades, the approximate algorithm performs well and with quite good quality.

1 INTRODUCTION

Pattern mining in large graphs has attracted considerable attention, since it finds applications in many real world scenarios like fraud detection [31], biological structures identification [16], anticipation of user intention [33], graph similarity search [20], traffic control [21], and query optimization [42]. It has been studied for graph collections [41], for attributed [35], probabilistic [26], or even generic large graphs [10]. The goal is to identify patterns that occur frequently, given that frequency indicates importance. An interesting property regarding frequency is that a pattern

cannot be more frequent than any of its sub-patterns, known as the *apriori* property. This property enables efficient implementations [43], as it ensures that the frequency of a pattern decreases monotonically as the pattern grows in size, thus allowing the mining process to start from small patterns and extend to larger ones only when the frequency of the pattern is above a certain frequency threshold.

In graph databases the frequency of a pattern has been effectively computed as the number of distinct graphs containing an appearance of the pattern. However, the same implementation cannot be used in single large graphs, as each pattern would have frequency either equal to 0 or to 1. Furthermore, if we simply define the frequency as the number of distinct occurrences of the pattern, we may break the *apriori* property [38]. In fact, this implementation counts every overlap that may occur among the occurrences, hence assigning larger frequencies to larger patterns, causing an unwanted (and unjustified) skew in the value of importance for some patterns. For this reason, alternative metrics have been considered in the literature [6, 11, 38], with the more prevalent one being the MNI support, as it enjoys high effectiveness [10].

Many real world scenarios are naturally modeled through weighted graphs, and in these cases, the importance of a pattern should be determined not only by the frequency, but also by the weights of its appearances. Examples include the discovery of metabolic pathways in genomic networks [23], where weights indicate strength between genomes [8], the identification of topics of interest in large knowledge graphs [29], where weights quantify the degree a piece of data is qualified as an answer to a user [39], or the detection of common problematic cases in computer networks, where weights indicate congestion [5]. Unfortunately, weighted graphs do not possess the *apriori* property, since the weights of the extra edges/nodes of a larger pattern may offset its lower frequency. As a consequence, some works that considered weighted graphs for pattern mining proposed solutions that are less efficient than those based on the *apriori* property [43].

A requirement in modern applications is to offer personalized products and services rather than generic preferences [34]. Such generic preferences suit the user on average but fail to deliver the right answer for each specific user. The same argument holds for graph patterns. For instance, social network systems record user interactions [22] and activities [4] and build graphs by modeling the relationships among users and web content to find frequent patterns of interactions [30]. Advertisers subsequently exploit such patterns to target the right customer for a certain product. Some patterns of interactions may be more important than others to an advertiser depending on the product or the specific business model; in such case, multiple weights are valuable. Other

examples include online retailers like Amazon, which build large graphs on product co-purchases and then exploit the discovered patterns to recommend future offers [36]. Frequency, number of items, recency of the purchase, as well as the company’s business intentions affect the importance of some co-purchases with respect to others [34]. Such examples highlight the need for a solution that accounts for the individual preferences expressed as a multi-weighted graph, as opposed to “one size fits all” solutions. However, the straightforward approach to multi-weighted pattern mining that runs the mining algorithm on each weighted graph separately, is clearly impractical due to the graph size and the large number of users.

In this paper, we propose a novel approach to mine patterns in weighted graphs that goes beyond frequencies, yet has performance not significantly different from the pattern mining in unweighted graphs. We achieve this by defining a family of scoring functions that are based on the MNI score [6], a metric that is widely used in graph mining due to its characteristic of respecting the apriori property, while being efficient to compute. The solution we have devised is modeled as a constraint satisfaction problem (CSP), as proposed also for unweighted pattern mining [10], and implements the pattern growth approach, as introduced by gSpan [41]. Furthermore, we extend the idea above for the case of graphs with multiple weights on their edges/nodes. To avoid running the algorithm one time for each different weighting function, we compute all the scores of each pattern at the moment we are visiting it, and keep the patterns that return a high score with respect to at least one weighting function.

In particular we make the following contributions:

- (a) We extend the task of pattern mining in weighted large graphs for a novel family of scoring functions based on the MNI support [6] (Section 2).
- (b) We introduce and formally define the problem of pattern mining in multi-weight graphs with different weighting functions.
- (c) We devise two efficient and effective techniques for solving the pattern mining problem on weighted graphs (Section 3). The first one is an exact solution, called **RESUM**, that is less time and space consuming than the (naive) brute force method. It avoids redundant revisits of the graph, by aggregating and performing once multiple computations on the same parts of the graph, and storing the relevant patterns in a compact way. The second one is a conservative approximate solution, called **RESUM approximate**, that reduces the number of weighting functions to consider, by aggregating those having a high probability to generate similar results (Section 4) into a single representative function. In addition, we show that this method introduces only few false positives, while running considerably faster than the exact approach.
- (d) We study four different scoring functions (all based on the MNI support) for devising the score of a pattern in an efficient way (Section 5).
- (e) We evaluate our approach with an extensive set of experiments and discuss our findings (Section 7).

2 PROBLEM DEFINITION

We assume the existence of a countable set of labels Σ that includes the special symbol \perp , and a set $\mathcal{I}_0^1 = [0, 1] \cup \{\perp\}$ of weights. The symbol \perp in Σ and \mathcal{I}_0^1 is used to denote *no label* and *no weight*, respectively. A weighted graph is a structure that consists of a set of nodes, a set of edges between them, an assignment of labels

Figure 1: Example of an edge-labeled, weighted graph.

to all the nodes and edges, and an assignment of weights to all the edges.

Definition 2.1. A **weighted labeled graph**, or simply a **graph**, is a tuple $\langle V, E, \ell, \omega \rangle$ where V is a set of vertices, $E \subseteq V \times V$ is a set of edges, $\ell : E \cup V \rightarrow \Sigma$ is a labeling function, and $\omega : E \rightarrow \mathcal{I}_0^1$ is a weighting function. The symbol \mathcal{G} is used to denote the set of all the possible graphs.

Note that we assume weights on edges only, mainly for presentation purposes. Weights on nodes can also be considered with no need for any major modification. A graph $S : \langle V_S, E_S, \ell, \omega \rangle$ is said to be a **subgraph** of another graph $G : \langle V_G, E_G, \ell, \omega \rangle$, denoted as $S \sqsubseteq G$, if $V_S \subseteq V_G$ and $E_S \subseteq E_G$. Note that the two graphs have the same labeling and weighting function.

To express the fact that two graphs have the same topological structure, we use the notion of *isomorphism*, which is a bijective mapping between the nodes of the two graphs such that the edges between the nodes, alongside their labels, are preserved through the mapping.

Definition 2.2. A graph $G : \langle V, E, \ell, \omega \rangle$ is **isomorphic** to a graph $G' : \langle V', E', \ell', \omega' \rangle$, denoted as $G \simeq G'$, if there exists a bijective function $\phi : V \rightarrow V'$ such that: $\forall \langle u, v \rangle \in E : \langle \phi(u), \phi(v) \rangle \in E'$ and $\ell(\langle u, v \rangle) = \ell'(\langle \phi(u), \phi(v) \rangle)$.

A graph G may have multiple isomorphic graphs. To collectively represent those graphs, we introduce the concept of *pattern*. Intuitively, a pattern is a graph with no weights, serving as a representative of a set of isomorphic graphs and describing their common structure.

Definition 2.3. A **pattern** is a graph $\langle V, E, \ell, \omega \rangle$, such that $\forall e \in E : \omega(e) = \perp$. The symbol \mathcal{P} denotes the set of all possible patterns. Given a graph G , and a pattern P , the *support set* of the pattern P is the set $S_G(P) = \{g | g \sqsubseteq G \wedge g \simeq P \wedge P \in \mathcal{P}\}$. Each element in $S_G(P)$ is referred to as an *appearance* (or *matching*) of P in G .

By definition, the support set of P is the set of all the subgraphs of G that are isomorphic to P . By abuse of notation we write $P \sqsubseteq G$ and call the pattern P a subgraph of G if its support set is non-empty. Then, We denote by ϕ_g^P the bijection that maps an isomorphic subgraph g of G to the pattern P .

Given a **scoring function** $f : \mathcal{P} \times \mathcal{G} \rightarrow \mathbb{R}$, we will refer to the value $f(P, G)$ as the **score** of P in G . Graph pattern mining is the task that aims at identifying those patterns that have score higher than a threshold τ , or the k patterns with the highest score [10]. A natural scoring function is the one that returns the cardinality of $S_G(P)$, i.e., the number of appearances of the pattern P in the graph G , and the patterns identified by this function are called *frequent patterns*. Nevertheless, it has been shown that this simple function violates the a-priori property, due to the presence of overlapping isomorphisms in G [6]. As an example, the frequency of the pattern $P_1 : [v_1] - B - [v_2] - A - [v_3]$ in the graph in Figure 1

Figure 2: Graph with two weights $\langle \omega_1, \omega_2 \rangle$ on each edge.

is 3, while the frequency of its sub-pattern $P_2 : [v_1] - B - [v_2]$ is 1. For this reason a number of works have investigated alternative scoring functions [11, 15, 25, 38]. Among them, the MNI support is highly effective and efficient to compute [6].

Definition 2.4. Given a graph $G : \langle V, E, \ell, \omega \rangle$, the **MNI support** of a pattern $P : \langle V_P, E_P, \ell_P, \omega_P \rangle$ in G is the number $MNI(P, G) = \min_{v' \in V_P} |\mathcal{N}(G, v')|$ where $\mathcal{N}(G, v') = \{v \mid v \in V \wedge \exists g \in S_G(P) \text{ such that } \phi_g^P(v) = v'\}$.

Intuitively, the set $\mathcal{N}(G, v')$ contains all the nodes of G that are mapped to the pattern node v' by some isomorphism ϕ_g^P from g to P . Then, the MNI support is the minimum cardinality of this set across all the nodes of the pattern P . We can define similar sets also for the pattern edges, i.e., for each $e' \in E_P$, the set $\mathcal{E}(G, e') = \{e \mid e \in E \wedge \exists g \in S_G(P) \text{ such that } \phi_g^P(e) = e'\}$ contains all the edges of G that are mapped to the pattern edge e' by some isomorphism ϕ_g^P . Consider, for instance, the graph G in Figure 1 and the pattern $P : [v_1] - B - [v_2] - A - [v_3]$. Since $\mathcal{N}(G, v_1) = \{1, 3\}$, $\mathcal{N}(G, v_2) = \{1, 3\}$, and $\mathcal{N}(G, v_3) = \{2, 4, 5\}$, the MNI support of P is 2. On the other hand, the number of appearances of P in G is 3: $S_G(P) = \{[3] - B - [1] - A - [2], [1] - B - [3] - A - [4], [1] - B - [3] - A - [5]\}$.

In the presence of weights on edges, the score of a pattern cannot be based only on the frequency, but should strike a balance between frequency and weights, allowing also the weights to play a role in assessing the relevance of the pattern. Thus, there is a need for a different scoring function that looks beyond the structure of the subgraphs, by considering the importance of their edges as well. In this case, we talk about *weighted frequent patterns*, or *relevant patterns*. This alternative scoring function, however, has to be carefully selected to satisfy the apriori property [43].

Furthermore, if there are multiple weighting functions, i.e., several functions that assign weights on the graph edges/nodes, then the pattern mining task must be carried out for each individual function. An example of graph with multiple weights on the edges is illustrated in Figure 2. Such situation leads to the following specification of the mining task.

Pattern Mining in Multi-Weighted Graphs. Given a threshold τ , a scoring function f and a graph $G : \langle V, E, \ell, W \rangle$, where W is a finite set of weighting functions, we must discover, $\forall \omega_i \in W$, the set of patterns $R_i = \{P \mid G' = \langle V, E, \ell, \omega \rangle \wedge f(P, G') \geq \tau\}$.

3 SCORE-BASED PATTERN MINING

Our solution to the pattern mining on weighted graphs problem consists of two steps. The first step is the identification of the frequent patterns and the elimination of the appearances that do not satisfy the constraints on the weights imposed by the scoring function used. In the second step, a score is computed for each pattern (and for each weighting function in the case of multi-weighted graphs) in terms of the appearances in its support set that were selected in the first step.

Algorithm 1 RELEVANTPATTERNMINING

Input: Graph $G : \langle V, E, \ell, \omega \rangle$, min score τ

Output: Set of relevant patterns R

```

1:  $R \leftarrow \text{RELEVANTEDGES}(G)$ 
2:  $fE \leftarrow \text{FREQUENTEDGES}(G)$ 
3: while  $fE \neq \emptyset$  do
4:    $e \leftarrow fE.\text{pop}$ 
5:    $R \leftarrow R \cup \text{PATTERNEXTENSION}(G, e, \tau, fE \cup \{e\})$ 
6: return  $R$ 

7: function  $\text{PATTERNEXTENSION}(G, g, \tau, fE)$ 
8:    $Cand \leftarrow \emptyset; \mathfrak{S} \leftarrow \emptyset$ 
9:   for each  $e \in fE$  do
10:     $Cand \leftarrow Cand \cup \{g \diamond e\}$ 
11:   for each  $c \in Cand$  do
12:     $(score, sup) \leftarrow \text{EXAMINEPATTERN}(G, c)$ 
13:    if  $sup \geq \tau$  then
14:       $\mathfrak{S} \leftarrow \mathfrak{S} \cup \text{PATTERNEXTENSION}(G, c, \tau, fE)$ 
15:    if  $score \geq \tau$  then
16:       $\mathfrak{S} \leftarrow \mathfrak{S} \cup \{c\}$ 
17:   return  $\mathfrak{S}$ 

```

3.1 Assessing the relevance of a pattern

A scoring function can have many different properties, which may be desirable for certain applications but not for others. As a consequence there may be no scoring function that is consistently better than others in all the applications. Therefore, in this work we do not advocate a single one-size-fits-all scoring function, but we propose a framework that can accommodate a wide range of functions.

Assuming w.l.o.g. that larger weights signify higher importance, the function f must satisfy the following key properties:

P1: the score $f(P, G)$ monotonically increases with the weights of its appearances.

P2: the score $f(P, G)$ monotonically increases with the number of appearances with large weights.

P3: f is *MNI-compatible*, i.e., $f(P, G) \geq \tau \implies MNI(P, G) \geq \tau$.

Properties **P1** and **P2** are a natural consequence of our assumption on the importance of the weights, while **P3** ensures the time practicality of the solution.

3.2 Mining weighted graphs

Finding the frequent patterns on weighted graphs requires the computation of the frequency and the score of each pattern. To this end, we propose RESUM, an efficient and effective general algorithm for *any* MNI-compatible score that exploits the pruning power of the anti-monotonicity property of the MNI support.

We model the frequent subgraph mining as a *constraint satisfaction problem* (CSP) [9]. An instance of the CSP problem is a tuple (X, D, C) where X is a set of variables, D is a set of domains corresponding to the variables in X , and C is a set of constraints between the variables in X . A solution for an instance of CSP is an assignment from the candidates in D to the variables in X that satisfies all the constraints in C . The matching problem for a pattern $P \sqsubseteq G$ is then translated into $CSP(P) = (X_P, D_P, C_P)$, so that any solution for $CSP(P)$ corresponds to a subgraph g isomorphic to P .

Specifically, each node $v \in V_P$ is mapped to a variable $x_v \in X_P$, each domain $D_v \in D_P$ is a subset of V containing all the graph

Algorithm 2 EXAMINEPATTERN

Input: Graph $G:(V, E, \ell, \omega)$, pattern P , score threshold τ **Output:** Score and MNI support of P

```
1: for each  $v \in V_P$  do
2:    $sup_v \leftarrow \emptyset$ 
3:    $D_v \leftarrow \{v' \in V | \ell(v') = \ell(v)\}$ 
4:    $\mathcal{A} \leftarrow$  automorphisms of  $P$ 
5:   STRUCTURALCONSISTENCY( $\{D_v | v \in V_P\}, P$ )
6:   for each  $v \in V_P$  do
7:     if  $\exists w = \mathcal{A}(v)$  s.t.  $D_w$  already computed then
8:        $D_v \leftarrow D_w$ 
9:       continue
10:    STRUCTURALCONSISTENCY( $\{D_v | v \in V_P\}, P$ )
11:    if  $\exists D_u$  s.t.  $|D_u| < \tau$  then return  $(-1, -1)$ 
12:    for each  $n \in D_v$  do
13:      search for  $g$  s.t.  $g \simeq P \wedge n \in V_g \wedge n \mapsto v$ 
14:      if  $g \neq Nil$  then
15:        Valid  $\leftarrow$  ISVALID( $g, \omega$ )
16:        for each  $n' \in V_g, v' \in V_P$  s.t.  $n' \mapsto v'$  do
17:          mark  $n'$  in  $D_{v'}$ 
18:          if Valid then
19:             $sup_{v'} \leftarrow sup_{v'} \cup \{n'\}$ 
20:        else
21:          remove  $n$  from  $D_v$ 
22:   $score \leftarrow$  RELEVANCESCORE( $\{sup_v | v \in V_P\}$ )
23:   $mni \leftarrow \min_{v \in V_P} |D_v|$ 
24:  return  $(score, mni)$ 
```

nodes isomorphic to v , and C includes consistency constraints that enforce a topology isomorphic to that of P [28]. Then, for each candidate node $n \in D_v$ we search for a valid assignment that maps n to v . If no assignment is found, n is removed from the domain D_v and the topology constraints are checked again until no invalid candidate is found in the other domains. At the end of the process, the number of elements in the smallest domain, i.e., $\text{argmin}_{D_v \in D_P} |D_v|$, corresponds to the MNI support of P , as defined in Definition 2.4. Therefore, given a score threshold τ , P is frequent if each variable in X_P has at least τ distinct valid assignments. This means that if the size of some domain D_u is lower than τ , P cannot be frequent. Notice that in general not all the matching subgraphs of a pattern satisfy the constraints on the weights forced by the scoring function used, and thus we must additionally check each of them to determine if it contributes to the score of the pattern. The aggregated score is then computed considering only the matches not discarded.

Algorithm 1 outlines the RESUM framework. First, the relevant and the frequent edges are found (Lines 1-2). Then, each subgraph is recursively extended following the pattern-growth approach introduced by gSpan [41] (Line 5), until no other extension is possible. Each extension is a candidate relevant pattern, whose MNI support is computed alongside its *score* by the EXAMINEPATTERN procedure (Algorithm 2). This procedure first initializes the candidate domain D_v of each pattern node $v \in V_P$ with all the nodes in G with the same label as v (Lines 1-3), and the support set sup_v of each node $v \in V_P$ with the empty set. Then, the algorithm computes the automorphisms of the pattern (Line 4). Automorphisms are isomorphisms of a graph to itself and can be used to compute the valid assignments more efficiently (Lines 7-8), since each assignment valid for a pattern node v is valid for each automorphic node w too. Finally the

algorithm iterates over each candidate node $n \in D_v$ to determine if it belongs to some subgraph g isomorphic to P (Lines 12-13). As soon as such subgraph is found, all the domains are updated (Lines 16-17) and the subgraph is checked for validity (Line 15). In particular, the ISVALID procedure compares the edge weights in g against the constraints specified by the scoring function f , and if g satisfies the condition, the nodes of the subgraph are stored in the corresponding support sets (Line 19). These nodes will contribute to the relevance *score* of P .

On the other hand, if n does not participate in any isomorphism, it is removed from D_v . As a consequence, in the subsequent iteration, structural constraints like the minimum degree of a node mapped to a $v \in V_P$ are enforced, to remove candidates that can no longer participate to any isomorphism of P (Line 10). The algorithm terminates either when all the pattern nodes have been examined, or when the size of some domain becomes lower than τ , as in this case P can be neither relevant nor frequent (Line 11). In the first case, instead, the MNI support and the relevance *score* of P are calculated and returned. We refer to Section 5 for a discussion about suitable scoring functions that can be implemented in Procedure ISVALID.

Finally in Lines 13-17 of Algorithm 1, all the frequent patterns are further extended, while all the relevant patterns are included in the final set of relevant patterns R . Since we enforce the use of MNI-compatible scoring functions, the MNI support of P is an upper-bound of its *score*, and thus the pruning strategy ensures that all the relevant patterns are returned.

Complexity. Even though the computation of the automorphisms ($\mathcal{O}(|V_P|^{V_P})$) and the pruning strategy improve the expected performance of the algorithm, in the worst case it takes $C = \mathcal{O}(2^{|V|^2} |V|^{V_P})$ time, which is exponential in the number of nodes and the size of the patterns. In particular, $\mathcal{O}(2^{|V|^2})$ is the time required to compute all the patterns in G , and $\mathcal{O}(|V|^{V_P})$ is that needed to find all the isomorphisms of a pattern P .

3.3 Mining in multi-weighted graphs

In the case of multiple edge weights assigned by m weighting functions $W = \{\omega_1, \dots, \omega_m\}$, the naive approach for solving the Pattern Mining in Multi-Weighted Graphs problem runs Algorithm 1 $|W|$ times, once for each function. Evidently, this approach becomes impractical for large m , as the process of mining the patterns is computationally intense. In fact, this process would take $\mathcal{O}(C^m)$ to terminate.

The naive approach recomputes the same patterns multiple times, incurring in a significant time overhead that can be avoided by running the algorithm only once and keeping track of the relevant patterns for each weighting function. This strategy replaces Line 12 in Algorithm 1 with Algorithm 3, which searches for the isomorphisms of the pattern P , while checking their validity with respect to each $\omega_i \in W$, at the same time. Similarly to the single weight case, we initialize each candidate domain and all the support sets for each weighting function (Lines 1-4). When an isomorphic subgraph is found, procedure ISVALID checks *in parallel* each set of edge weights against the constraints set by the scoring function and stores the results in the auxiliary array VAL . If the weights assigned by ω_i satisfy the constraints, the nodes of the subgraph are stored in the corresponding sets $SUP_v[i]$ (Line 21).

Finally, all the scores of the candidate pattern c are evaluated in Line 16 of Algorithm 1, and c is added to the final set R only if at least one of its scores is larger than τ . As a further optimization,

Algorithm 3 EXAMINESUBGRAPHMULTI

Input: Graph $G: \langle V, E, \ell, W \rangle$, pattern P , score threshold τ **Output:** Scores and MNI support of P

```
1: for each  $v \in V_P$  do
2:    $D_v \leftarrow \{v' \in V \mid \ell(v') = \ell(v)\}$ 
3:   for each  $i \in 1, \dots, |W|$  do

19:       for each  $i \in 1, \dots, |W|$  do
20:         if  $VAL[i]$  then
21:            $SUP_{v'}[i] \leftarrow SUP_{v'}[i] \cup \{n'\}$ 
22:       else
23:         remove  $n$  from  $D_v$ 
24:  $\mathcal{S} \leftarrow$  RELEVANCESCORES( $\{SUP_v \mid v \in V_P\}$ )
25:  $mni \leftarrow \min_{v \in V_P} |D_v|$ 
26: return ( $\mathcal{S}, mni$ )
```

instead of storing in memory the sets of relevant patterns for each function ω_i , we maintain a binary vector of size m for each relevant pattern P , where position i is set to 1 if P is relevant for ω_i .

4 APPROXIMATE ALGORITHM

The exact algorithm introduced in Section 3 incurs a significant memory overhead when the number of weighting functions is in the order of thousands, which, for example, is the case for recommender systems for big retailers (e.g., Amazon). For such applications, we devise a more conservative approximate solution, called *ReSUM approximate*, that significantly reduces the memory consumption by taking advantage of the similarities between the weighting functions $\omega_1, \dots, \omega_m \in W$.

The *ReSUM approximate* algorithm first generates $k \ll m$ representative functions ω_j^* , by clustering and aggregating the original functions ω_i . Then, it runs Algorithm 3 to compute k sets of relevant patterns R_1^*, \dots, R_k^* , which are used to build m approximate sets of relevant patterns A_1, \dots, A_m , returned in place of the exact sets R_1, \dots, R_m . Clearly, the quality of the approximate result depends on the way the representative functions are generated. With our implementation, we aim at returning a set A_j for each ω_i that resembles the exact set R_i as much as possible.

4.1 Generation of the representative functions

The generation of the representative functions is shown in Algorithm 4 and consists of three steps. First, each weighting function

Algorithm 4 GENERATE REPRESENTATIVE FUNCTIONS

Input: Graph $G : \langle V, E, \ell, W \rangle$, number of buckets b , number of clusters k **Output:** Set of representative functions W^*

```
1:  $\mathcal{F} \leftarrow$  CREATEFEATUREVECTORS( $E, W, b$ )
2:  $C \leftarrow$  COMPUTECLUSTERING( $\mathcal{F}, k$ )
3:  $W^* \leftarrow$  GENERATEMAXWEIGHTVECTORS( $C, W$ )
4: return  $W^*$ 
```

Algorithm 5 CREATEBUCKETFEATUREVECTORS

```
1: function CREATEBUCKETFEATUREVECTORS( $E, W, b$ )
2:   for each  $l \in \Sigma_E$  do
3:      $BucketList_l \leftarrow$  COMPUTEBUCKETLIMITS( $E_l, W, b$ )
4:     for each  $\omega_i \in W$  do
5:        $r_i^l \leftarrow$  FILLBUCKETS( $E_l, \omega_i, BucketList_l$ )
6:   for each  $\omega_i \in W$  do
7:      $r_i \leftarrow$  CONCAT( $\{r_i^l \mid l \in \Sigma_E\}$ )
8:   return  $\{r_1, \dots, r_{|W|}\}$ 
```

$\omega_i \in W$ is transformed into a feature vector (Line 1). Secondly, the weighting functions are clustered into k groups of similar functions (Line 2). Thirdly, the set of k representative functions $W^* = \{\omega_1^*, \dots, \omega_k^*\}$ is returned (Lines 3-4).

Creation of the feature vectors.

In the first step, we construct a feature vector r_i for each ω_i , which is used in the second step to determine the similarities between the functions. Since our final goal is to assign a set of patterns A_i to each ω_i that is as close as possible to the exact set R_i , a straightforward choice is to use the edge weights as features. We call this approach *full-vector strategy*. According to this strategy, Procedure 1 decides an ordering of the graph edges and creates m vectors r_1, \dots, r_m of size $|E|$, where $r_i[x]$ is the weight assigned by ω_i to the edge in the x^{th} position.

Although similar edge weights lead, with high probability, to similar sets of relevant patterns, the effectiveness and the efficacy of the full-vector strategy decrease as the size of the graph increases. In fact, the high dimensionality of the vectors complicates the detection of functions with similar properties, as a consequence of the curse of dimensionality phenomenon [37].

Thus, we propose also a more efficient approach called *bucket-based strategy*, which overcomes the problem of high dimensionality by considering the edge labels in place of the graph edges, as features to build the vectors. The underlying idea is that, in real scenarios, a preference for an edge is highly correlated with the preference for the label of that edge. This strategy is implemented in Procedure CREATEBUCKETFEATUREVECTORS (Algorithm 5), which takes the set of weighting functions W and the number of buckets b , and generates a set of feature vectors r_1, \dots, r_m each of size $|\Sigma_E| \cdot b$, where Σ_E indicates the set of distinct edge labels. In particular, each vector r_i is the concatenation of $|\Sigma_E|$ summaries of the edge-weights of ω_i , one for each edge label, and b is the resolution of each summary.

The summary for a label l is obtained by splitting the range of admissible weights $[0, 1]$ into b of sub-ranges (buckets) (Line 3), e.g., $[0, x_1)$, $[x_1, x_2)$, and $[x_2, 1.0]$ for $b = 3$. Then Procedure FILLBUCKETS (Line 5) counts, for each sub-range, how many times the function ω_i assigns a weight within that sub-range to an edge with label l . Note that, in the degenerate case of $b = 1$, the vector

r_i simply keeps, for each label, the number of edges with that label and whose weight is greater than 0.

The *bucketization* of a label l is performed by Procedure COMPUTEBUCKETLIMITS (Line 3) following the equi-depth paradigm [13], which assigns the input values to buckets, while trying to balance the number of elements in each bucket. Thus, we consider all the weights assigned by all the weighting functions to edges with label l , and split the range $[0, 1]$ into b depth-balanced intervals.

For example, given $b = 2$, the label ordering $A|C$, and the two weighting functions ω_1 and ω_2 in Figure 1, we obtain the vectors $r_1 = [1, 3, 2, 0]$ and $r_2 = [3, 1, 0, 2]$. As such, the buckets of A are the ranges of values $[0, 0.3]$ and $[0.3, 1]$, and those of C the ranges $[0, 0.5]$ and $[0.5, 1]$.

Note that the bucket-based strategy allows us to decide the size of the feature vectors a priori and tune the parameter b to improve the accuracy of the clustering.

Identification of similar functions. Procedure COMPUTECLUSTERING (Algorithm 4, Line 2) implements the Lloyd’s clustering algorithm [27], which identifies groups of similar ω_i by comparing the feature vectors $r_1, \dots, r_m \in \mathcal{F}$ using the cosine similarity.

The algorithm can be initialized either providing k random seeds among all the vectors in \mathcal{F} , or by selecting the k most diverse feature vectors. Note that finding the most diverse vectors may increase the running time of the algorithm, but this strategy allows the discovery of better separated clusters. Moreover, the algorithm can either be executed until convergence or can be run in iterative steps. In the first case it finds k clusters, while in the second case it runs multiple times with k ranging from 2 to some maximum value k_{max} , and then returns the clustering with largest silhouette coefficient.

Generation of the representative functions. Given the set of clusters C , Procedure GENERATEMAXWEIGHTVECTORS (Algorithm 4, Line 3) generates a representative function ω_j^* for each cluster C_j . Different choices of ω_j^* can lead to different sets of patterns R_j^* , which can contain patterns not relevant for some $\omega_i \in C_j$, as well as missing out patterns relevant for some other $\omega_l \in C_j$. However, as stated in the following theorem, we resort to take the *maximum* among the weights to prevent missing any relevant pattern:

THEOREM 4.1. *Given a cluster C_i , and a MNI-compatible scoring function f , a complete set of relevant patterns for C_i can be mined using the representative function ω_i^* defined as $\forall e \in E, \omega_i^*(e) = \max_{\omega_j \in C_i} \omega_j(e)$.*

PROOF. By definition, only the subgraphs that satisfy the constraints on the weights through the scoring function f can contribute to the score of a pattern. Moreover, the larger the weights of a subgraph, the higher the chances that such subgraph fulfill those constraints. Since the function ω_i^* assigns to each edge $e \in E$ the largest weight among those of the weighting functions in the cluster C_i , i.e., $\forall \omega_j \in C_i, \omega_i^*(e) \geq \omega_j(e)$, the chances that a matching subgraph contributes to the score of a pattern is higher for ω_i^* than for any $\omega_j \in C_i$. It follows that $\forall \omega_j \in C_i, f(P, \omega_i^*) \geq f(P, \omega_j)$, so if a pattern is relevant for some $\omega_j \in C_i$, it is also relevant for ω_i^* . Thus, the set of mined patterns is complete. \square

Given the sets of relevant patterns R_1^*, \dots, R_k^* discovered by Algorithm 1 using the representative functions $\omega_1^*, \dots, \omega_k^*$, we create a pattern set A_i for each function ω_i using the patterns in

the set R_j^* for $j \leq k$. $\omega_i \in C_j$, i.e., each function ω_i receives the set of relevant patterns of the cluster to which it belongs.

4.2 Quality of REsUM approximate

The REsUM *approximate* algorithm reduces the problem of mining patterns in graphs with m weights on each edge to finding k sets of relevant patterns R_j^* , with $k \ll m$. The quality Q of the solution can be measured in different ways, according to the requirements of the user or the application. The most common quality measure used in the literature is the accuracy, which is defined in terms of precision and recall. In our case, since Theorem 4.1 ensures a total recall, we consider the average precision of the sets A_i with respect to the exact sets R_i :

$$Q = \frac{1}{m} \sum_{i=1}^m |R_i \cap A_i| / |R_i| \quad (1)$$

The quality Q can be measured also in terms of the average distance between the patterns in the sets R_i and those in the sets A_i . As shown in Section 7, the distance between two patterns can be calculated using the normalized Levenshtein distance, and the distance between two pattern sets as the average normalized Levenshtein distance among the pairs of closest patterns in the two sets. According to this measure, A_i is a good solution for ω_i if the patterns in A_i have structure and labels similar to the patterns in R_i .

5 PATTERN EVALUATION

A number of scoring function satisfying properties **P1**, **P2**, and **P3** can be proposed and implemented in Procedure ISVALID and RELEVANCESCORE in Algorithm 2 and 3. Nevertheless, to demonstrate the flexibility of our framework, we propose here four different scoring functions that can be used to assess the relevance of a pattern in a weighted graph. They are called *ALL*, *ANY*, *SUM* and *AVG*. We chose these functions because of their intuitive semantics and their suitability for various scenarios that may pose different requirements or provide a different interpretation of the edge weights. Moreover, as they are defined by the MNI support of the pattern over a specific restriction of its support set, they are *MNI-compatible* by definition, and thus they preserve the apriori property.

ALL, *ANY*, *SUM* and *AVG* differ in the choice of which subgraphs they include in the support sets of the patterns P and in how they aggregate the edge weights of such subgraphs. In particular, *ALL*, *ANY*, and *SUM* rely on an additional system-dependent parameter, called relevance threshold α , that is used to select the subgraphs that contribute to the *score*, while *AVG* is parameter-free.

In the following we provide a formal definition of the four scoring functions.

ALL. The *ALL* score considers only the subgraphs whose edge weights are larger than the threshold α as valid appearances of a pattern P . Specifically, the *ALL score* of P is its MNI support computed over the restricted set of appearances $S'_G(P) = \{g \mid g = \langle V_g, E_g, \ell, \omega \rangle \wedge g \in S_G(P) \wedge \forall e \in E_g, \omega(e) > \alpha\}$, i.e., $f_{ALL}(P, G) = \min_{v_P \in V_P} |\mathcal{N}(G, v_P) \upharpoonright_{S'_G(P)}|$, where $\mathcal{N}(G, v_P) \upharpoonright_{S'_G(P)} = \{v \mid v \in V \wedge \exists g \in S'_G(P), \phi_g^P(v) = v_P\}$ is the restriction of $\mathcal{N}(G, v_P)$ to the subset $S'_G(P) \subseteq S_G(P)$.

In graphs like protein-to-protein interaction networks, this *score* retrieves patterns characterized by an overall confidence greater than a certain value.

ANY. The *ANY score* takes into account only the appearances of a pattern having at least one edge with weight above the threshold α . Hence, the *ANY score* of P is the MNI support of P over the set of appearances $S'_G(P) = \{g \mid g = \langle V_g, E_g, \ell, \omega \rangle \wedge g \in S_G(P) \wedge \exists e \in E_g. \omega(e) > \alpha\}$, i.e., $f_{ANY}(P, G) = \min_{v_P \in V_P} |\mathcal{N}(G, v_P) \upharpoonright_{S'_G(P)}|$.

This score is suitable especially for the cases in which only partial weights are available (e.g., product reviews for some product), to find patterns that are overall interesting (e.g., the entire transaction comprising the product), as well as super-patterns around relevant core structures.

By definition, the *ANY score* of P is always equal or larger than its *ALL score*, as any appearance of P considered by f_{ALL} is considered also by f_{ANY} , while in general, the opposite is not true. For example, given the graph in Figure 2 and the relevance threshold $\alpha = 0.4$, the subgraph $g : [1]-A-[2]-C-[4]$ does not contribute to the *ALL score* of $P : [v_1]-A-[v_2]-C-[v_3]$, but contributes to its *ANY score*.

SUM. For the *SUM score* of P , a subgraph g contributes if the sum of its weights is larger than the threshold α . The restricted support set obtained in this way is $S'_G(P) = \{g \mid g = \langle V_g, E_g, \ell, \omega \rangle \wedge g \in S_G(P) \wedge \sum_{e \in E_g} \omega(e) > \alpha\}$. The MNI support over this set is the *SUM score* of P : $f_{SUM}(P, G) = \min_{v_P \in V_P} |\mathcal{N}(G, v_P) \upharpoonright_{S'_G(P)}|$.

This score accounts for the overall pattern weight in scenarios like money transactions, where it is beneficial to sum each single contribution in order to judge the complete value of a structure.

Note that if an appearance of P has some weight greater than α , then the sum of all its weights is at least α , and therefore $f_{SUM}(P, G) \geq f_{ANY}(P, G)$. For example, all the appearances considered by *ANY* in computing the score of $P : [v_1]-A-[v_2]-A-[v_3]$ for $\alpha=0.4$ in Figure 2 are considered also by *SUM*, whereas the subgraph $g : [3]-A-[4]-A-[8]$ contributes to the *SUM score* only.

AVG. In contrast to the previous scoring functions, the *AVG score* is not defined in terms of the minimum cardinality among some node sets of the pattern, but in terms of the relative weights of its appearances. In general, the score of a pattern P can be a function of the sum of the weights of the subgraphs in its support set, and this is called the *weighted support (WSUP)* of P . In particular, WIGM [43] proposes a measure called *normalized weighted support (NWSUP)*, which is the weighted support of P divided by its size $|E_P|$, i.e., $NWSUP(G, P) = WSUP(G, P)/|E_P|$. Nevertheless, this scoring function is not MNI-compatible. In order to guarantee the apriori property and be consistent with the other MNI-compatible scoring functions, we compute $WSUP(G, P)$ by first retaining, for each edge set $\mathcal{E}(G, e_P)$ with $e_P \in E_P$, the set $\mathcal{E}(G, e_P) \upharpoonright_\mu$ of μ edges with largest weight, and then summing up all those weights, i.e., $WSUP(G, P) = \sum_{e_P \in E_P} \sum_{e \in \mathcal{E}(G, e_P) \upharpoonright_\mu} \omega(e)$. Setting μ to be the MNI support of P we guarantee that the *AVG score* is bounded by the MNI support, as stated in the following theorem:

THEOREM 5.1. *Given a graph $G: \langle V, E, \ell, \omega \rangle$, a pattern P , and an edge $e \in E$, it holds that $f_{AVG}(P \diamond e, G) \leq MNI(P, G)$, where $P \diamond e$ is an extension of P with $E_{P \diamond e} = E_P \cup \{e\}$.*

PROOF. Since the MNI support has the apriori property [6], $MNI(P \diamond e, G) \leq MNI(P, G)$. By definition, the pattern $P \diamond e$ has the maximum normalized weight $f_{AVG}^*(P \diamond e, G)$ when all the edges in $\mathcal{E}(G, e) \upharpoonright_\mu$ have weight 1, and hence each subgraph contributes with a total weight of $(|E_P| + 1)$. In this case, $f_{AVG}^*(P \diamond e, G) =$

$MNI(P \diamond e, G) \cdot (|E_P| + 1)/(|E_P| + 1)$, and thus $f_{AVG}(P \diamond e, G) \leq f_{AVG}^*(P \diamond e, G) = MNI(P \diamond e, G) \leq MNI(P, G)$. \square

According to this theorem, although *AVG* does not have the apriori property, the *AVG score* of a pattern is at least bounded by the frequency of its sub-patterns, making it MNI-compatible and allowing early pruning during the pattern search. In fact, if the MNI support of P is lower than τ , then all its super-patterns can be discarded. On the other hand, $f_{AVG}(P \diamond e, G)$ can be higher than $f_{AVG}(P, G)$ even though the frequency of $P \diamond e$ is lower, because the weights of the edges in $\mathcal{E}(G, e) \upharpoonright_\mu$ can be so large that they compensate for the lower frequency. For example, the *AVG score* of $P : [v_1]-C-[v_2]$ in the graph G in Figure 2 is 0.6, because $MNI(P, G) = 1$ and $\mathcal{E}(G, C) \upharpoonright_1 = \{(1, 4)\}$. Instead, the *AVG score* of $P : [v_1]-C-[v_2]-B-[v_3]-A-[v_4]$ is 0.8, because $\mathcal{E}(G, C) \upharpoonright_1 = \{(1, 4)\}$, $\mathcal{E}(G, B) \upharpoonright_1 = \{(1, 3)\}$, and $\mathcal{E}(G, A) \upharpoonright_1 = \{(3, 5)\}$.

Implementation. To implement *ALL*, *ANY*, and *SUM* in our framework, function `isVALID` checks every match g of P in its support set, by comparing its edge weights against the relevance threshold α , according to the corresponding definition of $S'_G(P)$. Then, Procedure `RELEVANCESCORE` computes the MNI support over the support set $S'_G(P)$. On the other hand, for the *AVG score*, Procedure `isVALID` returns always *True*, while Procedure `RELEVANCESCORE` calculates the normalized sum of the top- k edge weights of every pattern edge, where $k = \min_{v \in V_g} |D_v|$.

6 RELATED WORK

We survey the main solutions for pattern mining in *graph databases*, *single graphs*, and *probabilistic graphs*. While previous work has tackled the problem of pattern mining in weighted graphs to a certain extent, no solution has been proposed for pattern mining in multi-weighted graphs.

Graph databases. Graph databases are collections of graphs such as chemical compounds, transactions, and workflows. Two main approaches have been proposed for pattern mining in *unweighted* collections of graphs: apriori-based methods, and pattern-growth methods. The *apriori-based* approaches generate frequent structures incrementally, by merging smaller frequent patterns [24]. Pattern-growth methods, on the other hand, generate one structure at a time, expanding each pattern in a depth-first fashion [17, 41].

In *weighted* graphs, a few pattern-growth methods have been recently introduced [19] to embody weights into the support measure. Additionally, WFSM-MR [3] further extends such approaches in a distributed manner on top of the MapReduce framework.

Nevertheless, frequent pattern mining in graph databases employs a support measure, i.e., the number of graphs containing a specific pattern, that cannot be used to mine patterns in large graphs, as each pattern would have a support equal to 1 or 0.

Single Large Graphs. Pattern mining in large graphs requires the support measure to be adjusted to account for edges shared by multiple subgraphs [6]. To this end, alternative support measures satisfying the apriori property have been proposed, alongside efficient algorithms using such measures. SUBDUE [15] is the first pattern mining algorithm in single graphs and adopts an approximate greedy strategy based on the Minimum Description Length (MDL). Other support measures include the maximum number of edge-disjoint matchings [38], the Maximum Independent Set (MIS) support [25], and the Harmful Overlap (HO) [11] support.

Nonetheless, the latter two measures require NP-complete problems to be solved, rendering them unsuitable in many practical scenarios. In contrast, the Minimum Image-based (MNI) support can be computed efficiently [11]. This measure is used by GraMi [10] and its parallel extension ScaleMine[1], which optimize the computation of the frequent patterns via a constraint satisfaction problem approach. Yet, as opposed to the problem we tackle in this work, GraMi and all the support-based approaches disregard weights on the edges of the graph and do not generalize to the case of multi-weights.

The first work on *weighted* large graphs is WTMaxMiner [12]. However, WTMaxMiner restricts the problem to mining *path* patterns, which can be efficiently discovered as opposed to subgraphs. To the best of our knowledge, WIGM [43] is the only work that deals with weighted pattern mining in large graphs, defining the importance of a pattern as the average weight over its appearances. Although weighted patterns do not naturally possess the apriori property, WIGM adopts a weaker pruning strategy based on the so-called *1-extension property*. Differently from WIGM, our solution, ReSuM is scalable and efficient since it uses measures (a.k.a. scoring functions) that satisfy the apriori property and are based on the MNI support. Additionally, ReSuM is a more general framework that supports multi-weighted graphs, as well as a broad family of scoring functions, showcasing the WIGM support measure as one example (see Section 5).

Uncertain graphs. Uncertain graphs include existence probabilities for edges or nodes of the graph. To some extent, uncertain graphs can be seen as a special case of weighted graphs in which probabilities arises, for instance, from random walk approaches, and represent the likelihood that an edge exists between two nodes. Few works have been proposed to mine frequent patterns in uncertain graphs [7, 18, 26, 32, 40, 44]. As opposed to weighted graphs, support measures for uncertain graphs must consider the uncertainty in the edges and compute the support as an expected value. Moreover, the time complexity of mining in such graphs is exponential in the worst case, since any edge can either exists or not, and hence all the possible combinations must be considered.

7 EXPERIMENTS

We experimentally show how the patterns found with ReSuM differ from those returned by frequency-based methods, thus proving the importance of our approach in pruning irrelevant patterns that are merely frequent. We also compare the scalability of our exact algorithm with the performance of our approximate algorithm. The results demonstrate that ReSuM *approximate* allows faster response time, yet retaining good accuracy in terms of the patterns returned.

Datasets. The experiments were performed on four real datasets of different sizes. Table 1 shows their characteristics, reporting the number of vertices $|V|$, edges $|E|$, and labels $|\mathcal{L}|$; the minimum, average, and maximum node degree; and the minimum, median, average, and maximum edge label frequency. For the AMAZON dataset we report statistics for both edge (top) and node labels (bottom). We also report the default frequency (τ) and relevance (α) values used in the experiments (unless otherwise stated).

- CITESEER [10], is a graph representing Computer Science publications and citations between them. The labels on the edges indicate the area in which the two papers were published (e.g., a database conference).

dataset	$ V $	$ E $	$ \Sigma $	degree		label frequency		τ	α
				min/avg/max	min/med/avg/max				
CITSEER	2.1k	3.6k	21	1/3.5/99	15/55/174.7/988	95	.05		
FREEBASE-T	7.2k	10k	40	1/2.8/504	3/70/251.3/2886	90	.05

AMAZON	163k	296k	4 1710	1/3.6/1072	2k/12k/30k/113k 1/1/95/142k	130	.05		

Table 1: Datasets and default τ , α parameters.

- FREEBASE-T and FREEBASE-C are directed subgraphs extracted from the knowledge graph FreeBase¹, which is a database collecting structured information about real-world entities like people, places and things for various topics. We obtained the two samples by restricting the graph to the topic *travel* and *computer* respectively, and then taking the largest weakly connected component in the restriction.

- AMAZON² [14] is a directed graph representing items, purchases, and user ratings. We considered the subgraph of electronic products, in which every node represents a product, a category, or a brand, and a link represents items bought together, bought in subsequent transactions, or viewed on the website one after the other. Weights represent individual user review scores (from 1 to 5), and we considered only users with more than 100 reviews. Given the sparsity of the weights, we used Personalized PageRank to spread the user preferences to products other than those they rated, as it is a standard technique for recommendations [2]. In this way we obtained weights not only for the items reviewed, but also for the most related items. Each edge weight is actually computed as the average between the PageRank value of its endpoint nodes.

Experimental setup. ReSuM is implemented in Java 1.8 on top of the constraint satisfaction problem presented in GRAMI [10] whose code was kindly provided by the authors³. The code of our implementation and all the datasets we used are publicly available⁴. We also compare with a frequent pattern mining approach (FREQ) based on GRAMI, which is also implemented in Java 1.8. All experiments were run on a 24 Cores (2.40GHz) Intel Xeon E5 – 2440 with 188Gb RAM with Linux 3.13.

Generating the weights. Since we had real weights only for the AMAZON graph, to test the scalability of our method with a larger number of weighting functions, for the other datasets we created synthetic weights based on the results of a user study we conducted on the Crowdfunder⁵ platform. We extracted a sample from the FreeBase knowledge base, restricting the domain of the edge labels to five topics (Music, Books, Celebrities, Movies, and Sport). Then we asked the users to rate each graph edge (i.e., fact) according to their preferences, using a relevance value between 1 and 5. Once collected the relevance values from 123 users, we modeled the distribution of the edge weights with respect to the number of facts. We found that the edge weights, after normalization, are distributed as a Gaussian with mean 0.452 and variance 0.02. In addition, we noted that, on average, a user rated above 0 between 10% and 20% of the labels, and thus we concluded that real graph weights are usually quite sparse. Therefore, we uniformly subset edge labels according to our findings and generated weights normally distributed in $[0, 1]$.

Furthermore, in order to evaluate the performance of ReSuM and ReSuM *approximate* with different weight distributions, we

generated sets of synthetic edge weights, varying a *focus* parameter representing the ratio of weighted edges for each edge label. The edge weights were sampled from a normal distribution $\mathcal{N}(\mu, \sigma^2)$ and a *Beta*(α, β) distribution, hence allowing us to prove the effectiveness of our algorithms under normally distributed weights and exponentially distributed weights. We set $\mu = 0.5$ and $\sigma = 0.25$ for the normal distribution and $\alpha = 0.7, \beta = 5$ and $\beta = 0.7, \alpha = 5$, for the *Beta* distribution. The two choices of the parameters for the *Beta* distribution represent two extreme of an exponential behavior: the former concentrates the probability mass on low weights, the latter on large weights. The focus parameter takes values in $\{0.5, 0.8\}$ for the normal distribution and in $\{0.25, 0.5, 0.75, 1\}$ for the *Beta* distribution.

7.1 Frequent vs Weighted Pattern Mining

We compared the patterns returned by a frequent pattern mining algorithm (FREQ) and our algorithm RESUM to validate our claim that frequent pattern mining returns a large number of low-weight patterns, which, instead, are correctly discarded in relevant pattern mining. Unless otherwise stated, we report the average of 10 different randomly sampled weighting functions. In particular, these weights were sampled from a normal distribution using focus 0.5, as previously described.

Figure 5 reports the average number of patterns found using different scoring functions on the four datasets, with default parameters, as shown in Table 1. We observe that FREQ returns patterns, at least half of which are irrelevant with respect to any of the four scoring functions. As expected, in all the datasets, ANY and SUM return more patterns than ALL and AVG, due to the less restrictive conditions on the weights. On the other hand, AVG returns a low number of patterns, mainly because more than 50% of the edges have low or zero weight. Therefore, AVG is particularly suited in biological or chemical datasets, where weights are uniformly distributed in the entire graph.

We now discuss quality (Table 2), number of patterns, and running time of RESUM compared to FREQ, when varying relevance (α) and frequency (τ) threshold (Figure 3 and 4). Due to space limits, we report results for two datasets (FREEBASE-C and FREEBASE-T); however, we observe similar results also on the other datasets. In particular, as an example, within the top-5 frequent patterns in the AMAZON graph, we found that the most frequently bought products are Sony appliances, but some relevant patterns actually involve Nikon products. This result shows that Sony products are popular but not interesting for all the users.

Quality of FREQ vs RESUM. Table 2 shows the quality of the patterns discovered by FREQ, measured on the k most frequent patterns. We selected 10 random weighting functions and mined the relevant patterns for each of them. The quality of FREQ is measured as the average Jaccard similarity between the top- k frequent patterns and the top- k relevant patterns. As expected, frequency is a bad predictor of relevance, since most of the relevant patterns are not in top- k frequent patterns. Notably, for AVG the quality is higher mostly due to the small or null number of patterns returned, as reported in Figure 5.

Relevance threshold (α). Recall that the relevance threshold α is a system-dependent parameter set only for ALL, ANY, and SUM. It can be easily tuned on demand and strongly affects the number of patterns (Figure 3(a) and Figure 3(b)), because the larger the value of α , the smaller is the number of appearances that are considered valid, and thus the smaller is the total number of relevant patterns mined. We observe that with $\alpha > 0$ the number of relevant patterns is less than half of the number of the frequent ones. This behavior reflects the characteristics of the weights in the datasets, as half of the edges have zero weight. Moreover, for FREEBASE-T SUM, being the most lenient scoring function, returns patterns even in the restrictive cases when $\alpha > 0.5$ (Figure 3(b)). Finally, since AVG does not depend on α , it always returns the same patterns.

Figure 3(c) and Figure 3(d) show that the threshold α affects the running time of RESUM mostly when ALL is used, as this function can prune the irrelevant patterns earlier in the process. In fact, an occurrence of a pattern is discarded and not included in the support set of any extension of the pattern, as soon as one edge weight is found to be below α . On the other hand, for all the other scoring functions, the extension of an invalid occurrence of a pattern can be valid for some super-pattern, and therefore cannot be discarded until all its edge weights have been examined. As a consequence, the running time of the algorithm is almost unaffected by α .

Frequency threshold (τ). Figure 4 reports the behavior of RESUM and FREQ when varying the frequency threshold τ . We performed preliminary tests to decide a reasonable range of values $[\tau_{min}, \tau_{max}]$ for each dataset. In particular, the τ_{min} corresponds to the smallest value that allowed FREQ to terminate the computation within 48 hours, and τ_{max} is the maximum value returning a non-empty set of frequent patterns. The choice of different ranges for each dataset is consistent with previous researches [10] and reflects the observation that pattern frequency is dataset-dependent, while relevance is user-dependent.

As we can see in Figure 4(a) and Figure 4(b), the number of frequent patterns decreases almost linearly with τ , and consequently the number of relevant patterns decreases as well. Regarding the performance, as opposed to the relevance threshold, the frequency threshold always alters the computation time, since higher values lead to an early pruning of many patterns, and thus the algorithm terminates earlier. Moreover, Figure 4(c) and Figure 4(d) show that when τ takes low values (i.e. between 150 and 180), RESUM runs up to two orders of magnitude faster in both the datasets. Finally, as previously noted, ALL performs significantly better than the other scoring functions.

7.2 Multiple Weighting Functions

We tested the scalability of RESUM in the case of multiple weighting functions, varying their number between 50 and 50,000. Similarly, we also measured time and quality of RESUM approximate. Nevertheless, in the following we do not further discuss and report the number of patterns retrieved for each weighting function and each scoring function, since these results are consistent with what reported in the single edge weight case.

Time. Figure 6 shows how the number of weighting functions affects the running time. Here we report the performance obtained when the weights were generated following a normal distribution with focus 0.5. In Figure 6(a) we present the comparison between RESUM and the brute-force (BF) approach, which computes the patterns for each weighting function separately. While BF scales

Table 4: Quality of ReSUM *approximate* using BUCK and A-POST clustering in FREEBASE-T and FREEBASE-C.

linearly with the number of weighting functions, the running time of ReSUM is nearly constant with 5000 functions, and slowly increases as the number of edge weights approaches 50000. As a drawback, the memory requirement grows linearly with the number of weights for both algorithms.

In Figure 6(b) and Figure 6(c) instead, we compare ReSUM and ReSUM *approximate*. For these set of experiments, we generated the representative functions by first clustering the weighting functions using the bucket-based strategy. The clustering phase is performed as a preprocessing and not reported, since it is

agnostic to the choice of the various thresholds and depends solely on the clustering algorithm (e.g., k -means, hierarchical, or spectral). In particular, we tried numbers of buckets b of different orders of magnitude and proportional to the frequency of the edge labels in the graph. Then, we run k -means using different k to study the impact of the number of clusters on the quality and the running time of ReSUM *approximate*. Finally, we set the default value of b of each dataset to the number of buckets that allowed the algorithm to use at least one order of magnitude less memory than those consumed using the full-vector strategy, i.e., 12 buckets for FREEBASE-T, 16 for FREEBASE-C, and 10 for CITESEER.

We observe that ReSUM becomes impractical as the number of weighting functions increases. As a matter of fact, when AVG is used, ReSUM exhausts the available memory, hence returning no patterns. This behavior reflects the characteristics of AVG, which requires the algorithm to exhaustively search for all the occurrences of a pattern before computing its score. In contrast, ReSUM *approximate* terminates the computation. On the other hand, when ANY is used, ReSUM is able to return the relevant patterns; however, ReSUM *approximate* outperforms the exact algorithm again, taking nearly constant time to terminate. In conclusion, in all the cases of large numbers of weighting functions, ReSUM *approximate* performs better than ReSUM by at least one order of magnitude.

Quality of ReSUM *approximate*. As mentioned in Section 4, we measure the quality of ReSUM *approximate* in terms of the average distance between the patterns it returns (sets A_i) and those returned by ReSUM (sets R_i). We define the distance between two patterns as the minimum number of edges that should be added or removed from the first to transform it into the second. Thus, the average distance between the two sets of patterns $\{A_1, \dots, A_m\}$ and $\{R_1, \dots, R_m\}$ measures the average number of operations required to transform a pattern in A_i to a pattern in R_i . We recall that our method is complete, and therefore no relevant pattern is missing. However, ReSUM *approximate* may return spurious patterns, which are patterns not relevant for any function in the cluster. Computing the distance between the

Table 5: Quality of ReSUM *approximate* with ALL and SUM on FREEBASE-C, with $Beta(\alpha, \beta)$ and normal $N(\mu, \sigma^2)$ weights generated using *focus* values in $\{0.25, 0.5, 0.75, 1\}$ and $\{0.5, 0.8\}$ respectively.

two pattern sets allows us to understand how much a spurious pattern, on average, differs from the patterns that are actually relevant for some weighting function in the cluster. Table 3 reports the distances obtained using the four scoring functions in FREEBASE-T. Here, ANY and SUM exhibit the best quality; ALL performs reasonably good, despite being more restrictive and therefore more sensitive to the approximation based on the maximum edge weights. On the other hand, when AVG is used, the quality of the answer is quite poor. Nevertheless, this behavior is due to the extremely low number of patterns this scoring function considers interesting, which skews the computation of the pattern set distance. Note that, we do not report any value for the case of 50000 weighting functions with AVG, since the algorithm exhausted all the available memory and did not terminate. We conclude that, the additional patterns returned by ReSUM *approximate* are indeed closely related to the relevant patterns of each individual weighting function.

Finally, we tested the capability of our bucket-based clustering (BUCK in short) to correctly identify groups of similar weighting functions. To this end, we compared the quality of the results mined using BUCK in the creation of the feature vectors of the weighting functions, with the quality measured using a *ground-truth* clustering (A-POST in short). The A-POST clustering was created using the sets of relevant patterns R_1, \dots, R_m as feature vectors of $\omega_1, \dots, \omega_m$, and then running a k -medoid algorithm.

We regard it as a ground-truth clustering, because it is obtained knowing what makes two weighting functions really similar, i.e. their relevant patterns, and maximizing the intra-cluster similarity. Table 4 reports the comparison between A-POST and BUCK on FREEBASE-C and FREEBASE-T. We recall that lower values mean higher quality, as they indicate distances. We can see that we experience a quality comparable with that obtained using A-POST, and thus we can conclude that our clustering technique is indeed effective.

Impact of the weights. For the experiments presented above, we weighted the Amazon graph using real weights, and the FREEBASE-T, FREEBASE-C, and CITESEER graphs with synthetic weights generated according to the results of our user study. The common feature of these two kinds of weights is that they are highly sparse. It is worth studying whether weights following other distributions or that are denser, affect the performance of our algorithms. To this end, we performed an additional set of experiments using weighting functions generated following a $Beta(5, 0.7)$, a $Beta(0.7, 5)$ and a normal distribution with different densities (*focus*), as described at the beginning of Section 7.

One would expect that, with higher densities, the cost of the computation would be higher too. Although these expectations are reasonable, in the following we show that the behavior of ReSUM and ReSUM *approximate* is consistent with what observed

in the case of sparse weights. Figure 7(a) and Figure 7(b) report the average number of patterns found using *SUM* and *ALL*, with weights generated using a *Beta*(0.7, 5) distribution with focus varying between 0.25 and 1 (i.e., all edges have weight > 0). Comparing these results with those in Figure 5 when *SUM* is used, we can see that the number of relevant patterns is largely affected by the presence of more (or all) edges with non-null weight, meaning that the patterns mined are actually many more. On the other hand, when *ALL* is used, *ReSUM* still finds a larger number of relevant patterns, but the increment is not as large as in the *SUM* case.

Regarding the running time, Figure 7(c) and Figure 7(d) show that the two algorithms behave accordingly to what already seen in the previous experiments, meaning that the fact there more patterns are mined do not downgrade the performance heavily.

Finally, Table 5 displays the quality of *ReSUM* in terms of average precision, as defined in Equation 1. As we can see, our approximate algorithm achieves similar quality values no matter which weight distribution is chosen. In addition, the denser the weights in the graph, the higher is the average precision of the pattern sets mined. Intuitively, this is due to the fact knowing a larger number of positive weights allows the clustering algorithm to better detect which weighting functions are similar.

8 CONCLUSIONS

In this paper we considered the problem of mining relevant patterns in weighted graphs. As opposed to the previous graph pattern mining approaches, which are solely based on the frequency of the patterns, our solution assesses the importance of a pattern also in terms of the weights on the edges of its appearances. Then, we proposed four different scoring functions that balance between frequency and weights, while retaining the apriori property, which is a powerful mean to an effective and early pruning of the search space. As a natural extension, we considered the complementary problem of mining patterns in graphs with multiple weights associated to the edges. We devised exact and approximate solutions and proved the effectiveness and efficiency of the algorithms on real datasets. As a future work, we plan to study the theoretical bounds on the clustering quality, and automatic approaches for parameter selection.

ABSTRACT

Large graphs are prevalent in social networks, traffic networks, and biology. These graphs are often inexact. For example, in a friendship network, an edge between two nodes u and v indicates that users u and v have a close relationship. This edge may only exist with a probability. To model such information, the *uncertain graph model* has been proposed, in which each edge e is augmented with a probability that indicates the chance e exists. Given a node q in an uncertain graph \mathcal{G} , we study the k -NN query of q , which looks for k nodes in \mathcal{G} whose distances from q are the shortest. The k -NN query can be used in friend-search, data mining, and pattern-recognition. Despite the importance of this query, it has not been well studied. In this paper, we develop a tree-based structure called the *U-tree*. Given a k -NN query, the *U-tree* produces a compact representation of \mathcal{G} , based on which the query can be executed efficiently. Our results on real and synthetic datasets show that our algorithm can scale to large graphs, and is 75% faster than state-of-the-art solutions.

1 INTRODUCTION

Graphs are prevalent in social networks [10, 12], traffic networks [11], biological networks [32], and mobile ad-hoc networks [13]. Due to noisy measurements [1], hardware limitation [2], inference models [9], and privacy-preserving perturbation [4, 23], these graphs are inherently uncertain. To model this error, *uncertain graphs* have been studied [1, 6, 15, 19]. In these graphs, each edge is associated with a probability distribution. Figure 1(a) shows the protein-protein interaction (PPI) network as an uncertain graph, where each node denotes a protein, and each edge is an interaction between a pair of proteins. The value on each edge denotes the probability that the interaction exists (called *existential probability*). For instance, the existential probability between nodes A and B is 0.7.

k -NN query. In this paper, we study the efficient evaluation of *k -nearest neighbor* (k -NN) queries on uncertain graphs [1]. Given a node q , the k -NN query returns k nodes with the shortest “distances” from q , based on a distance function (Table 1). The k -NN query can help biologists to perform tasks such as protein complex detection [2, 21], link discovery [17, 32], and protein function prediction [24]. Security experts can also use k -NN queries to design privacy-preserving algorithms to protect nodes in a graph from being identified [4].

Although k -NN queries are useful, the issues of evaluating them efficiently have only been briefly touched, e.g., [19]. Our experiments found that they are also not very efficient on large uncertain graphs. The major reason is that for correct query execution, queries running on the uncertain graph should follow the *Possible World Semantics* (PWS in short). Figure 1(b) shows

Figure 1: (a) an uncertain graph \mathcal{G} and (b) a possible world from \mathcal{G} with existence probability $0.3 \times 0.9 \times 0.6 \times 0.8 = 0.1296$.

Table 1: Distance functions for uncertain graphs.

Function	Formula
Most-probable [32]	$d_{mp}(s, t) = \arg \max \prod_{e \in PATH(s, t)} p(e)$
Reliability [35]	$d_{re}(s, t) = \sum_{d d < \infty} P_{s, t}(d)$
Median [30]	$d_{me}(s, t) = \arg \max \{ \sum_{d=0}^D P_{s, t}(d) \leq \frac{1}{2} \}$
Majority [30]	$d_{ma}(s, t) = \arg \max_d \{ P_{s, t}(d) \}$
Expected [32]	$d_{ex}(s, t) = \sum_{d=0}^{\infty} P_{s, t}(d) d$
Expected-reliable [35]	$d_{er}(s, t) = \sum_{d d < \infty} d \frac{P_{s, t}(d)}{1 - P_{s, t}(\infty)}$

a *possible world* instance sampled from \mathcal{G} in Figure 1(a). A simple way to evaluate the query is to get the answer from each possible world and then collect all these answers to form the final answer. For example, given a k -NN query of computing the k nearest neighbors from node A in Figure 1(a), we obtain 2^4 possible worlds, then for each of them, we compute the k nearest neighbors, and finally obtain the k nodes which are the closest to A considering all the possible worlds (according to a function in Table 1). Because an uncertain graph has an exponential number of *possible worlds*, a naïve solution can be extremely inefficient. Although existing solutions try to avoid enumerating all the possible worlds, they are still expensive.

The U-tree framework. In this paper, we develop a new indexing framework for k -NN requests, which (i) allows efficient and scalable k -NN query evaluation under the PWS; and (ii) can be easily adapted to different distance functions (e.g., Table 1). As shown in Figure 2, our framework consists of two stages:

- *offline index construction* (Figure 2(a)). Given an uncertain graph \mathcal{G} and a distance function d , we first employ *decomposition techniques* (Step A), which converts \mathcal{G} into a succinct index structure, whose edges are encoded with the probability information of \mathcal{G} [5, 14, 16, 22, 31, 33]. These techniques were not designed for k -NN queries. Hence, we perform *customization* of the index (Step B), which adjusts the information and structure of the index, in order to enhance the performance of k -NN queries.

- *online query evaluation* (Figure 2(b)). This stage is used to evaluate a k -NN request for a node q online. Particularly, we design an efficient query algorithm (Step C) that uses the U-tree developed

Figure 2: Answering k -NN query with the U-tree.

in the offline stage, which then yields the k nodes that are the closest to q according to distance function d .

Cost model. Upon receiving a k -NN request, the U-tree will generate another uncertain graph g (Step C above), which is a proper subgraph of \mathcal{G} , but contains the probability information essential to answering the k -NN query. Because g is often much smaller than \mathcal{G} , the query execution time can be significantly reduced. To achieve this goal, more information needs to be incorporated to the index during customization, which also renders a larger U-tree (Step B). As we will point out later, there is a trade-off between the U-tree’s size and the query cost. We will discuss a cost model that allows us to balance between these two factors, in order to improve query efficiency without significantly increasing the U-tree size.

Experiments. To evaluate the performance of the proposed methods, we conduct experiments on both real and synthetic datasets. We have also tested different decomposition methods and distance functions in the U-tree framework. The results show that U-tree is superior to the state-of-the-art algorithms, and the query time is significantly reduced by 75%; the overhead of U-tree is only 23% more than the index generated in Step A. Our solution is also scalable to large uncertain graphs with over one million nodes.

Organization. The rest of paper is organized as follows. We review the related works in Section 2. In Section 3, we present the formal definition of the problems, and discuss some basic techniques. We present the U-tree framework in Section 4. In Section 5, we present our experiment results. Section 6 concludes.

2 RELATED WORK

We review the existing queries for uncertain graphs, and then discuss the probabilistic distance functions.

2.1 Queries for Uncertain Graphs

In recent years, the k -NN query for uncertain graphs has received plenty of attention [19, 29, 30]. As mentioned before, to answer queries on uncertain graphs, the Possible World Semantics (PWS) are often used, which assumes that an uncertain graph can be expressed as a number of graph instances. Because there is an exponential no. of possible world instances, three methods are proposed in the literature: (1) The first one finds some representative deterministic graphs from the uncertain graph and answer the queries based on them [28]. (2) The second one is to reduce the size of the uncertain graph by removing some weak nodes and edges, or only sample part of the uncertain graph [30]. This, however, will lead to information loss. (3) The last method is to build some elegant index structures, which can significantly speed up the query process without information loss, and thus has received plenty of attention recently [19, 22]. Thus, in this paper we adopt the third method for the k -NN query.

In [30], Potamias et al. studied the k -NN query on uncertain graphs by using incremental Dijkstra [29] with *Monte Carlo* (MC) sampling. In [19], Khan et al. proposed a novel index for the probabilistic reliability search problem (reliable set query), which aims to find all the nodes reachable from a given source node with probability over a user-defined threshold. Moreover, it can be adapted for answering the top- k reliability query. However, it only focuses on reliability search, and it is not clear how to support other distance functions. Recently, Maniu et al. [22] proposed a novel tree index, called ProbTree, and studied how to perform source-to-target query (STQ) using ProbTree. However, as it is mainly designed for STQ, it works poorly for k -NN queries.

In summary, none of these works can answer the k -NN queries with arbitrary probabilistic distance functions, and thus they are not general enough. Therefore, it is desirable to develop a generic k -NN query framework for any probabilistic distance functions and graphs with different probability distributions.

2.2 Probabilistic Distance Functions

All the distance functions that can be used for k -NN queries are summarized in Table 1, where $P_{s,t}(a) = \sum_{G|d_G(s,t)=a} Pr(G)$ is the probability that the shortest path distance (SPD) between two nodes s and t equals to a [30]. Given a query node s , a k -NN query can return the top- k nodes with the smallest values of d_{me} , d_{ma} , d_{ex} , and d_{er} from s , or the top- k nodes with the biggest values of d_{mp} or d_{re} from s .

The function d_{mp} measures the length of the most-probable-path (i.e., a path with the highest probability) between nodes s and t . The function d_{re} measures the probability that there exists a path between nodes s and t , which is meaningful in situations such as delivering packages in a sensor network, but it cannot deal with the cases that prefer distance rather than reliability. The function d_{me} measures the median SPD among all the possible worlds, and it can be used when the user wants to get any k -th order statistic, but its value may be infinite. The function d_{ma} computes the SPD that is the most likely to be observed when sampling a graph from \mathcal{G} . It is useful in uncertain graphs with irregular distance distributions on edges, where the value has a limited discrete domain, but it cannot deal with infinity, e.g., most values of d_{ma} will become infinite when searching in the uncertain graphs with small probability on each edge. The functions d_{ex} and d_{er} are often used to compute the expected distances, and d_{er} is better when there are infinite distances in uncertain graphs. It is worth mentioning that, there is no consensus on which distance function is the best, because different functions can be used in different applications.

Consider the example graph in Figure 3(a), where the number on an edge represents the probability that it exists and ϵ is an infinitely small number. Suppose that our goal is to compute the SPD from S to T . Then, d_{me} will return the length of the path on the top, while d_{mp} will return the length of the path on the bottom as the SPD although it may contain infinite edges in the path.

Because of space limitations, we mainly focus on *reliability* and *expected-reliable* distances in this paper, as they are the most well studied ones in recent years [19, 22, 30], but other distance functions can also be easily incorporated into our indexing framework.

Figure 3: Examples for (a) distance functions and (b)PCD results.

3 PRELIMINARIES

In this section, we first introduce the problem we studied in Section 3.1, then discuss the MC sampling in Section 3.2, and finally present the uncertain graph decomposition (UGD) and UGD-based index in Sections 3.3 and 3.4.

3.1 Problem Definition

In line with previous studies [19, 30], we consider an uncertain graph as follows. Note that all the notations frequently used in the paper are summarized in Table 2.

DEFINITION 1 (UNCERTAIN GRAPH). An uncertain graph \mathcal{G} is a triple (V, E, p) , where V is the set of nodes, E is the set of edges, and p is the function of assigning probabilities, i.e., for any edge $e \in E$, the probability that it has a value w is $p(w|e)$, and $\sum_{w \in W} p(w|e) = 1$, where W contains all the possible values on the edges.

Let us take the graph in Figure 1(a) as an example, where each edge follows a Bernoulli distribution (e.g., for $e=(A, C)$ we have $p(0|e)=0.1$ and $p(1|e)=0.9$). For each edge, if its value $w=0$, it means that the edge does not exist; otherwise, it exists. Notice that the function p allows any kind of probability distributions (e.g., multi-valued or normal distributions) to be assigned for an edge.

According to the possible world semantics [19, 22, 30], an uncertain graph \mathcal{G} can be thought of as a probabilistic distribution, containing an exponential number of possible worlds, each having different probabilities. The probability of a possible world is defined as follows:

DEFINITION 2. Given an uncertain graph $\mathcal{G}=(V, E, p)$, the probability of observing a possible world $G=(V, E_G)$ is

$$\Pr(G) = \prod_{e \in E_G} p(i|e) \prod_{e \in E \setminus E_G} p(0|e). \quad (1)$$

For simplicity, if the edges follow Bernoulli distributions (see Figure 1(a)), the probability of observing a possible world is:

$$\Pr(G) = \prod_{e \in E_G} p(e) \prod_{e \in E \setminus E_G} (1 - p(e)). \quad (2)$$

Next, we formally define STQ and k -NN query as follows¹. We illustrate them via Example 1.

DEFINITION 3. Given an uncertain graph $\mathcal{G}(V, E, p)$, a distance function d , and two nodes s and t ($s, t \in V$), the source-to-target query (STQ) $q_d(s, t)$ aims to compute the distance between s and t based on the distance function d .

DEFINITION 4. Given an uncertain graph $\mathcal{G}(V, E, p)$, a function d , a node s ($s \in V$), and an integer $k > 0$, the k -nearest neighbors

¹For convenience, the subscript d can be omitted when the type of distance function is not required.

Table 2: Notations used in this paper.

Notation	Meaning
$\mathcal{G}(V, E, p)$	An uncertain graph
n, m	The sizes of V and E respectively
$G(V, E_G)$	A possible world from \mathcal{G}
STQ	The source-to-target query
SPD	The shortest path distance
$q(s, t)$	An STQ between two nodes s and t
$q_k(s)$	An k -NN query for a node s
$\phi(G)$	The diameter of the uncertain graph \mathcal{G}
$(\mathcal{B}, \mathcal{T})$	The tree index of an uncertain graph with the bag set \mathcal{B} and tree structure \mathcal{T}
$g(\mathcal{G}, \epsilon, \delta)$	The sampling times for \mathcal{G} with error rate ϵ and failure rate δ
$f(\mathcal{G})$	The cost function of the uncertain graph \mathcal{G}

query (k -NN) $q_k(s)$ aims to find a set of nodes C such that for any $r \in C$, the value of $d(s, r)$ is in the top- k list w.r.t. the function d .

In this paper, we will focus on the k -NN query. One naïve way to answer k -NN query is to run $(n-1)$ times of STQs like the way to answer $q_1(A)$ in Example 1. These STQs are called sub-queries of $q_k(s)$.

EXAMPLE 1. Consider the uncertain graph in Figure 1(a). (1) Let $s=A, t=B$ and $d = d_{er}$. There are 3 kinds of possible SPD values between A and B on \mathcal{G} , that is, $\Pr(\text{SPD} = 1) = 0.7, \Pr(\text{SPD} = 3) = 0.3 \times 0.9 \times 0.6 \times 0.8 = 0.1296$ (see Figure 1(b)) and $\Pr(\text{SPD} = 0) = 0.3 \times (1 - 0.9 \times 0.6 \times 0.8) = 0.1704$. Therefore, $q(A, B) = (0.7 + 0.1296 \times 3) / (1 - 0.1704) = 1.31$. (2) Let $s=A, k=1$ and $d = d_{er}$. We first calculate the three SPD values $d_{er}(A, B) = 1.31, d_{er}(A, C) = 1.07$ and $d_{er}(A, D) = 2$. Therefore, $q_1(A) = \{C\}$.

Since the number of possible worlds is exponentially large, it is impractical to enumerate all the possible worlds. To alleviate this issue, people often sample a small number of possible worlds, then perform queries on these sampled graphs, and obtain the final answer by accumulating the results in a particular manner. Next, we will introduce Monte Carlo Sampling, which is the popular way for approximate query processing in an efficient way.

3.2 Monte Carlo Sampling

To address the curse of exponentiation, the *Monte Carlo (MC) sampling* is used to sample a small number of graph instances [22, 30], and estimate the query results by performing queries on these sampled graph instances. To sample an instance graph G , we can sequentially consider each edge of \mathcal{G} and sample it as a deterministic edge in G following the probability distribution on the edge. Intuitively, if a possible world is repeatedly sampled multiple times, it should have a high probability to exist.

To achieve a theoretical estimation accuracy, the *Chernoff bound* [30] can be applied to determine the number of possible worlds needed for a k -NN query. Given an uncertain graph \mathcal{G} , a distance function d , and a pair of nodes s and t , the accuracy of estimating the value of $d(s, t)$ by MC sampling can be well guaranteed by Lemma 1:

LEMMA 1. [30] To achieve an error rate of $\epsilon > 0$ with a failure probability of $\delta > 0$, i.e., $\Pr(|d(s, t) - d'(s, t)| \geq \epsilon d(s, t)) \leq \delta$, the number of samples needed is

$$g(\mathcal{G}, s, t, \epsilon, \delta) = \max \left\{ \frac{3}{\epsilon^2 d(s, t)}, \frac{\phi(\mathcal{G})^2}{2\epsilon^2} \right\} \cdot \ln \left(\frac{2}{\delta} \right), \quad (3)$$

Table 3: UGD methods.

Method	Lossless	Time	Pros&cons
JSD [33]	Yes	Cubic	Smaller decomposition result, accurate but slow.
SPQR [14]	No	Linear	Smaller decomposition result but not lossless.
FWD [31]	Yes	Linear	Information lossless when $\mathcal{W} = 2$ with more redundancy.
LIN [22]	Yes	Linear	Compromise between SPQR and FWD.
PCD [5]	Yes	#P-hard	Layered decomposition without information loss.
PTD [16]	Yes	#P-hard	Layered decomposition without information loss.

where $d'(s, t)$ is the estimated value of $d(s, t)$, and the function $\phi(\mathcal{G}) = \max_{(s, t) \in V \times V} d(s, t)$ is the diameter of \mathcal{G} .

In practice, one usually focuses on finding the pairs with a given threshold ρ . Note that in general ρ is not too small [30], and thus we have $\frac{\phi(\mathcal{G})^2}{2\epsilon^2} \geq \frac{3}{\epsilon^2\rho}$. Therefore, the number of needed samples is:

$$g(\mathcal{G}, \epsilon, \delta) = \frac{\phi(\mathcal{G})^2}{2\epsilon^2} \ln\left(\frac{2}{\delta}\right). \quad (4)$$

3.3 Uncertain Graph Decomposition

To enable efficient k -NN queries, offline index are usually used [34, 36–38], often based on graph decomposition methods. In Table 2, we list all the uncertain graph decomposition (UGD) methods, including *junction scan* decomposition (JSD), SPQR decomposition [14], *lineage tree* decomposition (LIN) [22], *probabilistic core* decomposition (PCD) [5], and *probabilistic truss* decomposition (PTD) [16].

In [33], Na et al. proposed JSD² for dividing a deterministic graph into several partitions by finding the junction nodes. This method can also be adapted for UGD by simply regarding the probabilities of edges as their weights. SPQR [14] is named from the optimal tree obtained by decomposing the graph into a tree of tri-connected components. FWD [31] also decomposes the tree, but limits itself at bags which have at most a limited number of nodes, which is called their treewidth \mathcal{W} . LIN [22] behaves the same as FWD, but keeps more information in the bags for better query processing. SPQR can decompose the uncertain graph optimally, but during the process it will lose some information. FWD computes probabilities exactly in the bags, but can lead to decompositions that do not reduce much the graphs. LIN can both reduce the graph drastically and allow exact computation of probabilities, but comes at a high cost in space.

PCD [5] and PTD [16] are recently proposed layered uncertain graph decomposition methods. They can extract a dense part of the uncertain graph called (k, η) -core and (k, η) -truss respectively, which has higher probability to exist. This extraction can be executed iteratively. Note that even though the exact algorithm for finding (k, η) -core or (k, η) -truss is #P-hard, approximation algorithms are provided so that they can be completed in linear time [5, 16]. For example, there are three (k, η) -cores in Figure 3(b), and the smaller ones are more dense and reliable in the uncertain graph.

²Also called *partition-based road network index* in [33]. We call it JSD because it scans the junction nodes.

3.4 UGD-based Tree Index

A naïve index is to pre-compute all the pairwise distances and store them in a matrix, and then answer a query by simply looking up the matrix. This index, however, has a space complexity of $O(n^2)$, and it is not affordable if \mathcal{G} is large. Thus, it is desirable to develop more effective indexes. Recently, people often build an index based on UGD. The rationality behind is that, by decomposing \mathcal{G} into several sub-graphs, the k -NN query can be performed on a few sub-graphs, rather than the entire graph, resulting in high query efficiency.

To build an index for \mathcal{G} , a specific UGD method from Table 3 is used to decompose it into several bags, each of which contains a set of nodes of \mathcal{G} . The bags are then organized into a tree structure. Below, we present a formal definition of the tree index.

DEFINITION 5. Given an uncertain graph $\mathcal{G}(V, E, p)$, the index of \mathcal{G} is a tuple $(\mathcal{B}, \mathcal{T})$, where $\mathcal{B} = \{B_i | i = 1, 2, \dots, l\}$ is a set of l bags from the decomposition of \mathcal{G} and \mathcal{T} is a tree, such that:

- (1) $\cup_{B_i \in \mathcal{B}} B_i = V$;
- (2) For each $(u, v) \in E$, there is $B_i \in \mathcal{B}$, s.t. $u, v \in B_i$;
- (3) There is a link between B_i and B_j in \mathcal{T} if $B_i \cap B_j \neq \emptyset$.

We illustrate the index by taking FWD decomposition as an example. We first adopt FWD to compute all the bags limited by the tree width $\mathcal{W} = 2$. After that, for each pair of bags, if they share some nodes, we link them with an edge. Since only one bag serves as the root, this index is a tree structure. For example, the tree index in Figure 5 is an example from the FWD decomposition of Figure 4(a). Especially, for PCD and PTD, we only link the two bags when a bag is directly a subset of another bag, to keep the tree structure of the index. For example, if (k_1, η_1) -core $\subset (k_2, \eta_2)$ -core and (k_2, η_2) -core $\subset (k_3, \eta_3)$ -core, we only link (k_1, η_1) -core with (k_2, η_2) -core and (k_2, η_2) -core with (k_3, η_3) -core.

Recall that we have discussed six UGD methods in Section 3.3. Generally, all these methods can be adopted in the index. Due to the space limitation, in this paper we mainly focus on FWD and PCD, since most of existing k -NN queries on uncertain graphs are based on expected distance search [30] or density search [35]. For the expected distance based k -NN queries (e.g., the k -NN queries based on Expected-reliable distance [30]), FWD can be used; for the density based k -NN queries (e.g., top- k reliability query [35]), PCD can be used, since it is useful for extracting the dense components (e.g., (k, η) -core in Figure 3(b)) with high existence probabilities.

4 THE U-TREE INDEXING FRAMEWORK

Even with the sampling methods or indexes proposed in Section 3.3, it is challenging to answer k -NN queries in a large uncertain graphs. However, with an advanced index, we can speed up the searching process by generating an uncertain subgraph in much smaller size, with enough information to answer the k -NN query. Since the uncertain subgraph is smaller, query answering will be more efficient.

For example, the subgraph with essential information (Figure 4(b)) to answer the query $d_{er}(B, E)$ is much smaller compared to the whole graph in Figure 4(a). Since the reduction on nodes will lead to an exponential decrease in the sampling times based on Definition 3.2, the tree index will speed up the probabilistic searching in a dramatic way. In another aspect, a tree index has a reasonable cost compared to other indexes. It can decrease the number of distances to be computed compared to the matrix index. For example, we only need to compute 3 d_{er} values in

Figure 4: Tree index demonstration (a) An uncertain graph \mathcal{G} (b) $\mathcal{G}(q)$ for $q = der(B, E)$.

Figure 4(a) rather than the 21 der values for each pair of nodes in \mathcal{G} .

We will answer two questions in this section: how to build an index to efficiently answer the k -NN queries on uncertain graphs (Step A, B in Figure 2), and how to query the index when faced with a k -NN query (Step C in Figure 2). To answer the second question, we propose a novel structure and a cost evaluation model.

4.1 U-tree Index

In this section, we propose *U-tree* for k -NN search on an uncertain graph. After decomposing the uncertain graph into several bags by Definition 5, we want to dig more on the index structure.

There are two steps to build the U-tree: the basic index construction step, directly after the decomposition (Step A), and the index customization step (Step B), which will refine the index for efficient k -NN search.

Algorithm 1: Basic index construction

Input : Uncertain graph \mathcal{G}
Output : $(\mathcal{B}, \mathcal{T})$

- 1 $\mathcal{B} \leftarrow \emptyset, \mathcal{T} \leftarrow \emptyset;$
- 2 $G \leftarrow$ undirected, unweighted graph of $\mathcal{G};$
- 3 **for** $d \leftarrow 1$ to 2 **do**
- 4 **while** $degree(v) = d \ \& \ v \in G$ **do**
- 5 create bag $B;$
- 6 $V(B) \leftarrow v$ and all its neighbors;
- 7 **for all** unmarked $e \in V(B) \times V(B) \cap E(G)$ **do**
- 8 $E(B) \leftarrow E(B) \cup \{e\};$
- 9 mark $e;$
- 10 **end**
- 11 Delete v and link v 's neighbors in $G;$
- 12 $\mathcal{B} \leftarrow \mathcal{B} \cup \{B\};$
- 13 **end**
- 14 **end**
- 15 Create the root bag R with all unmarked edges;
- 16 $\mathcal{B} \leftarrow \mathcal{B} \cup \{R\};$
- 17 Organize the bags in \mathcal{B} into \mathcal{T} by their generating orders;
- 18 Add an edge between two bags in \mathcal{T} if they share nodes;
- 19 Calculate distance distributions between nodes $v \in G;$
- 20 **return** $(\mathcal{B}, \mathcal{T});$

Step A. First we adapt the STQ index from [22] into a k -NN index, representing the basic index construction method (see Algorithm 1). After the initialization (line 1 to 2), we iteratively

Figure 5: The basic tree index for the uncertain graph in Figure 4(a).

add the node in degree 0 or 1 into a bag with its neighbors³, as well as the edges among them to form a bag (line 3 to 14). Every time we add the node into one bag, it will be deleted from the original graph G . Then we create the root bag with the nodes left (line 15 to 16). Next, we link the bags and form a tree (line 17 to 18). This basic index is evaluated in the indexing framework named PTI in Section 5.

The index is a bottom-up structure, the root of the tree is where the query will be answered, so computations will be launched in a bottom-up way up to the root. Normally, we need several bags to answer a single sub-query; in the following, we study whether it is possible to use fewer bags to answer it after adding extra information into the index.

Note that a bag in higher level of U-tree will contain more information, because we aggregate all the information into a root bag in a bottom-up way in Algorithm 1. Consequently, only the root bag contains the complete distance distribution from the uncertain graph \mathcal{G} with respect to the nodes and edges in this bag. Then we can use the root bag itself to reduce an uncertain graph; this is not true for any other bag \mathcal{B} in the graph.

For example, node B in bag β of Figure 5 can only see the information from its child bag γ . Assume now we need to query $q_{er}(B, C)$. Even though we have known the distance distribution on the edge (B, C) in bag β , before we search the root bag α , we do not know if there exists another path in another part of the uncertain graph \mathcal{G} , that is, the subgraph of nodes $\{C, D, E, F, G\}$ in \mathcal{G} . So if the starting bag is far from the root, then we must search several bags before reaching the root bag, thus making the reduced sub-graph relatively large in size.

Step B. To reduce the bags to be scanned, we propose a novel method to customize the basic index from Step A. After generating the root bag, we make each edge contain distance information for both sides. Here both-side information means the bag can see the information of its child bags as well as the parent bags.

³We use here FWD ($\mathcal{W} = 2$) to decompose the uncertain graph into several bags. Other decomposition methods can be used with minor changes.

Then each bag will obtain a global view on \mathcal{G} . Therefore, if the sub-query $q(s, t)$ only concerns the nodes in one bag, we can use this single bag to answer $q(s, t)$, and thus the size of the uncertain subgraph will be significantly reduced.

We summarize U-tree in Algorithm 2. First we obtain the set of bags \mathcal{B} and the tree structure \mathcal{T} from the basic index (line 1). Then we initialize a queue Q and add the root bag R of \mathcal{T} into Q (line 2 to 3). Next, we iteratively pop out the head P of Q until it is not a leaf node of \mathcal{T} (line 4 to 7). For every edge that is shared by P and its child bags, we calculate the distance distribution in the corresponding child bags, with the help of the information provided by P (line 8 to 14).

Different from the basic index $(\mathcal{B}, \mathcal{T})$ from Algorithm 1, two points are developed in the index from Algorithm 2. First, each bag is embedded with more information. Second, we actually change the structure of \mathcal{T} . Since every bag now can see the whole uncertain graph and thus can serve as the root, we can terminate the index searching earlier. Because fewer bags are searched and a smaller sub-graph is generated, query time is saved when running the query on this smaller sub-graph.

Algorithm 2: U-tree construction

Input : Uncertain graph \mathcal{G}
Output : $(\mathcal{B}, \mathcal{T})$

- 1 $(\mathcal{B}, \mathcal{T}) = \text{Basic index construction}(\mathcal{G})$;
- 2 $Q \leftarrow \emptyset, P \leftarrow \text{null}$;
- 3 $Q.add(R)$;
- 4 **while** Q is not empty **do**
- 5 **while** P is null or P is the leafnode of \mathcal{T} **do**
- 6 $P \leftarrow Q.pop()$;
- 7 **end**
- 8 **for each child** S of P **do**
- 9 **if edge** e is shared by P and S **then**
- 10 Compute the distance distribution of e in S ;
- 11 $Q.add(S)$;
- 12 **end**
- 13 **end**
- 14 **end**
- 15 **return** $(\mathcal{B}, \mathcal{T})$;

For example, when answering $q_3(S)$, we need to answer the sub-query $q_{er}(A, D)$. So we start searching the U-tree in Figure 6 from bag γ and stop searching when reaching bag β . However, if we answer it by the index in Figure 5, we can only terminate the searching when reaching the root bag α . Thus, instead of generating the uncertain subgraph from $\{\alpha, \beta, \gamma\}$, a smaller uncertain subgraph is generated from $\{\beta, \gamma\}$.

Compared to the basic index, U-tree may help us utilize *graph locality* [27]. This is because the nodes, which may be queried by the users, are usually localized in some area of \mathcal{G} rather than uniformly distributed. For example, if s and t is within the same bag, a single bag is enough to answer the sub-query $q(s, t)$. From graph locality, only few bags are searched when answering each sub-query and thus the query time is significantly reduced.

The resulting extra cost is reasonable: the space complexity is still linear, and the index updating cost is only increased linearly. Using this efficient index, we can design the query algorithm for k -NN queries now.

Figure 6: U-tree for the uncertain graph in Figure 4(a).

Algorithm 3: U-tree query algorithm

Input : U-tree $(\mathcal{B}, \mathcal{T})$, source node $s \in V$, integer k
Output : the k -NN set C

- 1 $C \leftarrow \emptyset$;
- 2 From s to get r on \mathcal{G} ;
- 3 Generate E-table and update the bags information;
- 4 Re-order E-table;
- 5 Initiate a queue Q and load the tuples into Q ;
- 6 Perform r -pruning;
- 7 **if** $Q = \emptyset$ **then**
- 8 **return** $NULL$
- 9 **end**
- 10 $p \leftarrow Q.pop()$;
- 11 **while** $Q \neq \emptyset$ **do**

4.2 Query processing by E-table

To analyze the search process on U-tree, and then develop an efficient query algorithm, we propose a novel data structure called *E-table* (from *execution table*) to keep track of the indexing querying process.

DEFINITION 6. Given a k -NN query $q_k(s)$, an *Execution-table* (*E-table*) is a collection of tuples $u = \{id, t, r, B\}$ that:

1. $u.id$ is the identifier for u .

2. $u.t$ is the target node in the sub-query $q(s, t)$ mapped to u .
3. $u.r$ is the lower bound for $d(s, t)$.
4. $u.B$ is the set of minimum bags to answer $q(s, t)$.

Note that each tuple u in the E-table corresponds to a sub-query $q(s, t)$ for the given k -NN query $q_k(s)$. A k -NN query $q_k(s)$ can be divided into $(n - 1)$ sub-queries $q(s, t_i)$ where $t_i \in V$ and $t_i \neq s$, which are actually STQs. For example, the d_{er} based NN query⁴ can be divided into $(n - 1)$ STQs and then return the node with the minimum d_{er} value. We demonstrate the use of E-table in Example 2.

EXAMPLE 2. To find the nearest neighbors for node B in Figure 4(a), we can build a E-table like Table 4, in which each row is a sub-query and each column is an attribute of the sub-query, including the id, the target node, the lower bound for d_{er} , and the bags needed to answer this sub-query. Note that for $d_{er}(s, t)$, r can be calculated from $SPD(s, t)$ since $SPD(s, t)$ can serve as the lower bound of $d_{er}(s, t)$.

Table 4: E-table for NN(B).

id	t	r	B	Sub-query
1	A	1	$\{\alpha, \beta, \gamma\}$	$d(B, A)$
2	C	1	$\{\alpha, \beta\}$	$d(B, C)$
3	D	1	$\{\alpha, \beta\}$	$d(B, D)$
4	E	2	$\{\alpha, \beta\}$	$d(B, E)$
5	F	2	$\{\alpha, \beta, \delta, \epsilon\}$	$d(B, F)$
6	G	2	$\{\alpha, \beta, \delta\}$	$d(B, G)$

Obviously, it will be very time-consuming if we run every STQ in the E-table. Alternatively, we find that a tuple in the E-table can actually answer several sub-queries. For example, in Table 4, we can find that bag α and β contain enough information to answer three sub-queries, that is, the $d_{er}(B, C)$, $d_{er}(B, D)$ and $d_{er}(B, E)$.

For a k -NN query to find the nodes t with top- k smallest $d(s, t)$, we can filter the tuples u_i whose r_i is bigger than the current maximum $d(s, t_k)$ named as d_{max} . Here t_k is the node that has been searched and added in the k -NN set to be returned. We name the k -NN set to be returned as C . It is actually the candidate set before it is returned. Note that if C is not full, the current maximum $d(s, t_k)$ is set to be $+\infty$. The filtering theory can be formalized by Lemma 2.

LEMMA 2. All the tuples t_i whose $r_i > d(s, C)$ can be safely pruned if $|C| > k$ is satisfied. Here $d(s, C) = \max_{i \in C} d(s, i)$.

The lemma can be easily proved by the fact that the k -NN solution can only be found in the subset whose r value is not bigger than the current $d_{max} = d_{er}(s, C)$. We call this pruning technique r -pruning.

Thus, our goal is to find the proper C and use it to prune the tuples in the E-table as more as possible, especially the tuple with huge amount of bags. For example, it will be nice if tuple 5 and 6 in Table 4 are all pruned at the very first stage because these two tuples will generate uncertain graphs of bigger size.

We follow two steps to generate the candidate set C . First, we rank the E-table according to r . Then, we rank the tuples according to the number of bags, that is, the tuple with fewer

⁴NN query is the k -NN query when $k = 1$.

Table 5: Executed tuples in Table 4.

id	t	r	B	sub-query	$d_{er}(s, t)$
1	A	1	$\{\alpha, \beta, \gamma\}$	$d(B, A)$	1.3 340
2	C	1	$\{\alpha, \beta\}$	$d(B, C)$	1.1631
3	D	1	$\{\alpha, \beta\}$	$d(B, D)$	1.4708

bags will be searched first even they have the same r value. It is from the instinct that the tuple u_i with fewer bags will generate a smaller uncertain sub-graph and thus may terminate in an earlier stage. We demonstrate the process in Example 3.

EXAMPLE 3. For a NN query q_1s , we load the first tuple u_1 and generate the corresponding reduced uncertain graph \mathcal{G}_1 from B_1 . Then, we sample the reduced uncertain graph \mathcal{G}_1 and get the result of $d_{er}(s, t_1)$. We add t_1 into C and update $d_{max} = d_{er}(s, t_1)$. Next, we prune the tuples whose r value is even bigger than $d_{er}(s, t_1)$. So on so forth, we load the tuple u_i which is not filtered, and generate \mathcal{G}_i from B_i to answer $d_{er}(s, t_i)$ and then launch tuple filtering and if a smaller $d_{er}(s, t_i)$ is found, update $C = t_i$ and $d_{max} = d_{er}(s, t_i)$. After searching all the tuples that are not filtered, we can return C .

4.3 Query scheduling by cost evaluation

In the steps above, we notice that the set of bags of one sub-query maybe the upper set of another sub-query, that is $B_i \subset B_j$ happens time to time. At this time, we can safely use the upper set B_j to answer u_i and u_j . For example, the uncertain graph generated from u_1 contains all the information needed to answer u_2, u_3 and u_4 . However, some sub-queries' bag sets have overlap but not belong to each other, e.g., B_1 and B_6 . Faced with this condition, we have two choices. The first choice is to combine these two tuples and generate an uncertain graph of big size to answer these two sub-queries. The second choice is to generate two small uncertain graphs and answer the two sub-queries respectively. Thus, we can choose the one with smaller cost. The cost evaluation is summarized by the function below.

DEFINITION 7. Cost Evaluation is a function f to compare the cost of combining two tuples with the cost of answering them respectively. Here each uncertain graph \mathcal{G}_i is generated by the corresponding tuple t_i , and $\mathcal{G}_{i \cup j}$ is generated by $B_i \cup B_j$. If $f(B_i \cup B_j) < f(B_i) + f(B_j)$ then we will use B_i and B_j to generate a single uncertain subgraph. Otherwise, we will generate two uncertain subgraphs respectively.

$$f(B_i \cup B_j) = g(\mathcal{G}_{i \cup j}, \epsilon, \delta) \cdot |E(\mathcal{G}_{i \cup j})| \quad (5)$$

$$f(B_i) + f(B_j) = \sum_{p=i, j} g(\mathcal{G}_p, \epsilon, \delta) \cdot |E(\mathcal{G}_p)| \quad (6)$$

If we combine all the possible tuples to generate a single uncertain graph which contains all the information to answer the k -NN query, then this reduced uncertain graph is called *Equivalent Uncertain Graph* (EUG) of \mathcal{G} for the given query. Figure 7 is the EUG for $q_1(B) = NN(B)$ on the uncertain graph in Figure 4(a). When the candidate set is big in size or the k -NN query has a large k value, the EUG cannot be reduced much. This shows another reason why we need a cost evaluation.

According to section 3.2, $\phi(\mathcal{G})$ can be roughly approximated by $(n-1)$, then the cost function can be written as $f(\mathcal{G}) = (n-1)^2 \cdot m$.

EXAMPLE 4. If there comes three tuples in the E-table, and they need the bags $\{\alpha, \beta, \gamma\}$, $\{\alpha, \delta, \epsilon\}$ and $\{\alpha, \beta, \delta\}$ respectively (see Figure 8). Thus we get three reduced uncertain graph $\mathcal{G}_1, \mathcal{G}_2$ and \mathcal{G}_3 .

Figure 7: The EUG for Figure 4(a) considering NN(B).

Figure 8: The uncertain graph generated from bags (a) $\{\alpha, \beta, \gamma\}$, (b) $\{\alpha, \delta, \epsilon\}$ and (c) $\{\alpha, \beta, \delta\}$.

We can merge these reduced graphs to answer multiple tuples or answer them one by one. There are 5 ways to answer these tuples and the costs are listed below.

$$\begin{aligned}
 f(\mathcal{G}_1, \mathcal{G}_2, \mathcal{G}_3) &= f(\mathcal{G}_1) + f(\mathcal{G}_2) + f(\mathcal{G}_3) = 4^2 \times (7 + 6 + 7) = 320 \\
 f(\mathcal{G}_1 \cup \mathcal{G}_2, \mathcal{G}_3) &= f(\mathcal{G}_1 \cup \mathcal{G}_2) + f(\mathcal{G}_3) = 6^2 \times 10 + 4^2 \times 7 = 472 \\
 f(\mathcal{G}_1, \mathcal{G}_2 \cup \mathcal{G}_3) &= f(\mathcal{G}_1) + f(\mathcal{G}_2 \cup \mathcal{G}_3) = 4^2 \times 7 + 5^2 \times 8 = 312 \\
 f(\mathcal{G}_2, \mathcal{G}_1 \cup \mathcal{G}_3) &= f(\mathcal{G}_2) + f(\mathcal{G}_1 \cup \mathcal{G}_3) = 4^2 \times 6 + 5^2 \times 9 = 321 \\
 f(\mathcal{G}_1 \cup \mathcal{G}_2 \cup \mathcal{G}_3) &= f(\mathcal{G}_1 \cup \mathcal{G}_2 \cup \mathcal{G}_3) = 6^2 \times 10 = 360
 \end{aligned}$$

Here we see the optimal solution for this E-table is not to answer each tuple respectively or to generate an EUG, but only to merge \mathcal{G}_2 and \mathcal{G}_3 . Therefore, we form Algorithm 3 to find the local optimal solution of the minimum cost. We find that the local optimal solution works well; on the other hand, finding the global optimal solution is relatively cumbersome.

Given the initial uncertain graph $\mathcal{G}_0 = (V_0, E_0, p)$ and two reduced uncertain graph $\mathcal{G}_1 = (V_1, E_1, p)$, $\mathcal{G}_2 = (V_2, E_2, p)$, the function $merge(\mathcal{G}_1, \mathcal{G}_2)$ generates an uncertain graph $\mathcal{G}_{1,2} = (V_1 \cup V_2, E, p)$ where $E = (V_1 \cup V_2)^2 \cap E_0$. The function pop will pop up the queue's head and delete it from the queue.

Discussion. We notice that the basic index has a fixed root, that is, every time when the index is queried, we need to reach the root. But every bag in the U-tree can serve as the root, meaning the index retrieval can be done in any part of the tree. So when the query node is far away from the root, the query time from the basic index will become too high, because many bags are required and the reduced subgraph will not decrease much in size. U-tree overcomes this drawback but the index construction time is increased. Therefore, we study whether there is any trade-off and balance between the two indexes, and then we can enjoy both the quick indexing and efficient querying. We answer this question by graph locality. With the help of the history queries, we can obtain the popular nodes which may be frequently queried [18]. And with the help of graph locality, most k -NN queries will be around these nodes. Then we can build multiple basic indexes rooted on each popular node. Every time a query comes, it can be assigned to an index with the smallest cost. In this way, the cost of index updating is reduced and the query is accelerated.

5 EXPERIMENTAL EVALUATION

We now present the experimental results. We first describe the datasets in Section 5.1, then introduce the competitors in Section 5.2, and finally report the experimental results on indexing cost, query time, time proportion, accuracy and generality in Sections 5.3, 5.4, 5.5, 5.6, and 5.7 respectively.

5.1 Datasets

5.1.1 Real-world Graphs. We use six real-world datasets. Table 6 reports their statistics. All datasets are transformed into undirected uncertain graphs with meaningful probability distribution on each edge. Note that PPI, DBLP and FBN have Bernoulli distributions on each edge, whereas BJT has no limitation on the type of the distribution on each edge, and they do not follow any standard distributions [8].

For each uncertain graph, we calculate the diameter to better show the size and density of the dataset. To calculate the diameter, we ignore the probabilities and treat each uncertain graph as an unweighted graph, and then find the largest SPD. For the dataset with multiple connected components, we report the one with the biggest diameter. We evaluate scalability of the indexing framework by testing its performance when faced with datasets with different size (see Table 6) and different density (See Table 7).

PPI⁵ We have two protein-protein interaction (PPI) networks (PPIC, PPIK) [25]. We use these networks in which a node denotes a protein and an edge denotes a possible interaction encoded with a specific probability calculated from biology experiments, meaning the existence confidence of this edge. *Collins's* network PPIC is the core dataset which is believed to have strong interactions among the nodes [7]. *Krogan's* network PPIK, however, contains less reliable interactions and thus is bigger in size [20].

DBLP⁶ It is a subset of the co-authorship network. The nodes denote the authors and if two authors have coauthored a paper, there will be an edge between them. We follow the popular way of generating co-authorship probability between two authors [19]. If two authors coauthored c times, the probability is $1 - e^{-c/\mu}$ on the corresponding edge where smaller μ means smaller probabilities in general. Following the trend [19], we adopt $\mu = 5$ which makes the most edges with an existing probability around 0.05.

FBN⁷ The dataset called Facebook-like Social Network is from an online community for students at University of California, Irvine [26]. It includes the users who sent or received at least one message. Each node denotes a user and if there are messages between two users, there will be an edge. The probability on an edge means the probability of the corresponding users having an interaction. The method to generate the probability is same as the method in DBLP but we set $\mu = 2$ to make the most edges with a probability around 0.4.

BJT⁸ The dataset is generated from mapping 15 million Beijing Taxi trajectories [39, 40] on a Beijing map with about 3 million road segments (BJT) and 1 million road segments (BJTA, only the arterial roads) respectively [33]. The probability distribution on an edge means the speed distribution of the vehicles on the corresponding road segment. It can be generated by analyzing the trajectories [8]. Note that the diameters of BJT and BJTA is obviously bigger than the other datasets, since long roads (tens

S ₆	1,000,000	4,213,833	15

of kilometers) will be separated into many road segments (ten meters).

5.1.2 Synthetic Graphs. Given an unweighted graph, algorithms from [4] can generate a graph with disturbances on the edges and calculate a probability of existence for each edge. The algorithm from [23] can encrypt a given weighted graph into an uncertain graph encoded with a probability on each edge.

Here we encrypt a synthetic graph generated from the *Barabási-Albert model* [3], which is a widely used model to simulate real graphs. To vary the density of the graph, we set the diameter as 15 but vary the number of the edges for each synthetic graph. Then the unweighted graphs with different size are encrypted by $(20, 10^{-3})$ -obfuscation [4]. We use these graphs to test the scalability of the indexes.

5.2 Competitors

In our experiments, we try to find the k -nearest neighbors for 100 randomly generated query nodes. We use three competitors: Incremental k -NN (IKNN) from [30], RQ -tree reliability search (RQRS) from [19], and the basic index (see Algorithm 1) adapted from *ProbTree* indexing framework (PTI) [22].

We adapt PTI into a single-source version to deal with k -NN queries. They have been discussed in the related works. IKNN is popular in finding k -NN in the uncertain graphs, and RQRS is the state-of-the-art probabilistic k -NN index based on reliability search. PTI is the current indexing framework which can adopt different decomposition methods and distance functions.

We implement the whole U-tree indexing framework in Java, and run experiments on a machine having a 4-core Intel i5-3570 3.40GHz processor and 16GB of memory, with Ubuntu installed.

5.3 Evaluation on Indexing Cost

Here we evaluate the space cost and the index construction time of U-tree, PTI and RQRS.

The space cost is composed by the tree structure and the distance distribution stored in the bags. From Figure 9, we see that the U-tree index needs more memory since it stores more distance distributions into each bag, and RQRS needs more memory because it stores the whole node set at each level of the tree index. Compared with the query efficiency improvement in Figure 13,

Figure 9: Scalability Evaluation on index size and index construction Time on real-world datasets (top) and synthetic datasets (bottom).

we find that the extra memory cost in U-tree index is reasonable, because the space cost rises 23% but the query time is 75% faster on average.

We compare the time cost to construct each index in Figure 9. To avoid affecting the comparison, here we only evaluate the time to construct the tree index and the uncertain graphs are assumed to be decomposed beforehand. Note that RQRS needs to recursively perform balanced bi-partition clustering, which can also be seen as a decomposition method.

To test the scalability of U-tree, we use the synthetic graph with the graph anonymization technique. We vary the size of the synthetic graph (see Table 7) and compare the index construction time and index storage in Figure 9. *Semilog* is used on the y -axis because of the big difference of the index size and construction time when the number of nodes sharply changes. From the figure, we find the index construction cost of U-tree is linear to the number of nodes in the uncertain graph. This shows good scalability over uncertain graphs of different size.

5.4 Evaluation on Query Time

Here we evaluate the query time on six real-world networks and six synthetic datasets. We use the popular probabilistic k -NN algorithm IKNN [30] to show the efficiency of the query time without index acceleration, and the ability of U-tree, PTI and RQRS to speed up the searching. This comparison makes sense because they all need to find the probability distribution among nodes, which is the most expensive part in the algorithms.

In Figure 13, we vary the k value to see the changes of each curve. For each k value, we randomly pick 100 nodes as the source nodes to initiate 100 probabilistic k -NN queries, and calculate the average query time as the value on y -axis. We use *semilog* on the query time because of the wide range between different methods.

From Figure 13, U-tree is superior to the other methods, and the index based methods have a much smaller query time than IKNN (about two magnitudes). However, the curve of RQRS and that of PTI index twist together. This might be because both RQRS

Figure 10: Proportion of (a) probability computation time out of index construction time (b) index retrieval time out of query time.

Figure 11: Comparison of (a) k -NN query in d_{re} and (b) k -NN query in d_{er} on the U-tree from JSD, PCD and FWD.

and PTI construct a tree whose height $h \in [10, 20]$ and they all have to search on the tree from the leaves until reaching the big root. These similarities make their retrieval time in the same level. Also, the figures show good scalability of U-tree despite of the dataset size and density.

5.5 Evaluation on Time Proportion

From Figure 10 we see that the Probability Computation Time (PCT) takes the most part of the index construction time and the Sampling Time (ST) takes the most part of the query time. Note that the query time minus ST is the Index Query Time (IQT) and the index construction time minus PCT is the Tree Structure Construction Time (TSCT).

It makes sense because in the index construction period, to calculate the distance distributions is required in both phase one and phase two which asks for sampling the corresponding subgraphs. Also, when we run the queries on the index, the bags containing essential information are collected and then sample the reduced uncertain subgraph.

Since bigger proportion of TSCT means more complex index structure, e.g., a bigger tree height, and thus requires more time to answer a k -NN query. Also, IQT is the time to be spent on searching the index. The bigger proportion of an IQT, the bigger probability that more bags are required to generate the uncertain subgraph, thus making the query time unbearable. From Figure 10, U-tree performs good when searching the index and answering the k -NN queries.

Figure 12: Indexing framework accuracy evaluation.

5.6 Evaluation on Accuracy

In U-tree indexing framework, there are two parts that may cause precision loss. The first part is the choice of decomposition methods. If a decomposition method which may lose information is used, e.g., FWD with $\mathcal{W} > 2$, the uncertain subgraph to be generated from searching the index will become not accurate, thus making error in k -NN results. The second part is the sampling method. Since sampling is a technique for approximate query processing, it will lose information while accelerating the querying process. In general, less sampling times will lead to bigger error in the k -NN results.

Here we vary the FWD tree width \mathcal{W} and construct the corresponding U-tree respectively. Then, we run k -NN query on these U-trees with different pair of parameters (ϵ, δ) in the sampling. We set $(\epsilon, \delta) = (x, x)$ and vary x from 0.1 to 0.9.

The k -NN results are collected and compared with the k -NN result from a baseline which simply runs big number of samplings times to find the k -nearest neighbors on uncertain graphs. We run the experiment on PPIC and PPIK and d_{er} is used. Here k is set to 100 and the Mean Squared Error is reported.

From Figure 12, we see that the Mean Squared Error is generally small even when the sampling parameters are setting in a bad way, e.g., ϵ and δ are very near to 1. Especially, with parameters below 0.25, we can achieve high accurate k -NN results even with decomposition methods that may lose information.

5.7 Evaluation on Framework Generality

To show the generality of the indexing framework, we will use another distance function and another decomposition method to construct U-tree. We run two different k -NN queries on each U-tree, i.e., the k -NN query which asks for the set of nodes with top- k biggest reliabilities d_{re} from the query node, and the k -NN query which asks for the k -nearest neighbors in Expected-reliable distance d_{er} .

We use three different decomposition methods to construct U-tree, i.e., JSD which can find the nodes and edges to divide the graph into several partitions [33], PCD (see Figure 3(b)), and FWD where we set the tree width $\mathcal{W} = 2$ [22].

We run this evaluation on DBLP. The results are collected in Figure 11. We can see that the U-tree with PCD and the U-tree with FWD are similar in performance, and PCD has a little advantage over FWD for k -NN in d_{re} while FWD is better for k -NN in d_{er} . The above two U-trees have significant advantage over the U-tree with JSD, since JSD performs poor in capturing hierarchical structure of an uncertain graph.

Figure 13: Query efficiency comparison.

6 CONCLUSION

In this paper, we examine the k -NN query on uncertain graphs. We first propose a generic index which can be built with several uncertain graph decomposition methods. Then, based on this index, we develop an efficient k -NN query algorithm, which supports various probabilistic distance functions. Finally, we evaluate the proposed indexing frameworks on both real and synthetic large uncertain graphs. The experimental results show that our index is effective and scalable to large graphs, and our query algorithm is very efficient.

In the future, we will study how to efficiently maintain the index for dynamic graphs, in which the nodes and edges are inserted and deleted frequently. Another interesting direction is to study how to extend the indexing framework for answering k -NN queries on a distributed platform. The research on the insight of the uncertain graph decomposition will be valuable, since a better decomposition method will largely benefit the index performance. We will also perform more experimental evaluations on other real uncertain graphs.

A APPENDIX

In this appendix, we present the algorithm listing of the competitors from the research literature.

Algorithm 4: Incremental k -NN (IKNN)

Input : uncertain graph $\mathcal{G} = (V, E, P, W)$, query node $s \in V$, sampling times r , distance increment γ , k
Output : k -NN result T_k

- 1 $T_k \leftarrow \emptyset, D \leftarrow 0$;
- 2 Initiate r executions of *Dijkstra* from s ;
- 3 **while** $|T_k| < k$ **do**
- 4 $D \leftarrow D + \gamma$;
- 5 **for** $i \leftarrow 1$ **to** r **do**
- 6 Continue visiting nodes until reaching D by *Dijkstra*;
- 7 **for each node** $t \in V$ **visited do**
- 8 | Update the distance distribution and get d_{er} ;
- 9 **end**
- 10 **end**
- 11 **for node** $t \notin T_k$ **do**
- 12 | **if** $d_{er}(s, t) < D$ **then**
- 13 | $T_k \leftarrow T_k \cup \{t\}$
- 14 | **end**
- 15 **end**
- 16 **end**
- 17 **return** T_k ;

Algorithm 5: *RQ*-tree reliability search (RQRS)

Input : uncertain graph $\mathcal{G} = (V, E, P)$, query node $s \in V$,
sampling times r, k

Output : k -NN result T_k

- 1 $T_k \leftarrow \emptyset$;
 - 2 Initiate *RQ*-tree based on binary clustering;
 - 3 Compute the upper bound U_{out} for each cluster C ;
 - 4 Generate the candidate set C^* ;
 - 5 Travel the clusters in *RQ*-tree in bottom-up until
 $C^*({s}, \eta) = \arg \max_{\{S\} \subseteq C, U_{out}(\{s\}, C) < \eta} U_{out}(\{s\}, C)$;
 - 6 Get the reduced graph G' by C^* ;
 - 7 Initiate r executions of *DFS* on G' from s ;
 - 8 Calculate the reliability and select the biggest *top-k* as T_k ;
 - 9 return T_k ;
-

Algorithm 6: *ProbTree* indexing (PTI) (\mathcal{G})

Input : uncertain graph $\mathcal{G} = (V, E, P)$, query node $s \in V$,
sampling times r, k

Output : k -NN result T_k

- 1 # Index construction:
 - 2 Run Algorithm 1 to build the *FWD* tree with $\mathcal{W} = 2$;
 - 3 # Information Retrieval:
 - 4 $T_k \leftarrow \emptyset$;
 - 5 **for** $v \in V$ **do**
 - 6 | Calculate $d_{er}(s, v)$ with the help of the *FWD* tree;
 - 7 **end**
 - 8 Put the k nodes with the *top-k* smallest $d_{er}(s, v)$ in T_k ;
 - 9 return T_k ;
-

ABSTRACT

Blocking is a fundamental step in entity matching (EM). Much work has examined the design and runtime of blockers. However, very little if any work has examined the problem of debugging blocking accuracy. In practice, blockers' accuracy can vary drastically, and using an accurate blocker is critical for many EM applications. To address this problem, we describe the MatchCatcher solution. Given two tables to be matched and a blocker, MatchCatcher finds matches killed off by the blocker, so that the user can examine these matches to understand how well the blocker does accuracy-wise and what can be done to improve its accuracy. We show how to quickly find such matches using string similarity joins, iterative user engagement, rank aggregation, and active/online learning. Extensive experiments show that MatchCatcher is highly effective in helping users develop blockers, can help improve accuracy of even the best blockers manually created or automatically learned. MatchCatcher has been open sourced and used by 300+ students in data science class projects and 7 teams at 6 organizations.

1 INTRODUCTION

Entity matching (EM) finds data instances referring to the same real-world entity [6, 14], such as tuples (Dave Smith, San Francisco, CA) and (David Smith, S.F., CA). This problem is critical for many Big Data and data science applications.

When doing EM, we often must perform blocking. Consider for example matching two tables A and B . Real-world tables often have hundreds of thousands, or millions, of tuples. Trying to match all tuple pairs in $A \times B$ is practically infeasible. So we often perform a step called *blocking* which uses domain heuristics to quickly drop many pairs judged obviously non-matched (e.g., person tuples that do not have the same state). The next step, called *matching*, matches the remaining pairs, using rule- or learning-based techniques. Blocking can greatly reduce the number of pairs considered in the matching step, drastically reducing the total EM time. As a result, virtually all real-world EM applications use blocking.

Numerous blocking methods have been developed [6]. For example, *hash blocking* drops all tuple pairs that do not have the same hash value, using a predefined hash function. This method is popular because it is easy to understand and fast. Other methods include sorted neighborhood, overlap, phonetic, rule-based, etc. (see Section 2).

Given two tables A and B to match, we often want a blocker Q that is *fast*, *selective*, and *accurate*. "Fastness" is measured by the time to apply Q to A and B to produce a set of tuple pairs C . "Selectivity" is typically measured as the ratio $|C|/|A \times B|$. "Accuracy" is typically measured as the fraction of *true matches* surviving blocker Q , i.e., $|M \cap C|/|M|$, where M is the set of

(unknown) true matches in $A \times B$. As such, it is also referred to as *recall*.

In practice, blockers can vary drastically in recall, and using a blocker with high recall is critical for many EM applications (see Section 2). Yet today there is still no good way to develop such blockers. For example, given the popularity of hash blockers, suppose we have decided to use a hash blocker Q on two tables. While fast, Q may have low recall if the attribute values to be hashed are dirty, misspelt, missing, or have many natural variations (e.g., "New York", "NY", "NYC"). A common way to address this problem is to use multiple hash blockers and take the union of their outputs, to maximize recall. However, even in this case, the recall can still be quite low. For instance, a recent work [8] describes two real-world datasets where extensive effort at combining hash blockers achieves only 38.8% and 72.6% recall. Such low recalls are simply unacceptable for many EM applications. To improve recall, we can revise the current hash blockers, replace some of them, or adding more blockers (of the non-hash types). *To do any of these, however, we need a way to understand whether the current blocker has low recall, and if so, then what the possible problems are, so that we can improve it.*

The MatchCatcher Solution: In this paper we take the first step toward solving the above problems. We describe MatchCatcher, a solution to debug blocker accuracy. Given two tables A and B to be matched and a blocker Q , MatchCatcher attempts to find matches that are "killed off" by Q , i.e., those that do not survive the blocking step. We can examine these matches to see if they are indeed true matches, and if so, then why they get killed off by Q . This tells us whether Q has low recall, and if so, then how to improve it. The following example illustrates our solution:

Example 1.1. Consider matching tables A and B in Figure 1.a. Suppose a user U begins by creating a blocker Q_1 that keeps only tuple pairs sharing the same value for "City". Figure 1.b shows this blocker as $Q_1: a.City = b.City$. (This is attribute-equivalence blocking, a special type of hash blocking.) Applying Q_1 to A and B produces a set of tuple pairs C_1 (see Figure 1.b).

User U wants to know if blocker Q_1 kills off too many true matches. To answer this, U applies MatchCatcher, which operates in iterations. In the first iteration, MatchCatcher shows the user n tuple pairs judged most likely to be matches killed off by Q_1 . These pairs are listed on Figure 1.b, under "Debugger Output, Iter 1" (here $n = 3$).

User U finds that the first two pairs, (a_1, b_1) and (a_3, b_2) , are indeed true matches (shown in red color on the figure). A closer examination reveals that they do not survive blocking because their "City" values do not match due to misspellings and abbreviation, e.g., "Atlanta" vs. "Atlanta", "New York" vs. "NY".

Next, U wants to know if there are any more true matches. Toward this goal, U flags the true matches in the first iteration (i.e., the above two pairs). MatchCatcher uses this feedback to find the next n pairs judged most likely to be killed-off matches, then shows those pairs in the second iteration (see Figure 1.b, under "Iter 2").

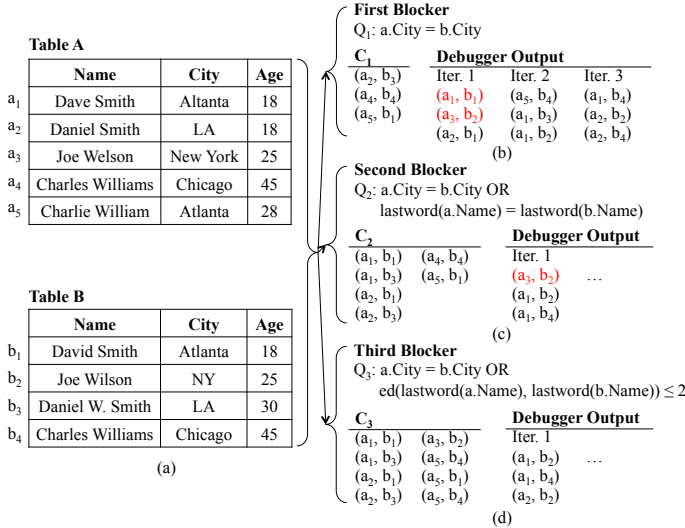

Figure 1: An example to illustrate MatchCatcher

U finds no true matches in this iteration, as well as in the third iteration.

At this point, U decides to stop looking for more killed-off matches, to focus on revising blocker Q_1 to improve its recall. U observes that the problem with pair (a_1, b_1) , which disagree on “City”, can be fixed by adding a new hash blocker that blocks on the last word of “Name”, i.e., keeps a tuple pair if they agree on this word (which is typically the last name). Figure 1.c shows Q_2 , the revised blocker, which is the union of two hash blockers.

Invoking MatchCatcher for Q_2 produces the list shown under “Debugger Output, Iter 1” in Figure 1.c. This list shows that while the new blocker Q_2 successfully keeps (a_1, b_1) , it still kills off (a_3, b_2) , a true match. A closer examination reveals that this is due to a misspelt last word: “Welson” vs. “Wilson”.

To fix such misspelling problems, U decides to keep a tuple pair if the last words of “Name” are very similar, e.g., within an edit distance of 2. This produces blocker Q_3 in Figure 1.d. Here, the hash blocker $lastword(a.Name) = lastword(b.Name)$ has been replaced by $ed(lastword(a.Name), lastword(b.Name)) \leq 2$, a more general blocker where “ed” computes the edit distance. Invoking MatchCatcher for Q_3 brings back no true matches, even after several iterations. Thus, user U stops, deciding to use Q_3 as the final blocker for A and B .

It is important to emphasize that MatchCatcher works with any of the current blocker types. Indeed, it requires as input only the two tables A and B and the set C resulting from applying the target blocker to the tables. MatchCatcher thus is *blocker independent*. We intentionally designed MatchCatcher this way to maximize its real-world applicability, i.e, to make sure that no matter which blocker a user has created, he or she can use MatchCatcher. Subsequent work will examine extending MatchCatcher to exploit the particularities of a specific blocker type.

Further, MatchCatcher does not estimate the *actual* recall, i.e., the fraction of matches surviving blocking. Doing so would require it to know the set of true matches in $A \times B$, which would be solving the EM problem itself! Indeed, MatchCatcher does not attempt to match A and B . Instead, its goal is to quickly find a large set of plausible matches killed off by the blocker and bring them to the user’s attention, so that the user can examine them to find true matches, get a sense about whether the blocker kills off too many such matches, and if so, what the problems are, so that

he/she can fix them. Section 6 shows that real-world users indeed find MatchCatcher very helpful in answering these questions.

Challenges: While promising, developing MatchCatcher raises difficult challenges. First, we must quickly search the vast space $D = A \times B - C$ (where C is the blocker’s output) to find plausible matches killed off by the blocker, and we must do so without materializing D . This search is further complicated by the fact that at this point MatchCatcher does not even know what it means to be a match (only the user knows). To address these problems, we observe that matching tuples tend to have similar values for certain attributes (e.g., Name, City). So we convert each tuple into a string that concatenates these attributes, e.g., converting tuple a_1 of Table A in Figure 1.a into “Dave Smith Atlanta”. We then perform a *top-k string similarity join (SSJ)* to find the k tuple pairs with the highest score with respect to these strings, and output these pairs as plausible matches. The state-of-the-art solution for top-k SSJs [34] proves too slow for our interactive setting. So we develop a new solution that is significantly faster.

Second, to find as many plausible matches as possible, we need to repeat the above procedure, but for different sets of attributes (e.g., find tuple pairs that are similar with respect to Name only, City only, both Name and City, etc.). We cannot consider all such sets, called *configs*, as there are too many. So we develop a solution to find a good set of configs.

Third, we must perform multiple related top-k SSJs, one for each config. This raises the challenge of how to perform them jointly across the configs. We develop an efficient solution that perform them in parallel on multiple cores yet reuse computations across the joins.

Finally, top-k SSJs over the configs produce a large set E of plausible matches (e.g., in the thousands). We cannot realistically expect the user to examine all of these matches. So we develop a solution that uses rank aggregation and active/online learning to rank the pairs in E , show the top n pairs to the user, ask him/her to identify the true matches, use this feedback to rerank the pairs, and so on, until the user has been satisfied or a stopping condition is reached. In summary, we make the following contributions:

- We show that debugging blocker accuracy is critical for EM.
- We describe MatchCatcher. As far as we know, this is the first in-depth solution to address the above problem. Our solution advances the state of the art in top-k string similarity joins, and exploits active/online learning to effectively engage with the user.
- Over the past two years, MatchCatcher has been successfully used by 300+ students in data science projects and by 7 teams at 6 organizations. We briefly report on this experience. We also describe extensive experiments showing that MatchCatcher is highly effective in helping users develop blockers, and that it can help improve the accuracy of even the best blockers manually created or automatically learned.

2 DEBUGGING BLOCKER ACCURACY

In this section we show that debugging blocker accuracy is critical for EM, discuss the limitations of current solutions, then provide an overview of the MatchCatcher solution.

Entity Matching (EM): This problem has received significant attention (see [6, 14, 30] for recent books and surveys). Many EM scenarios exist, e.g., matching two tables, matching within a table,

matching a table with a knowledge base, etc. [6]. In this paper, as a first step, we will consider the common EM scenario that matches two tables A and B , i.e., finds all tuple pairs $(a \in A, b \in B)$ that refer to the same real-world entity.

Types of Blockers: As discussed in the introduction, for large tables A and B we typically perform EM by creating a blocker Q , apply Q to A and B to produce a relatively small set of tuple pairs C , then apply a matcher to pairs in C . Over the past few decades blocking has received much attention. The focus has been on developing different blocker types and scaling up blockers, e.g., [18, 22, 33] (see [7, 13] for surveys).

Many blocker types have been developed. MatchCatcher works with all of them. In what follows we briefly discuss the most important types, as Section 6 experiments with many of them.

Well-known blocker types are attribute equivalence, hash, and sorted neighborhood. *Attribute equivalence (AE)* outputs a pair of tuples if they share the same values of a set of attributes (e.g., blocker $Q_1: a.City = b.City$ in Figure 1.b). *Hash blocking* (also called *key-based blocking*) is a generalization of AE, which outputs a pair of tuples if they share the same hash value, using a pre-specified hash function. For example, blocker Q_2 in Figure 1.c combines the hash blocker $lastword(a.Name) = lastword(b.Name)$ and the AE blocker Q_1 . *Sorted neighborhood* outputs a pair of tuples if their hash values (also called *key values*) are within a pre-defined distance.

More complex types of blockers include similarity- and rule-based [6, 8, 18]. *Similarity-based blocking (SIM)* is similar to AE, except that it accounts for dirty values, misspellings, abbreviations, and natural variations by using a predicate involving string similarity measures, such as edit distance, Jaccard, overlap, etc. [36]. Examples include $ed(lastword(a.Name), lastword(b.Name)) \leq 2$, a blocker which outputs tuple pairs where the last words of their names have an edit distance of at most 2, and blocker $jaccard(a.title, b.title) \geq 0.4$, which outputs pairs of books whose titles have a Jaccard similarity score of at least 0.4. *Rule-based blocking* is perhaps most general. It outputs a tuple pair satisfying a rule or a set of rules encoding domain heuristics, e.g., blocker Q_3 in Figure 1.d consists of two rules. Such blockers can be viewed as the union of multiple blockers, one per rule.

Other types of blockers include phonetic (e.g., soundex), suffix-array, canopy, etc. (see [6, 14] for an extensive discussion).

Efficient Execution of Blockers: Efficient techniques have been developed to execute the above blocker types, both on a single machine and a cluster of machines (e.g., [8, 18, 22]). To execute hash/AE blocking, we partition the tuples in A and B into *blocks*, such that all tuples in each block share the same hash value, then output only pairs of tuples that are in the same block.

To execute a SIM blocker, e.g., $ed(lastword(a.Name), lastword(b.Name)) \leq 2$, we build an index I (e.g., prefix filtering index [36]) on the tuples in A , say. Next, for each tuple $b \in B$, we consult I to identify all tuples $a \in A$ such that the pair (a, b) can possibly satisfy $ed(lastword(a.Name), lastword(b.Name)) \leq 2$. We check if (a, b) indeed satisfies this predicate, and if yes, then output the pair. Many efficient string indexing techniques [36] can be used to implement SIM blockers. Recent work [8] has also discussed efficient techniques (e.g., using indexing and MapReduce) to execute rule-based blockers.

Accuracy of Blockers: Blocker accuracy is typically measured using recall, defined as follows:

Definition 2.1. [Blocker recall] Suppose applying blocker Q to two tables A and B produces the output C . Let $M \subseteq A \times B$ be the (unknown) set of true matches between A and B , then $recall(Q) = |M \cap C|/|M|$.

Due to dirty data, misspellings, natural variations, synonyms, missing values, etc., no single blocker type produces the highest recall on all datasets. In fact, on any particular dataset, blockers can vary drastically in recalls (e.g., 2.5-98.2% in our experiments).

Finding a blocker with high recall, however, is critical for many EM applications. Counter-terrorism EM applications often need very high coverage, i.e., finding *all* person descriptions that match, and thus want 100% blocking recall. Similar high-coverage examples arise in fraud detection, e-commerce, law, medicine, insurance, and pharmaceutical industry, among others. EM applications with inherently small numbers of matches naturally do not want the blocker to kill off many of these. Finally, EM applications often compute statistics over the matches (e.g., the percentage of patients attending both hospitals), which can be seriously distorted by blockers with low recall.

Limitations of State of the Art: As a result, the topic of blocker accuracy has received growing attention. Proposed solutions include combining multiple blockers to maximize recall (e.g., [12, 20, 22]), and using a sample of tuple pairs labeled as match/no-match to learn blockers with high recall [2, 8, 18, 25].

While promising, these solutions can still produce blockers with varying recalls, oftentimes falling short of 100%. For example, a recent work [8] shows that extensive manual effort to combine hash blockers achieves only 38.8% and 72.6% recall on two datasets. (Obviously we cannot combine *all* possible blockers as there are too many of them.) Another recent work [18] learns blockers using samples labeled by crowdsourcing, but achieves only 92% recall on a data set. In general, due to the difficulties in obtaining a good sample, sampling flukes, etc., today there is still no guarantee that a blocker learned on a *sample* provably achieves high recall when applied to the original tables.

Since there is still no “fool-proof” method to develop a blocker with high recall, it follows that given a blocker Q (either created manually or learned), it is still highly desirable to know how well Q does recall-wise, and what the possible problems are, so that we can improve it. MatchCatcher helps answer these questions, and thus can be considered *complementary* to the above solutions. For example, Section 6 describes a scenario where after the solution in [8] had been used to learn a blocker, we applied MatchCatcher to this blocker and uncovered multiple problems, which can be addressed to further improve the blocker recall.

Overview of MatchCatcher: As discussed, MatchCatcher addresses the following problem:

Definition 2.2. [Finding killed-off matches] Let C be the output of applying blocker Q to tables A and B . Then $D = A \times B - C$ is the set of all pairs killed off by Q . Help the user quickly find as many true matches as possible in D (without materializing it). Examining these matches helps the user understand how well Q does recall-wise, and what can be done to improve its recall.

Figure 2 shows the architecture of MatchCatcher. Given two tables A and B , the Config Generator examines the two tables to generate a set of configs, each of which is a set of attributes (e.g., $\{Name, City\}$). For each config g , the Top-k SSJs module performs a top-k string similarity join to find the k tuple pairs that (a) have the highest score with respect to the attributes in g , and (b) are killed off by blocker Q . Note that to check Condition

Figure 2: The MatchCatcher architecture

(b), this module does not need to know Q . It only needs to know C , the output of applying Q to A and B . Hence MatchCatcher works independently of the blocker type.

The Top- k SSJs module sends all top- k lists (one per config) to the Match Verifier. This module uses a rank aggregator to combine the lists into a single global list, shows the top n pairs to user U , asks U to identify true matches, uses this feedback together with active and online learning to rerank the pairs, and so on, until U is satisfied or a stopping condition is met. U can examine the true matches to understand how well blocker Q does recall-wise, and to obtain explanations for why these matches are killed off. This helps U decide if Q should be revised, and if so, then how. The next few sections describe MatchCatcher in detail.

3 GENERATION OF CONFIGURATIONS

We now describe the Config Generator, which outputs a set of configs, each being a set of attributes. We cannot consider all possible configs, so the key challenge is to select a good subset of configs. We show how to do so, by carefully managing attributes with many missing values, few unique values, or long string values.

3.1 How Configurations Are Used

We first motivate the notion of configurations (or “configs” for short) and explain how they are being used. Later we build on this to discuss how to select a good set of configs.

Recall that we want to quickly search $D = A \times B - C$, the set of tuple pairs killed off by blocker Q , to find pairs that can be matches. This raises three problems. First, D is not materialized, we only have A , B , and C . Second, even if D is materialized, it would be too large to search quickly. Finally, we do not even know what to search for, since at this point MatchCatcher does not know what a match is (only the user knows).

To address these problems, we begin by assuming that tables A and B share the same schema S (extending MatchCatcher to the case of different schemas is future work). We observe that matching tuples tend to share similar values in a set of attributes, say g (e.g., $\{Name, City\}$). So we want to quickly find tuple pairs in D that share similar values for g and return those as possible matches.

To do so, we convert each tuple a in A into a string $str_g(a)$ that concatenates the values of all attributes in g . For example, if a is (David Smith, Atlanta, 43) and $g = \{Name, City\}$, then $str_g(a)$ is “David Smith Atlanta”. This converts Table A into a set A_g of such strings. We convert Table B into a set B_g of strings similarly.

Let $h(x, y)$ be a string similarity measure which computes a score in $[0, 1]$ between two strings x and y . Examples of such measures are Jaccard, cosine, overlap, edit distance, etc. [36]. Then next we perform a top- k string similarity join (SSJ) between A_g and B_g to find the k tuple pairs in $A \times B$ with the highest $h(x, y)$ score. Techniques have been developed to quickly perform top- k

SSJs [34, 37]. Of course, our goal is not to find pairs in $A \times B$, but rather in $D = A \times B - C$. We can modify the above techniques slightly to ensure this, by dropping a found pair if it is in C . We then return the k pairs in D with the highest $h(x, y)$ score as possible matches.

The above procedure does not require a materialized D , only tables A , B , and C (the output of blocker Q). It can quickly search D using a modified version of top- k SSJs to return possible matches. Of course, at this point we still do not know if these are indeed matches. But later we can work with the Match Verifier to quickly shift through them to find true matches, if any. We now discuss several important aspects of the above procedure.

Why Concatenating the Attributes? We can use a variety of methods to find tuples that share similar values for attributes in g , e.g., finding pairs that share similar values for *each* attribute in g , then taking their intersection, say. However, given the interactive nature of debugging, we want this step to be as fast as possible. Hence we decide not to treat the attributes in g separately, but concatenate all of them into a single string, then compare them using SSJs. Section 4 shows that this method can quickly search a very large set D . But a drawback is that we can return *false positives* such as tuple pair (Jim Madison, Smithville, 32) and (Jim Smith, Madison, 32), because their concatenated strings are very similar given certain similarity measures. Such false positives, however, can be “weeded out” in the Match Verifier, using user feedback and active/online learning (see Section 5).

Which String Similarity Measure to Use? Given that similar attribute values can still vary significantly (e.g., “Dave Smith” vs “David Frederic Smith”), measures that treat strings as sets (e.g., Jaccard, cosine, etc.) typically work better than those that treat strings as sequences of characters (e.g., edit distance) [9]. So for MatchCatcher, we use the well-known Jaccard measure that tokenizes two strings x and y into two sets of words P_x and P_y , then returns $|P_x \cap P_y| / |P_x \cup P_y|$ [34]. However, Theorem 4.2 shows that our solution can also work with other set-based similarity measures, namely overlap, cosine, and Dice [34].

Why Multiple Configurations? So far we have used just one config g to find match candidates. Using multiple configs, however, can produce more matches. For example, config $\{Name, City\}$ may not return the pair (David Smith, Seattle) and (Dave Smith, Redmond) because the cities are different. Config $\{Name\}$ however can. Conversely, config $\{Name\}$ may not return the pair (Chuck Smith, San Francisco) and (Charles F. Smith, San Francisco) because the names are too different, but config $\{Name, City\}$ can. Together, these two configs can return more matches than either of them in isolation. Generating a good set of configs however is a major challenge, which we address next.

3.2 Generating Multiple Configurations

As a baseline, we can use all subsets of attributes in S (the schema of A and B) as configs. But this generates too many configs even for a moderate size (e.g., $|S| = 8$ produces $2^{|S|} - 1 = 255$ configs). We cannot use all of them because the total SSJ time would be too high. So we must select a smaller set of configs.

To do so, we select a set of promising attributes in S , then use them to generate configs, in a top-down fashion. In each step of the process, we select which configs to generate next by carefully considering the impact of attributes with many missing values, few unique values, or long string values. The end result is a *config tree* consisting of multiple configs. Later the Top- k SSJs module

Figure 3: An example of generating config trees.

will traverse this tree to perform top-k SSJs on the configs in a joint fashion. We now elaborate on these steps.

Selecting the Most Promising Attributes: We first classify attributes in S as string, numeric, categorical, and boolean, using a rule-based classifier. Next, we drop numeric attributes (e.g., Salary, Price) because matching tuples still often differ in their values (e.g., the same product having different prices). Finally, we drop categorical and boolean attributes whose appearances in tables A and B are different. For example, if Gender has values $\{Male, Female\}$ in A but $\{M, F, U\}$ in B , then we drop it as these two sets share no value (in general if the Jaccard score of these two sets is less than a pre-specified threshold then we drop the attribute). The remaining attributes are string, or categorical/boolean but with similar sets of values. We return these as T , the set of the most promising attributes to be used for config generation. (Of course, the user can also manually curate schema S to generate T . The experiments in Section 6 however do not involve any manual curation.)

Generating a Config Tree: Given the set T of promising attributes, we generate a *config tree* in a top-down fashion, then return all configs in the tree. Specifically, we start with T as the config at the root of the tree. Next, we “expand” this node by removing each attribute from T to obtain a smaller config of size $|T| - 1$. This produces $|T|$ new configs, which form the nodes at the *next level* of the tree. We then select just one node at this level to “expand” further, and so on (we will discuss how to select shortly). This continues until we have reached configs of just one node. Figure 3.a shows an example config tree, assuming $T = \{n, c, s, d\}$ (which stand for Name, City, State, and Description, respectively).

Intuitively, this strategy ensures that we generate a diverse set of $|T|(|T| + 1)/2$ configs of varying size $|T|, |T| - 1, \dots, 1$. The config tree will also be used to guide the joint execution of top-k SSJs on the configs (see Section 4.2). We now turn to the challenge of how to select a node to expand in the config tree.

Managing Many Missing Values and Few Unique Values: Consider again the config tree in Figure 3.a. Suppose we are currently at the second level of the tree, and need to select one node among the four nodes csd , nsd , ncd , and ncs , to expand. This selection is equivalent to *selecting an attribute to exclude from subsequent config generation*. Indeed, if we exclude attribute s , then we select node ncd to expand (as shown in the figure). Otherwise if we exclude d , then we select the rightmost node ncs to expand, and so on.

So which attribute should we exclude? We observe that if an attribute has many missing values, then keeping it for subsequent config generation is not desirable, because we will end up with configs that produce similar top-k lists. For example, suppose we have selected config ncd to expand (as shown in Figure 3.a), and suppose that d has many missing values, then many strings for config ncd and config nc will be identical, potentially leading to similar top-k lists. In the extreme case, if all values for d are

Figure 4: Examples of tuples with long string attributes.

missing, then these two top-k lists are identical. Clearly, we want different configs to produce substantially different top-k lists, to avoid redundant work and to maximize the number of matches we can retrieve.

Another observation is that if an attribute has more unique values than another, e.g., c vs s (which stand for City and State, respectively), then it is better to exclude s , the one with fewer unique values, because intuitively, if two tuples agree on c , they are more likely to match than if they agree on s , all else being equal. Thus, to maximize the number of matches we can retrieve, we should strive to keep the “more specific” attributes, i.e., the ones with more unique values.

Combining the above two observations, we define the *e-score* (shorthand for “expected benefit”) of an attribute as follows:

*Definition 3.1. [E-score of an attribute] Let $n_A(f)$ be the ratio of the number of non-missing values of attribute f in A over the number of tuples in A , and $u_A(f)$ be the ratio of number of unique values of f in A over the number of non-missing values of f in A . We define $n_B(f)$ and $u_B(f)$ similarly. Define $e_A(f) = 2n_A(f)u_A(f)/[n_A(f) + u_A(f)]$ and define $e_B(f)$ similarly. Then we define the *e-score* of attribute f as $e(f) = e_A(f)e_B(f)$.*

We then select the attribute with the lowest *e-score* to exclude at each level of the config tree. For example, suppose $e(n) > e(d) > e(c) > e(s)$. Then at the second level of the tree in Figure 3.a, we exclude attribute s , which means selecting node ncd to expand. At the third level of the tree, we exclude c , which means selecting node nd to expand.

Managing Long String Attributes: Many datasets contain attributes with long string values, e.g., Comment, Desc, etc. Figure 4 shows two tuples where attribute Desc has such long values. Such long attributes can cause two problems. First, they can cause multiple configs to generate very similar top-k lists.

Example 3.2. Consider again the config tree in Figure 3.a. Suppose attribute d has long string values (such as those shown in Figure 4). Then all seven configs involving d can generate similar top-k lists because the long values of d “overwhelm” the short values of the remaining attributes. So when moving from a config involving d to another (e.g., from ncd to nd), the strings do not change much, and therefore their similarity scores also do not change much (we formalize this notion below), leading to similar top-k lists.

The second problem is that if the long string values are different for matching tuples, then a config involving this long attribute will fail to return the match. For example, the two tuples in Figure 4 match, but any config involving attribute Desc will not return this match, because the values for Desc here are very different, and so the score between the two tuples will be low.

To address this, we modify our config-tree generation procedure as follows. Suppose we need to select a config node in the tree to expand. Before, we select $g_{default}$, the one without the attribute with the smallest *e-score*. Now, we first run a procedure FindLongAttr to see if there is any attribute that is “too long” (i.e., likely to adversely affect selecting good configs). If such an

Figure 5: Finding attributes judged too long.

attribute f_{long} exists, then we select the config without f_{long} to expand. Otherwise we select $g_{default}$, as usual.

Example 3.3. Consider again Figure 3.a, which shows the “default” config tree with root $ncsd$. To handle long attributes, once we are at the second level, we do not automatically select ncd (the config without s , the attribute with the smallest e -score) for expansion. Instead, we run FindLongAttr at this level. Suppose it returns d (thus judging d to be too long). Then we select ncs , the config without d , for expansion. This produces new configs cs , ns , and nc (see Figure 3.b). Suppose running FindLongAttr at the level of these new configs returns no attribute. Then we select config nc (the config without s , the attribute with the smallest e -score) for expansion (see Figure 3.b).

We now explain procedure FindLongAttr. The key challenge is to formalize what it means to be “too long”. Let p be a node in the config tree. Suppose that when running the default config generation procedure (the one that does not consider long attributes), we end up selecting q , a child node of p , for expansion, and that we eventually generate a subtree T_q rooted at q (see Figure 5.a).

We say that an attribute f is too long if it “overwhelms” many config nodes in subtree T_q , specifically if it overwhelms at least half of the configs in $F(T_q)$, the set of configs in T_q that contain f . In turn, we say that f overwhelms a config $r \in F(T_q)$ (see Figure 5.a) if the top- k list obtained from config r is “roughly the same” as the top- k list obtained from config q (we formalize this below). Intuitively, we want to avoid such cases, because we want each config to return a different top- k list, to maximize the number of true matches that we will find. So if we find that f overwhelms at least half of the configs in $F(T_q)$, then we judge f to be too long and should be removed. That is, instead of selecting q for expansion, we will select the config (in the same tree level as q) that does not contain f .

Of course, we do not have access to the top- k lists of r and q . So we develop a condition which if true would suggest that the two lists are “roughly the same”. Specifically, let $sim_g(a, b) = h(str_g(a), str_g(b))$ be the string similarity function between the string values of two tuples a and b , for config g . Suppose that for all tuple pairs (a, b) in $D = A \times B - C$ we have

$$\text{Condition 1: } |sim_q(a, b) - sim_r(a, b)| / sim_q(a, b) \leq \alpha,$$

for a small pre-specified α value, say 0.2. Then we can say that when we switch config from q to r , the score of each tuple pair does not change much, so the top- k list for r will stay roughly the same as that of q .

Checking Condition 1 for all pairs (a, b) in D is not feasible. Hence we perform a theoretical analysis for an idealized scenario (described below). Of course, this idealized scenario rarely happens in practice. But understanding it helps us come up with an efficient heuristic to check Condition 1.

Let $L_f(a)$ be the length (i.e., the total number of words) of attribute f in tuple a , $L_q(a)$ be the sum of the lengths of all attributes in q , for tuple a , and so on. The idealized scenario

assumes that (a) attribute f takes the same proportion of the total length of q in both a and b , i.e., $L_f(a)/L_q(a) = L_f(b)/L_q(b) = \beta$, and (b) the remaining length of q is equally distributed among the remaining attributes of q , i.e., $L_k(a) = [(1-\beta)L_q(a)]/(|q|-1)$ for all attribute k in $q - \{f\}$, and the same condition applies to tuple b .

Example 3.4. Consider the two tuples a and b in Figure 5.b, where $q = \{u, v, w, f\}$ and $r = \{w, f\}$. We assume that $L_f(a)/L_q(a) = L_f(b)/L_q(b) = \beta$, and $L_u(a)/L_q(a) = L_v(a)/L_q(a)$ and $L_u(b)/L_q(b) = L_v(b)/L_q(b)$.

Then we can show that (see [24] for a proof sketch):

THEOREM 3.5. Let $a \in A$ and $b \in B$ be two tuples that satisfy the above assumptions. If

- (R_1) $sim_q(a, b) \geq [\sqrt{(1+\alpha)^2 + 8} - (1+\alpha)]/4$, and
- (R_2) $\beta \geq 1 - \frac{(|q|-1)}{|q \setminus r|} \cdot \frac{\alpha}{(1+\alpha)} \cdot \frac{\max\{L_q(a), L_q(b)\}}{L_q(a)+L_q(b)}$,

then pair (a, b) satisfies Condition 1.

Intuitively, this theorem says that if $sim_q(a, b)$ is sufficiently high (Requirement R_1), and attribute f is sufficiently long (Requirement R_2), then $sim_r(a, b)$ will be close to $sim_q(a, b)$. It is not difficult to show that the quantity on the right-hand side of R_1 is upper bounded by 0.5. In practice, we observe that users typically examine only the top few tens of pairs in each top- k list (see Section 5), and that if these pairs are true matches, their scores often exceed 0.5, making R_1 true. As a result, if R_2 is also true, then attribute f is long enough to “overwhelm” these pairs. That is, these pairs will change little score-wise when switching from config q to r , thus typically will still show up in the top few tens of pairs of the top- k list for r , an undesirable situation.

To avoid such situations, we will focus on checking R_2 . Checking R_2 for many pairs (a, b) is not practical. So we approximate this checking using average lengths, i.e., we (a) replace β in the left-hand side of R_2 with $\min\{AL_f(A)/AL_q(A), AL_f(B)/AL_q(B)\}$, where $AL_f(A)$ for example is the average length of attribute f in Table A, and (b) replace $L_q(a)$ and $L_q(b)$ in the right-hand side of R_2 with $AL_q(A)$ and $AL_q(B)$, respectively.

Procedure FindLongAttr then works as follows. Suppose we have selected config q for expansion (because it does not contain s , the attribute with the least e -score). Then for each attribute f (other than s), we (a) identify $F(T_q)$, the set of configs in T_q that contain f , (b) declare f “too long” if the above approximate checking is true for at least half of the configs $r \in F(T_q)$. It is not difficult to prove that at most one attribute f will be found too long. If so, we do not select q , but select instead the config that does not contain f for expansion. Otherwise, we select q , as usual. This procedure takes less than a second in our experiments.

Discussion: Note that we do not completely remove attributes with many missing values, few unique values, or long values from config generation. Instead, each such attribute f may be removed only at some point during the generation process. Configs generated earlier still contain f .

Further, our work here is related to, but very different from work such as [3, 10]. Those works find attributes that are discriminative for classification, often using a labeled sample (as many works in learning do). Here we do not look for discriminative attributes. Instead, we look for attributes such that if two tuples agree on their values, then they are likely to match. For example, suppose all tuples in table A have the same value “US” for “Country”, and all tuples in table B have the same value “Canada”.

Then “Country” is a discriminative attribute because if two tuples disagree on it, they definitely do not match. For our purpose, however, “Country” has little expected benefits, because if two tuples agree on it, it is still not likely that they match (not as much as if they agree on “State” and “City” say).

In fact, the work [29] also treats attributes with missing values and few unique values in a way similar to ours (for blocking and matching). However, it does not handle long attributes, and uses only one config, and thus is significantly outperformed by MatchCatcher (see Section 6).

4 TOP-K STRING SIMILARITY JOINS

So far we have discussed generating a set of configs. We now discuss performing top-k SSJs over these configs (one per config). Previous work has discussed top-k SSJs for a single config [34]. Here we significantly improve that work (and our solution can be applied to top-k SSJ situations beyond this paper). We then discuss executing multiple top-k SSJs jointly, by reusing results across the configs, in a parallel fashion.

MatchCatcher currently works with the Jaccard string similarity measure, and we will explain it using that measure. However, it is important to note that all algorithms discussed below also work with the set-based similarity measures cosine, overlap, and Dice.

4.1 Improving Top-k Join for a Single Config

As far as we can tell, the state of the art in top-k SSJs is TopKJoin [34]. Given a set J of strings, TopKJoin finds the k string pairs with the highest similarity scores, for a pre-specified k , in a branch-and-bound fashion. Specifically, it maintains a prefix for each string in J , incrementally extends these prefixes, finds string pairs whose prefixes overlap, computes their similarity scores, use these scores to maintain a top-k list, then extends the prefixes again, and so on.

Example 4.1. Suppose J consists of the four strings w, x, y, z in Figure 6.a. We begin by creating a prefix $p(w) = “a”$ for w , then a prefix $p(x) = “a”$ for x . At this point the prefixes of the pair (x, w) overlap. Hence we compute the Jaccard score 0.8 for this pair, then initializes the top-k list K to be containing just this pair. (Here we assume $k = 2$.)

Next, we create prefix $p(y) = “b”$. This does not produce any new pair whose prefixes overlap. So we continue by creating prefix $p(z) = “b”$. This produces a new pair whose prefixes overlap: (z, y) with score 0.43. Figure 6.b shows the updated top-k list K .

Next, we select one prefix to extend (we will discuss shortly how). Suppose we select $p(x)$ and extend it by one token. Then $p(x) = “ab”$ (see Figure 6.a). This produces two new pairs whose prefixes overlap: (x, y) with score 0.67 and (x, z) with score 0.43. Figure 6.c shows the updated top-k list K . We then select another prefix to extend, and so on. Finding new pairs with overlapping prefix can be done efficiently using an inverted index from token to the prefixes of the strings [34].

We now discuss how to select a prefix to extend. Suppose we have imposed a global ordering on all tokens, and sorted the tokens in each string w, x, y, z in that order (see Figure 6.a). Suppose also that we have created prefixes of size 1, namely $p(w) = “a”, p(x) = “a”, p(y) = “b”, p(z) = “b”$, and are now deciding which prefix to extend. Suppose we select $p(w)$ and extend it by one token, to be “ab”. Then it is easy to show that the scores of all new pairs generated by this extension are capped by 0.75. Indeed, any new pair must involve w . Let such a pair

Figure 6: An illustration of top-k computation.

be (w, v) . Then the first common token that they share should be “b” (the token just being added to $p(w)$). So they can share at most this token b and the remaining “unseen” tokens of w . Thus $|w \cap v| \leq 3$. Since $|w \cup v| \leq |w| = 4$, it follows that the Jaccard score of (w, v) is capped by $3/4=0.75$. We write 0.75 on top of token “b” in w to indicate that when we extend $p(w)$ to include this token, the score of any new pair generated by TopKJoin will be capped by 0.75. Similarly, we can write 0.8 for the second tokens of x, y, z (see Figure 6.a).

We then select the prefix that when extended will include the token with the highest “cap” number (in the hope that it will generate new pairs with the highest possible scores). In this case, we select $p(x)$ (but $p(y)$ and $p(z)$ also work).

We now discuss how to stop. Observe that the “cap” number for “c” in x is 0.6. By the time we have to consider whether to extend $p(x)$ to include “c”, the top-k list already has a lower-bound score of 0.67 (see Figure 6.c), greater than 0.6. As a result, we do not have to extend $p(x)$ to include “c”, and in fact, prefix extension on x can be stopped at this point. TopKJoin terminates when all prefix extensions have stopped, either early (as described above) or because the prefix has covered the entire string. The paper [34] describes TopKJoin in detail, including optimizations to avoid redundant computations.

The QJoin Algorithm: TopKJoin has a major limitation. Every time it generates a new pair (u, v) , it immediately computes the similarity score of (u, v) (then updates the top-k list). Computing this score turns out to be very expensive, especially if u and v are long strings. In a sense, it is also “premature”, because it can be shown that when we generate (u, v) (as a new pair), we only know that they share a single token. There is no evidence yet that they share more tokens and thus are likely to have high similarity score. If they indeed share only one or few tokens, and yet we still compute their score, then that score is likely to be low. So the pair will not make it into the top-k list, yet we have wasted time computing its score.

To address this problem, when generating new pairs, we do not immediately compute their scores. Instead, we keep track of the number of common tokens each pair has, and update this number whenever a prefix is extended. We then compute the score of a pair only if it has q common tokens, and thus is likely to have a high score. It is difficult to select q analytically, so we select it empirically as follows. Assuming at least four CPU cores, we begin by running the modified TopKJoin for $q = 1, q = 2$, etc., on all cores, one q value for each core, for $k = 50$. (Note that TopKJoin always does $q = 1$.) Then whichever core finishes first, we keep the process on that core running to produce the rest of the top-k list (effectively selecting the q value associated with that core), and kill the processes on the other cores.

It is straightforward to adapt the above algorithm to work with two tables (instead of just one), and to remove a pair from the top-k list (during the top-k computation) if it happens to be in the candidate set C . Henceforth we refer to this new algorithm as QJoin.

Figure 7: Reusing across top-k computations.

4.2 Joint Top-k Joins Across All Configs

TopKJoin can only be applied to a single config [34]. Our setting however involves multiple related configs. We now describe a solution to find top-k lists *jointly across the configs*. To do so, we use QJoin, but modify it to reuse similarity score computations and top-k lists across the configs, and process the configs in parallel.

Reusing Similarity Score Computations: As discussed in Section 4.1, computing the similarity score of a pair (a, b) is very expensive, especially for long strings. Hence, we want to reuse such computations across the configs. To do so, we process the configs in the config tree in a breadth-first order, e.g., processing the root config $f_1f_2f_3$ of the config tree in Figure 7 (where the f_i -s are attributes), then the next-level configs, f_2f_3, f_1f_3, f_1f_2 , and so on.

When processing a config g (i.e., finding its top-k list), we keep track of certain information, then reuse it when processing configs in the subtree of g . For example, consider again the config tree in Figure 7. We start by tokenizing the strings wrt the root config $f_1f_2f_3$ into multisets of word-level tokens. Next, we process the config $f_1f_2f_3$. This process computes the Jaccard score of multiple tuple pairs. When computing the score of such a pair, say (a, b) , we compute and store the number of overlapping tokens between any two attributes f_i of a and f_j of b in an in-memory database H . Figure 7 illustrates this step. Here, $o(f_1, f_1) = 2$ means attributes f_1 of a and f_1 of b share two tokens. (We only store in H attribute pairs that share tokens.)

Then we can reuse H to drastically speed up processing configs in the subtree rooted at $f_1f_2f_3$. For example, consider processing config f_1f_2 . If during this process we need to re-compute the score of (a, b) (now with respect to only f_1 and f_2), then we can use H to compute $Overlap_{f_1f_2}(a, b) = o(f_1, f_1) + o(f_1, f_2) + o(f_2, f_1) + o(f_2, f_2)$, then compute the above score as

$$Overlap_{f_1f_2}(a, b) / (L_{f_1f_2}(a) + L_{f_1f_2}(b) - Overlap_{f_1f_2}(a, b)),$$

where $L_{f_1f_2}(a)$ for instance is the length in tokens of the concatenation of f_1 and f_2 for a . Computing the score of (a, b) this way is far faster than computing from scratch.

Note that while processing config f_1f_2 , if we have to compute the score of a new pair (c, d) not yet in H , then we will store similar overlap information for (c, d) in H , to enable reuse when processing configs in the subtree rooted at f_1f_2 , and so on.

Reusing Top-k Lists: When applying to a config g , algorithm QJoin starts with an empty top-k list K , then gradually grows K as it iteratively expands the prefixes. In our setting, however, since we process multiple configs, a promising idea is to use the top-k list of a previous config to initialize the top-k list of the current config.

For example, after processing config $g = f_1f_2f_3$ (Figure 7), we store its top-k list K_g . Then when processing config $h = f_1f_2$, we use the database H described earlier (which stores overlap information) to re-adjust all scores in K_g . This is necessary because these scores are computed wrt $f_1f_2f_3$, but now we want

them to be adjusted to consider only f_1f_2 . This re-adjustment is fairly straightforward (and inexpensive) because the overlap information for all pairs in K_g should already be in H . Next, we run the algorithm QJoin as usual to process config $h = f_1f_2$, but using the K_g list with the adjusted scores as the initial top-k list K_h (instead of using an empty list).

Observe that the above procedure enables reusing top-k lists from a parent to a direct child (e.g., from $f_1f_2f_3$ to f_1f_2). Reusing across the “siblings” appears much more difficult. For example, given the top-k list for f_1f_3 , there is no obvious way to quickly adjust its scores for f_1f_2 , using database H . Hence, currently we do not yet consider such sibling reuse.

Finally, reuse does not come for free. It helps avoid computing certain similarity scores from scratch, but incurs an overhead of storing and looking up the overlap information. If the tuples are short, then the overhead can easily overwhelm the savings. As a result, we trigger reuse only if the average tuple length is at least t tokens (currently set to 20).

Parallel Processing of the Configs: Finally we explore parallel processing on multiple cores. (We consider multicore single machines for now because it is a common setting for many domain science users [19].) An obvious idea is to process each config across multiple cores. For example, we can split Table A into two halves A_1 and A_2 and Table B into B_1 and B_2 , find the top-k list for A_1 and B_1 on the first core, the top-k list for A_1 and B_2 on the second core, etc., then merge the top-k lists. In practice, this approach suffers from severe skew: one core finishes quickly while another runs forever. While it is possible to split the tables intelligently to mitigate skew, this adds considerable overhead and implementation complexity.

As a result, we opted for processing one config per core. Specifically, we traverse the config tree breadth-first, and assign configs to cores in that order (when a core finishes, it gets the next config “in queue”). This solution *continuously utilizes all cores*. But it raises two problems. First, two configs (e.g., $f_1f_2f_3$ and f_1f_2) may concurrently write, or one reads and the other writes, into database H , causing concurrency control issues. To address concurrent writes, observe that only configs with non-empty subtrees (e.g., $f_1f_2f_3$ and f_1f_2 in Figure 7) will write. For each such config g , we require it to write into a separate in-memory database H_g .

To address dirty reads (e.g., $f_1f_2f_3$ writes into a database while f_2f_3 reads from it), we note that here each “write” just *inserts* a value; it never modifies or deletes. For such cases there are atomic hashmaps that perform *atomic inserts*, thus avoiding dirty reads. So we implement each database H_g as one such hashmap (using the Atomic Unordered Hashmap in Facebook’s C++ Folly package).

Finally, if a parent config, e.g., $g = f_1f_2f_3$, has not yet finished, then a direct-child config, $h = f_1f_2$, cannot reuse g ’s top-k list. In such situations, we start config h with an initial empty top-k list. When config g finishes, it sends its top-k list to h . Config h merges its current top-k list with the new top-k list from g , to obtain a potentially better top-k list, then continues. The technical report [24] shows the pseudo code of the complete algorithm, and the following theorem shows its correctness (see [24] for a proof sketch):

THEOREM 4.2. *Given two tables A and B , the output C of a blocker on A and B , a set of configs G , a string similarity measure which is Jaccard, cosine, overlap, or Dice, and a value k , the above algorithm returns a set of top-k lists, where each top-k list is the*

output of applying Algorithm QJoin to A, B , and C , using a config $g \in G$ and the given similarity measure and k value.

5 INTERACTIVE VERIFICATION

So far we have discussed processing configs to obtain a set of tuple pairs. We now discuss identifying true matches in this set, via user engagement, rank aggregation, and active/online learning.

Engaging the User: Let E be the union of the top- k lists obtained from processing all configs. Typically E is large (e.g., 3,011-7,089 in our experiments) and the true matches make up just a small portion of E . Thus expecting a user U to be able to examine the entire set E to find true matches is unrealistic.

A reasonable solution is to rank the pairs in E such that the true matches “bubble” to the top, then present the ranked list to U . However, our experiments with a variety of ranking methods (see below) suggest it is very difficult to do so. Typically, the top of the ranked list indeed contains multiple matches. But then the remaining matches tend to be scattered far and wide in the list.

As a result, we decided to engage user U : we rank the pairs in E , present the top- n pairs to U (currently $n = 20$), ask U to identify the true matches, use this feedback to rerank the list, then present the next top- n pairs to U , and so on. As such, we help U iteratively identify true matches, but use this identification to help “bubble” the remaining matches to the top of the ranking.

Using Rank Aggregation: Let m be the number of configs and L_1, \dots, L_m be the top- k lists obtained from these configs. To engage user U , we first need to aggregate these lists into a single list. Many aggregation methods exist, e.g., [4, 15]. Here we use MedRank [15], a popular method. To use MedRank, we first sort each list L_i in decreasing order of score, then associate each item in the list with a rank, i.e., an integer, such that the higher the score, the lower the rank and items with the same score receive the same rank. Next, we compute for each item a global rank which is the median of its ranks in the lists. Finally, we sort the items in increasing order of global rank, breaking ties randomly, to obtain a list L^* which is the aggregation of all top- k lists L_i -s.

Example 5.1. Figure 8 shows three top- k lists L_1, L_2, L_3 and the global list L^* . A line such as “a: 1.0 (1)” under L_1 means that item “a” in list L_1 has score 1.0 and has been assigned rank 1. The ranks for “a” is 1, 1, 2 (see Figure 8). So its global rank is 1. The ranks for “b” is 2, 4, 1 (here “b” is missing from L_2 , which has ranks 1-3; so we assign to it rank 4). Thus “b”’s global rank is 2. And so on.

Once we have obtained the global list L^* , we can present the top- n items of L^* to user U . But how do we incorporate the user feedback for the next iteration? A reasonable solution is to use weighted median ranking (WMR): we first assign an equal weight $w_i = 1/m$ to each top- k list L_i ($i \in [1, m]$). At the end of the first iteration, we adjust $w_i = w_i \cdot [1 + \log(1 + r_i)]$, where r_i is the number of true matches user U has identified that appear in L_i , then normalize all weights w_i . At the start of the next iteration, we merge the lists L_1, \dots, L_m again, using WMR to compute the global rank of each item. Next, we present the top- n pairs in this merged list to the user, and so on. Intuitively, the top- k lists in which more true matches appear will become more important, and the weighted global ranking will be “leaning toward” those lists.

Using Learning: WMR does not perform well in our experiments (see Section 6). It uses a very limited combination model

L_1	L_2	L_3	L^*
a: 1.0 (1)	a: 0.9 (1)	b: 0.8 (1)	a (1)
b: 0.8 (2)	c: 0.7 (2)	a: 0.5 (2)	b (2)
c: 0.8 (2)	d: 0.6 (3)	c: 0.3 (3)	c (2)
d: 0.6 (4)		d: 0.2 (4)	d (4)

Figure 8: Combining top- k lists using MedRank.

which fails to fully utilize user feedback. To address this, we explored active learning. Specifically, we iteratively show the next n items of L^* to user U , until we have obtained at least one match and one non-match. Suppose we have carried out t iterations, then this produces a set T of nt labeled items. We use T to train a random forest classifier F , use F to find n most informative items in L^* , show them to the user to label, add the newly labeled items to T , then retrain F , and so on.

Active learning alone however is not quite suited for our purpose. Its goal is to learn a good classifier as soon as possible. Hence it typically shows user U controversial items that it finds difficult to classify. But many or most of these items can be non-match. User U , however, wants to find many *true matches* as soon as possible (so that U can examine them to quickly understand the problems with the blocker).

The above two goals conflict. To address this problem, we adopt a hybrid solution. After we have obtained the training set T and trained a classifier F , as described above, for the next iteration, we show user U n items where $n/4$ items are the top controversial items chosen by F , as described above. The remaining $3n/4$ items however are those with the *highest positive prediction confidence*, where the confidence is computed as the fraction of decision trees in F that predict the item as a match. Intuitively, the first $n/4$ items are intended to help the active learner, whereas the remaining $3n/4$ items can contain many true matches, and are intended to help the user quickly find many true matches in the first few iterations.

After three such iterations, we stop active learning completely (judging that classifier F has received enough labeled controversial examples in order to do well), but continue the online-learning process with F . Specifically, in each subsequent iteration, we show user U the top n items with the highest positive prediction confidence, produced by F . Once these items have been labeled by U , we add them to the existing training set, retrain F , and so on.

When to Stop? A natural stopping point is when user U finds no new matches in 2 consecutive iterations. Of course, U can stop earlier or continue. If the required blocker recall is very high, U can continue for many iterations. Otherwise, U can stop after the first few iterations (because if these iterations contain many matches, then examining them often already reveals problems with the blocker, which U can then fix).

6 EMPIRICAL EVALUATION

We evaluated MatchCatcher in three ways. First, we experimented with a broad range of blockers that vary in recall, types, and complexity, representing blockers that users may write *at various points* during the blocker development process. We show that MatchCatcher works well with these blockers, thus can effectively support the users in the development process.

Second, we experimented with blockers that are either the best hash blockers manually developed or the best blockers automatically learned using a state-of-the-art solution. We show that even in these cases MatchCatcher can help uncover problems and improve the blockers.

Table 2: Blockers for the first set of experiments.

Finally, we asked real-world users in several data science classes, domain science projects, and at several organizations to use MatchCatcher. We show that MatchCatcher has proven highly effective in helping these users develop blockers.

6.1 Supporting Users in Developing Blockers

For this experiment we need “gold” matches, so we use the six datasets shown in the first six rows of Table 1. As far as we can tell, these datasets are the largest ones used in previous EM work for which “gold” matches are available. Here we created two versions of the Music dataset, Music1 and Music2, to ensure a diversity of size (from 331 to 100K to 500K of tuples per table). The technical report [24] describes these datasets in details.

For each dataset we asked volunteers to create multiple blockers (see Table 2). They are of the types described in Section 2: overlap (OL), hash (HASH), similarity-based (SIM), and rule-based (R). For example, the first row of Table 2 describes 4 blockers for dataset A-G. These include a hash blocker on attribute “manufacturer” and a rule-based blocker that combines two SIM blockers. See [24] for more details on these blockers. (The next subsection describes experiments with the best hash blockers manually created for these datasets.)

Developing a blocker is typically a *long process* in which users often start with a simple blocker, then revise it into more complex ones with higher recall. The above blockers differ in type, recall, and complexity, representing blockers that users may write at various points during the above process. We now show that MatchCatcher can help debug these blockers, suggesting that it can support the user during the entire development process.

Overall Accuracy: First we examine the top-k SSJs module. The first two columns of Table 3 list datasets and blockers. Column C lists the size of C , the output of the blocker on Tables A and B . Column M_D lists the number of true matches in $D = A \times B - C$. This number varies drastically, e.g., 137-1,267 for A-G, 87-566 for W-A, etc., suggesting that blocker recall often varies widely and that it is important to debug to improve recall.

Column E lists the size of E , the union of all top-k lists over the configs (for $k = 1000$). Column M_E lists the number of true matches in E (the numbers outside parentheses), and shows that set E contains a substantial fraction of true matches in D , e.g., 54-65% for A-G, 41-83% for W-A, 96-100% for A-D, etc. (see the

	Q	C	M_D	E	M_E	F	I

Table 3: Accuracy in retrieving the killed-off matches.

numbers in parentheses). This suggests that the top-k module can effectively find the true matches in D .

Next we examine the Match Verifier. We want to know its accuracy if run until its natural stopping point (see Section 5). It is difficult to recruit enough real users for this large-scale experiment involving 25 blockers. So we use synthetic users, whom we assume can identify the true matches accurately (we describe multiple experiments with real users below).

Column F of Table 3 show that this module can retrieve a large number of matches in E , e.g., 65-803 for A-G (see the numbers outside parentheses), and that the retrieval rate is very high, e.g., 70-98% for A-G, 77-91% for W-A, etc. (see the numbers inside parentheses). Finally, Column I shows that the total number of iterations is 5-13 in 12 cases, 16-40 in 8 cases, 47-61 in 4 cases, and 97 in 1 case. The higher number of iterations is often due to the larger number of matches that have to be retrieved from E , e.g., for blocker HASH of dataset A-G, the module needed 97 iterations to retrieve 803 matches, a reasonable number of iterations given that each iteration shows only 20 tuple pairs to the user.

Thus, if the user runs the Match Verifier until its natural stopping point, he/she can retrieve a large number of matches. This is good news for applications in which blocker recall is critical, thus the user may want to examine *all* matches that the module can retrieve.

Accuracy & Explanations for the First Few Iterations: To examine if users can quickly find many matches and explanations, we asked volunteers to *manually work with the Match Verifier for the first three iterations*. Table 4 shows the results (for space reasons we only list five blockers for five datasets, the results for other blockers are similar). The table shows that the user needed only 7-10 mins to examine the first three iterations, was able to identify a large number of matches (28-43), and was able to identify multiple reasons for why they are killed off (a reason such as “large threshold (18)” means that tuple pair #18 was killed off due to the blocker using a large threshold, and this was the first pair where the user observed this problem). Overall, the results suggest that after examining the first few iterations, the

Blocker	# iteration	Label time	Blocker problems
OL (A-G)	3 iterations 31 matches	8 mins	large threshold (18); attribute "manuf" is sprinkled in the attribute "title" (18)
HASH (W-A)	3 iterations 43 matches	10 mins	different words for the same brand (6); missing values in attribute "brand" (13)
SIM (A-D)	3 iterations 28 matches	7 mins	large threshold (16); attribute "title" contains subtitle in one table (22)
R (F-Z)	3 iterations 32 matches	7 mins	different descriptions for attribute "type" (11); unnormalized attribute "address" (33); attribute "city" is sprinkled in "name" (47)
R (M ₁)	3 iterations 41 matches	10 mins	input tables are not lower-cased (5); missing values in attribute "year" (12)

Table 4: Accuracy in the first 3 iterations and explanations. user can already identify multiple problems with the blocker (which he/she can then fix).

6.2 Debugging State-of-the-Art Blockers

Suppose a user has manually developed a good standard blocker, or has used state-of-the-art techniques to learn a blocker, we want to know if MatchCatcher can still help improve the blocker’s accuracy. Toward this goal, we performed two experiments.

Hash Blockers: First, we asked a user well-trained in EM to develop the best possible hash blockers for five datasets (the first five in Table 1). For example, for dataset A-G, this user created the blocker Q_1 which keeps a pair of tuples if they agree on “manufacturer” or on a hash of “price” or on a hash of “title”. Thus, Q_1 combines three hash blockers. ([24] describes all five blockers in details.) We selected hash blocking because it is well-known, easy to understand, and fast. Hence it is considered a standard blocking method commonly used in practice. On the five datasets A-G, W-A, A-D, F-Z, and Music1, the best hash blockers achieve 75.6, 95.1, 100, 97.3, and 100% recall, respectively.

We then asked the same user to use MatchCatcher to try improving the above hash blockers. For A-D and Music1, which already have 100% recall, using MatchCatcher the user did not find any killed-off matches (as expected), so debugging terminated early. For A-G, W-A, and F-Z, however, debugging significantly improved recall from 75.6 to 99.7, 95.1 to 99.6, and 97.3 to 100%, respectively. [24] describes one such debugging scenario in details.

Learned Blockers: From a group of researchers we obtained Papers, the dataset described in the last row of Table 1. For this dataset, they have applied the method in [8] to learn blockers using a sample labeled by crowdsourcing, and we were able to obtain three such blockers (learned on three separate samples). The technical report [24] describes these blockers, which are the best blockers that the learning method has found in a very large space of blockers, including hash ones. Unfortunately, we do not have the entire set of “gold” matches for Papers (we do have some “gold” matches, but not all of them). Hence, we are unable to report recalls for these blockers.

We then asked a user to apply MatchCatcher to these blockers. After 5 iterations, the user found 76, 61, and 65 matches for the three blockers, respectively. More importantly, the user was able to identify a set of reasons for why these matches were killed off and suggestions for improving the blockers (see [24]). Given the lack of “gold” matches, we were not able to improve the blockers then compare their recalls. Nevertheless, the above experiments suggest that blockers learned using state-of-the-art solutions can still have many problems and MatchCatcher can help pinpoint these, to help the user improve recall.

6.3 MatchCatcher “in the Wild”

Over the past two years variations of MatchCatcher have been used by 300+ students in 4 data science classes and 7 EM teams at

6 organizations. The feedback has been overwhelmingly positive. For example, 18 teams used MatchCatcher in a class project, and reported that it helped (a) discovering data that should be cleaned, (b) finding the correct blocker types and attributes, (c) tuning blocker parameters, and (d) knowing when to stop. We have reported on some of this experience in [23]. Overall, we found that many real-world users have used MatchCatcher as *an integral part of an end-to-end blocker development process*: start with a simple blocker, use MatchCatcher to identify problems, improve the blocker, and so on, until MatchCatcher no longer reports substantial problems with the blocker.

6.4 Runtime & Scalability

MatchCatcher was implemented in Cython, and all experiments used a RedHat 7.2 Linux machine with Intel E5-1650 CPU. The top-k module took 6.6-9.4 secs (for dataset A-G), 97-310 (W-A), 2.8-3.2 (A-D), 0.2 (F-Z), 12.1-24.4 (M₁), 57-230 (M₂), and 65-344 (Papers), respectively. For the first five datasets, these times are quite small except 97-310 secs for W-A. On W-A, the k-th pair on the top-k list (recall that $k = 1000$) often has a very low score, e.g., 0.21-0.225. Thus the top-k module took more time. The last two datasets (M₂ and Papers) are much larger (500K tuples per table), and so took longer to run. In all cases, however, the total time is still under 5.8 minutes.

To examine how the top-k module scales, we measure its time as we vary the size of the two largest datasets, M₂ and Papers, at various percentages of the original datasets (which have 500-600K tuples per table). Figure 9 shows the results for the first three blockers in Table 3 for M₂ and all three blockers for Papers, for $k = 100$ (the left two plots) and $k = 1000$. The results show that the top-k module scales linearly or sublinearly as the table size grows. Finally, on all datasets the Match Verifier took under 0.1 sec to aggregate the top-k lists, and 0.14-0.18 secs to process user feedback in each iteration.

6.5 Additional Experiments

The technical report [24] describe extensive experiments on the performance of the MatchCatcher components, sensitivity analysis, and comparison with a recent related work. For space reasons we only briefly summarize those experiments here.

Performance of the Components: We show that using multiple configs instead of just one config significantly increases the number of retrieved matches, by 10-74%. Handling long attributes increases the recall of E (the fraction of matches in D that are in E) by up to 11%, compared to not handling them in config generation. Our experiments also show that the joint top-k processing strategy over multiple configs significantly outperforms the baseline of executing each config individually, by as much as 3.5 times. Finally, we found that active/online learning significantly outperforms weighted median ranking in the Match Verifier.

Sensitivity Analysis: We found that increasing k (the number of pairs retrieved per config) does increase the number of true matches retrieved, but only up to a certain k , and comes at the cost of higher runtime, and that using 3 active learning iterations (as we currently do) provides a good balance between increasing the classifier accuracy and increasing recall in the Match Verifier.

Comparison with Recent Work: We found MatchCatcher significantly outperforms the work in [29], which uses a single config, e.g., improving the recall of E by 26-47% on the A-G dataset.

Figure 9: Runtime of top-k module for varying table sizes.

7 ADDITIONAL RELATED WORK

We have discussed related work throughout the paper. We now discuss additional related work. As far as we can tell, our recent work [23] is the first to raise the need for debugging for blocking. But that work focuses on developing end-to-end EM systems. It does not discuss any debugging solution in depth, as we do here. Other related works include debugging for data cleaning [17], schema mapping [5], and data errors in spreadsheets [1]. They do not address EM and their solutions do not apply to our context. But they do underscore the importance of debugging for data integration and cleaning.

SSJs have received much attention, e.g., [21, 35] (see [36] for a survey). Top-k SSJs are studied in [34, 37]. [37] proposes a B+ tree based index to scale top-K SSJs on edit distance. It does not work well for datasets with large textual difference [36], however, a common occurrence in our case. The work [34], which uses prefix filtering to find the top-k pairs, is better suited to our case. But it does not handle long strings well [36]. Here we have significantly improved this work and extended it to work over multiple configs.

The idea of computing the similarity score of a string pair only if their prefixes share at least q tokens (see Algorithm QJoin in Section 4.1) is also discussed in [32]. That work however focuses on SSJs with thresholding, e.g., matching two strings x and y if $jaccard(3g(x), 3g(y)) \geq \alpha$. Its solution uses threshold α to find the optimal q , and is not applicable to the top-k context considered in this paper (which has no threshold α).

The work [27] describes a blocking method that performs a variation of weighted overlap blocking to find tuples that are highly similar string-wise. MatchCatcher however does not use this method in top-k SSJs because it is not clear how to modify it to enable reuse (among the different configs). The work [16] is related to our work on config generation in that it defines the notion of matching dependencies, using which we can deduce a set of attributes for comparing tuple pairs. However, it is not applicable to our context because it requires the user to manually specify matching dependencies, using domain knowledge, in a potentially time consuming process.

Rank aggregation has been studied extensively in the database/IR communities, e.g., [4, 11, 15]. Active learning (AL) for EM has been studied in [18, 26, 28]. But they perform extensive AL to learn an accurate matcher. In contrast, we use only a few AL iterations to learn a classifier with reasonable accuracy, then use it to surface matches for debugging purposes. The above work also does not combine AL with online learning as we do. Finally, the work [31] uses a learning-based UI model similar to ours, but for IR tasks.

8 CONCLUSIONS & FUTURE WORK

We have shown that debugging blocker accuracy is critical for EM, and have described MatchCatcher, a solution to this problem.

As for future work, in certain cases the user may find a large number of killed-off matches. So we plan to develop a method to automatically explain why each match is killed off by the blocker, summarize these explanations, then present the summary to the user. When fixing a problem affecting a killed-off match, the user may want to know how pervasive this problem is (and focus on fixing the most pervasive ones first). For this purpose, given a killed-off match, we plan to develop a method to find all tuple pairs that are similar to that match (from a blocking point of view).

ABSTRACT

This paper presents a multiscale visibility graph representation for time series as well as feature extraction methods for time series classification (TSC). Unlike traditional TSC approaches that seek to find global similarities in time series databases (e.g., Nearest Neighbor with Dynamic Time Warping distance) or methods specializing in locating local patterns/subsequences (e.g., shapelets), we extract solely statistical features from graphs that are generated from time series. Specifically, we augment time series by means of their multiscale approximations, which are further transformed into a set of visibility graphs. After extracting probability distributions of small motifs, density, assortativity, etc., these features are used for building highly accurate classification models using generic classifiers (e.g., Support Vector Machine and eXtreme Gradient Boosting). Thanks to the way how we transform time series into graphs and extract features from them, we are able to capture both global and local features from time series. Based on extensive experiments on a large number of open datasets and comparison with five state-of-the-art TSC algorithms, our approach is shown to be both accurate and efficient: it is more accurate than Learning Shapelets and at the same time faster than Fast Shapelets.

1 INTRODUCTION

Time series data refer to sequences of data that are ordered either temporally, spatially or in another defined order. They can be frequently found in a variety of domains, including financial data analysis, medical and health monitoring and industrial automation applications. Recently, it turns out to be feasible to model software systems as time series in order to conduct malware detection and classification [40]. Due to their wide application scenarios and abundance, there has been an increasing need for efficient knowledge discovery methods to extract useful information from time series databases. One of the major tasks in time series mining is time series classification (TSC), which consists of applying a learning algorithm on labeled data to train a model that will then be used to predict the classes of samples from an unlabeled data set. Due to the sequential characteristic of time series data, state-of-the-art classification algorithms (such as SVM and Random Forest [13]) that perform well for generic data are generally not suitable for TSC. It is thus important and beneficial

to have a feature extraction mechanism that transforms the sequential characteristics of time series data into unordered feature vectors, so that any modern classification algorithm can be taken advantage of. After all, one of the most challenging aspects of TSC lies in the sequentiality property.

Traditionally, researchers often rely on one of the simplest classifiers for TSC: the k Nearest Neighbor (k NN) algorithm. As stated in [6], “all of the current empirical evidence suggests that simple nearest neighbor classification is very difficult to beat”. To perform well, k NN classifiers leverage the Dynamic Time Warping (DTW) [7] distance which mitigates problems caused by distortion in the time axis. One intrinsic issue with DTW, however, is that it focuses on finding *global* similarities, i.e., the overall curve *shape* of time series. It also requires applications to specify a proper warping window size or to properly align data samples. As a result, DTW can be sensitive to data alignment/segmentation and it performs better when data are properly curated. In practice, however, well-aligned time series data are difficult or expensive to come by [17].

To address the phase issue of DTW- and other distance-based 1NN approaches, the research community has proposed approaches that focuses on finding defining *local* features/subsequences in order to be invariant to data alignment and rotation. Popular methods that fall into this category include Bag-of-Patterns [27], SAX-VSM [36] and shapelets-based algorithms [44], such as Fast Shapelets (FS) [31] and Learning Shapelets (LS) [15]. The majority of these techniques have taken advantage of text feature extraction approaches – e.g., TF-IDF – after converting time series into alphabetical strings. Such conversion is often done via Symbolic Aggregate approxImation (SAX) [26], which requires two parameters (i.e., cardinality and PAA window size) to be set and it may not always be trivial to find the best pair. Besides, many approaches attempt to find time series subsequences that are representative of each class, e.g., shapelets by definition are defining time series subsequences that are calculated by exhaustive or optimized search. Overall, many of these methods have suffered from high computation complexity or suboptimal classification accuracy [39].

Graph representations for TSC, on the other hand, have not been investigated extensively by the time series mining research community possibly due to their high computation complexity. Nevertheless, thanks to recent development of graph mining algorithms [5, 29], some of the formerly complex problems can be solved extremely efficiently with optimization and parallelization techniques [2]. Such advances give us the opportunity to

re-evaluate the possibility of taking advantage of graph representations and extracting graph features for building an efficient and accurate TSC algorithm.

This paper proposes a novel approach for TSC that considers time series as complex graphs/networks and extracts from these networks important statistical features, which are fed to modern generic classifiers to learn structural knowledge from the original time series. After evaluating the classification performance with a large open dataset, we find out that our approach is capable of making efficient and accurate classification predictions. The main contributions of this paper are listed as follows:

- We present a multiscale graph representation for time series, so that both global and local features from time series can be captured, making this approach agnostic to time series alignment and outperform major distance-based TSC algorithms.
- Since we transform time series that are intrinsically sequential into unordered feature vectors, it is then suitable for taking advantage of modern generic classifiers (*e.g.*, RF, SVM and XGBoost) for efficient feature selection and classification. This clear separation of feature extraction and actual classification can help researcher focus on finding insightful characteristics in time series data without the need for reinventing the wheel and designing a classifier from scratch specifically for time series.
- We propose a novel feature extraction and classification method for time series based on calculating probability distributions of small motifs (*i.e.*, repeated patterns) in visibility graphs and other statistical features such as density, degree statistics, assortativity and coreness. This feature extraction mechanism is parameter-free, so that it can be easy to use and help yield reproducible results.
- We have intentionally chosen a collection of statistical features that are computationally efficient to extract from graphs and validated their effectiveness in controlled experiments. Moreover, since our feature extraction and classification process is inherently parallel, it is suitable for and capable of large scale data explorations.
- After extensively evaluating our approach with a large number of open datasets and comparing with related research efforts, experiment results indeed suggest that accurate and efficient classification can be obtained following this paradigm.

The remainder of this paper is structured as follows. Section 2 lays down the necessary background. Next, we present our approach in section 3 and detail TSC accuracy and efficiency evaluation results along with a case study in section 4. For interested readers, section 5 introduces research work related to ours. Finally, we conclude the paper with future research directions in section 6.

2 BACKGROUND

Traditionally, time series refer to a sequence of numbers that are chronologically ordered. However, in the research community time series have a much broader scope and do not associate strictly with timestamps:

Definition 2.1 (Time series). A time series instance T is an ordered sequence of n real-valued variables, *i.e.*, $T = (v_1, \dots, v_n), v_i \in \mathbb{R}$.

If we consider each point in a time series as a single feature in a vector, then time series data usually have a huge number

of features. When considering these features as a vector in an n -dimensional space, time series data are often high dimensional. Due to difficulties to conduct knowledge discovery tasks on high dimensional data, it is frequently required to reduce the dimensionality of time series in order to improve computation efficiency:

Definition 2.2 (Dimensionality reduction). The dimensionality of a time series sample T is the length of T , denoted by $|T|$. If T' is an approximated representation of T and $|T'| \ll |T|$, then T' is a dimension-reduced representation of T .

The research community has proposed a number of dimensionality reduction techniques for time series, including sampling [32], Piecewise Linear Representation (PLR) [19], Piecewise Aggregate Approximation (PAA) [20], *etc.*. Among them PAA is perhaps one of the simplest and most widely applied approaches. PAA reduces time series $T = (v_1, \dots, v_n)$ from n dimensions to s dimensions by firstly dividing the data into s segments of equal size, then the approximation is a vector of the mean values of the data readings per segment [20, 26]. Let $T' = (v'_1, \dots, v'_s)$ be this vector where v'_i is computed by equation 1. For the sake of simplicity, $\frac{n}{s}$ is often chosen to be an integer or rounded to the nearest one.

$$v'_i = \frac{s}{n} \sum_{k=\frac{n}{s}(i-1)+1}^{\frac{n}{s}i} v_k \quad (1)$$

One of the core routines in distance-based classification algorithms involves evaluating the dissimilarity (or similarity) of two time series. There are a number of dissimilarity measures for time series, two of the most frequently used measures in the research community are Euclidean distance and DTW distance. The Euclidean distance maintains a one-to-one mapping of all the points in two series. On the other hand, the DTW distance tries to find the best mapping of points in two series using the dynamic programming paradigm, so that the minimum distance between these two series is achieved. The paradigm is called “time warping” since the time axis of series can be expanded or compressed in order to ensure the minimum distance, *i.e.*, an i^{th} point in X can be mapped to a j^{th} point (it is possible that $i \neq j$), or one point in X may even be mapped to multiple points in Y .

2.1 Visibility Graph

Aiming for taking advantage of graph theories as a way of characterizing time series, an algorithm named visibility graph (VG) [23, 24] is proposed to transform time series into a network structure. The creation of VGs relies on an extremely simple idea: each point in a time series is treated as a vertical bar, whose height is the corresponding numerical value. When considering these bars on a landscape, it is then straightforward that the top of a bar may be visible from the top of other bars. Assume each time-step as a vertex in a graph, then two vertices are connected if the top of the vertical bars are visible to each other, *i.e.*, there exists a straight line from the top of the two bars without intersecting with other bars. More formally,

Definition 2.3 (Visibility graph). Given a time series $T = (v_1, \dots, v_n)$, its VG representation $G = (V, E)$ has n vertices: $V = (1, \dots, n)$. An edge $e = (i, j) \in E$ iff $\forall k$ such that $i < k < j$ ($1 \leq i, j \leq n$) inequality $v_k < v_j + (v_i - v_j) \frac{j-k}{j-i}$ is satisfied.

Figure 1: An example of converting time series to visibility graph and horizontal visibility graph.

It is obvious that VGs are undirected, although it is possible to create a directed version by limiting the direction of view-points from the vertical bars. Besides, VGs are always connected since each node will always be visible to its neighbors. Finally, VGs are invariant when time series undergo affine transformations, *i.e.*, the visibility criterion remains fulfilled when rescaling the time series either horizontally or vertically. However, VGs are not suitable for non-stationary time series, *i.e.*, those having monotonically increasing/decreasing trends in time. Such trends should be removed before applying VG generation. The goal of VGs is to characterize structural properties [24] of time series, such as periodicity, fractality, *etc.*, although it is shown that it can be extended to weighted VGs in order to quantitatively distinguish generic time series [38].

Creation of VGs from time series without optimization generally has $O(n^2)$ computation complexity, where n is the dimensionality of time series data. However, a more efficient VG generation algorithm [1] can have a sub-quadratic computation complexity. Specifically, this algorithm can reduce the complexity of time series VG generation down to $O(n \log^2(n))$. When further taking advantage of parallelization, $O(n \log^2(n))$ work can be effectively solved within $O(\log^2(n))$ time. Another simplified variant of VG, horizontal visibility graph (HVG) [28], only connects nodes i and j if a horizontal line can be drawn between these nodes. Creation of HVGs without any optimization generally has a computation complexity of $O(n)$.

Definition 2.4 (Horizontal visibility graph). Given a time series $T = (v_1, \dots, v_n)$, its HVG representation $\hat{G} = (V, E)$ has n vertices: $V = (1, \dots, n)$. An edge $e = (i, j) \in E$ iff $\forall k$ such that $i < k < j$ ($1 \leq i, j \leq n$) inequality $v_i, v_j > v_k$ is satisfied.

VG and its variants have been shown to be able to differentiate certain time series. For instance, [18] have extracted motifs from HVGs and claimed the motif statistics can be used for differentiating various types of time series data, including white Gaussian noises, fully chaotic logistic maps and noisy fully chaotic logistic maps. The authors further claimed that HVG motif profiles from heart rate time series can be used to cluster different types of meditative activities.

Intuitively, VGs and HVGs are very similar concepts and HVG is a subgraph of VG. However, when extracting statistics from them, VGs can be more capable of capturing global features, while HVGs are often more sensitive to local variations. As a result, VGs and HVGs can be joined to provide more accurate representations of time series data. We will discuss more about such heuristics in section 4.2. For simplicity, in the remainder of this paper the term VG indicates the combination of VG and HVG if HVG is not explicitly specified.

2.2 Graph Features

Extracting features from graphs has become a popular research topic thanks to the recent applications in social network analysis, physics as well as bio-informatics. There are a number of

research avenues in graph mining, the most popular ones are about finding communities or clusters within large graphs and characterizing graphs by means of finding and counting recurrent patterns. Since time series VGs are always connected, it is thus not immediately helpful to extract clusters, since clusters in these graphs will always correspond to subsequences of original time series. Graph motifs or graphlets, however, are especially interesting since they are sub-graph structures or patterns in a larger graph that are recurrent and statistically significant. Finding motifs in graphs is generally a complex problem, but there have been a number of research work for efficiently extracting motifs from graph data, such as GTrieScanner [34] and Parallel Parameterized Graphlet Decomposition (PGD) [2]. Due to the fact that the number of motifs increases exponentially with motif size, the complexity of finding motifs is also exponentially correlated with motif size. Researchers thus generally focus on optimizing computation efficiency of locating small motifs (of size up to four). PGD is the state-of-the-art approach for efficiently finding and counting small motifs in graphs and can be several magnitudes faster than other approaches. Table 1 shows all possible small graph motifs up to size four. Note that PGD works only for undirected graphs, while GTrieScanner works on both directed and undirected graphs. However, motifs extracted by GTrieScanner are only connected motifs and the running time is significantly slower than PGD. As a result, in this paper we take advantage of PGD for small motif counting.

Table 1: All graph motifs up to size 4. Note that connected graphs may contain disconnected motifs.

#	Motif	Name	#	Motif	Name
M_{21}		2-edge	M_{22}		2-node-independent
M_{31}		3-triangle	M_{33}		3-node-1-edge

M_{44}		4-cycle	M_{410}		4-node-1-edge
M_{45}		4-star	M_{411}		4-node-independent
M_{46}		4-path			

Researchers argue that motif distribution extracted from VGs can be extremely helpful for identifying different types of artificially generated time series. However, in practice motif distributions may not be as distinguishable as those from artificial data. For example, Figure 2 illustrates the motif distributions of three different classes of time series from the ArrowHead dataset. As shown, it can be very difficult to tell one class apart from another given only these distributions since the probability distributions of different classes tend to overlap, especially in this case for instances from class 2 and 3. Besides small motifs, other graph features are also easy to obtain, *e.g.*, vertex and edge statistics as well as structural metrics. In this paper we consider some additional graph features listed as follows:

- Density: the ratio of the number of edges to the number of all possible edges. Graph density is computed following equation 2 and has a computation complexity of $O(1)$.

$$p = \frac{2|E|}{|V|(|V| - 1)} \quad (2)$$

Figure 2: Boxplots of motif probability distribution of different classes from the ArrowHead Dataset’s training set.

- *K*-core: the *K*-core of a graph $G = (V, E)$ is a maximal subgraph $H = (V', E')$ in which each vertex has a degree of at least *K*, i.e., $\forall v \in V' : \deg_H(v) \geq K$. Consequently, it is a cohesiveness measurement of interlinked subgraphs within a network and *K* is computed by equation 3. Computing *K* has an $O(|E|)$ time complexity [5].

$$K = \operatorname{argmax}_{H \in G} \operatorname{Core}_H \geq K \quad (3)$$

- Assortativity coefficient: a metric to measure the correlation of vertices in a graph through calculating the Pearson correlation coefficient of degree between pairs of connected vertices. Equation 4 shows how assortativity coefficient is computed,

$$r = \frac{\sum_{xy} xy(e_{xy} - a_x b_y)}{\sigma_a \sigma_b} \quad (4)$$

where a_x and b_y represents respectively the fraction of edges that start and end at vertices with values x and y , and e_{xy} is the measure of assortativity, such that $\sum_{xy} e_{xy} = 1$, $\sum_y e_{xy} = a_x$ and $\sum_x e_{xy} = b_y$. Finally, σ_a and σ_b are the standard deviations of the distributions a_x and b_y . Computing r has an $O(|E|)$ time complexity [29].

- Degree statistics including max, min and mean degree per vertex. Naturally, computing such statistics has an $O(|V|)$ time complexity.

Note that there are a plethora of features that can be extracted from graphs [11], and such features are not necessarily equally easy to obtain. For instance, the diameter of a graph – which is the shortest distance between the two most distant vertices in the graph – can be computationally expensive to calculate since it demands $O(|V|(|V| + |E|))$ computation. Nonetheless, this paper does not intend to find the exclusive set of features that are both efficient and descriptive for time series VGs. Rather, we try to investigate if these aforementioned statistical features are indeed helpful for TSC.

3 MULTISCALE VISIBILITY GRAPH

Time series data differ greatly in characteristics depending on how they are captured, sampled and their underlying applications: in one domain global features may be helpful, while in another domain local features (i.e., defining subsequences) can become more important for classification. After transforming real-valued time series into VGs, specific features from such VGs – such as probability distributions of small motifs – are more reflective of local features than global ones. We refer to this type of

representation as Uniscale Visibility Graph (UVG) in the remainder of this paper. In this case, extracting more global features (i.e., probability distributions of large motifs) becomes exponentially expensive for computation. To mitigate this problem, we propose the Multiscale Visibility Graph (MVG) representation such that each time series sequence is transformed into a set of dimensionality-reduced approximations: these downscaled approximations are then converted into a set of VGs. Consequently, features are extracted from each graph in MVGs, thus approximating the process of extracting features of different scales. This approach is inspired by computationally efficient wavelet transform [10], with the exception that time series in each scale are represented with graph structures instead of numerical values. We first define the multiscale representation of time series as follows:

Definition 3.1 (Multiscale Approximation). Given a time series $T_0 = (v_1, \dots, v_n)$, its approximated multiscale representation is a set of time series $\hat{\mathbb{T}} = (T_1, T_2, \dots, T_m)$, where T_i ($1 \leq i \leq m$) is a downscaled approximation of T_0 , such that $|T_i| = |T_0|/2^i = n/2^i$. In addition, to avoid tiny and meaningless representations we enforce a constant threshold τ for the downscaled approximations, i.e., $|T_m| > \tau$.

The downscaling of T_0 can be achieved with widely used dimensionality reduction techniques such as PAA (cf. equation 1). Since the size of downscaled time series representations follows an exponential decay, time series multiscale representations $\hat{\mathbb{T}}$ often consists of a small number downscaled series. Besides, considering $\sum_{i=1}^{\infty} n * 2^{-i} = n$, theoretically the maximal dimension of $\hat{\mathbb{T}}$ when fully expanded is n .

Definition 3.2 (Multiscale representation). Given a time series T_0 and its approximated multiscale representation $\hat{\mathbb{T}} = (T_1, T_2, \dots, T_m)$, its multiscale representation is the union of $\hat{\mathbb{T}}$ and T_0 , i.e., $\mathbb{T} = (T_0, T_1, T_2, \dots, T_m)$.

Approximated multiscale representations can help smoothing time series and reducing noises, while full multiscale representations consist of both the original time series and augmented versions. Each series in multiscale representations can be transformed into VGs, thus we have a natural definition for multiscale visibility graphs, which are supersets of approximated multiscale visibility graphs (AMVGs):

Definition 3.3 (Multiscale visibility graph). Given a time series T and its multiscale representation $\mathbb{T} = (T_0, T_1, T_2, \dots, T_m)$, its multiscale visibility graph is a set of graphs $\mathbb{G} = (G_0, G_1, G_2, \dots, G_m)$, where G_i ($1 \leq i \leq m$) is the corresponding visibility graph created from T_i .

Since the number of vertices in G_i equals the dimensionality of T_i , to avoid meaningless trivial graphs it is natural to set τ to a small integer (e.g., $\tau = 15$), such that the smallest graph in \mathbb{G} contains more than τ vertices. Note that τ should not be considered as a parameter for the feature extraction process. Rather, it is more an optimization trick and bearing a default value of 0 will not cause any issues, since feature selection is done during classification.

3.1 Feature Extraction

As shown in Algorithm 1, feature extraction in MVGs follow the same paradigm as extracting features from individual graphs in an MVG and concatenating all features together, since graph features extracted in this paper are solely statistical and do not

pertain orders. Consequently, these features can be fed into any generic classification algorithms [13] well studied in the machine learning and data mining community. It is utterly important that this feature extraction transforms the sequential characteristics of time series data into unordered feature vectors, so that any modern classification algorithm can be taken advantage of.

Algorithm 1 Building time series MVGs and extracting features from them.

```

1: procedure EXTRACTFEATURES( $T$ )
2:    $\mathbb{F} \leftarrow \emptyset$  ▷ Feature set
3:    $\mathbb{G} \leftarrow \emptyset$  ▷ MVGs
4:    $T' \leftarrow T$ 
5:   while  $|T'| > \tau$  do ▷ Ignore trivial graphs
6:      $\mathbb{G} \leftarrow \mathbb{G} \cup \text{BuildVGAndHVG}(T')$ 
7:      $T' \leftarrow \text{DimensionalityReduction}(T)$  ▷  $|T'| \leq \frac{|T|}{2}$ 
8:   for  $G \in \mathbb{G}$  do
9:      $\mathbb{M} \leftarrow \text{MotifProbabilityDistribution}(G)$ 
10:     $\mathbb{M} \leftarrow \text{Normalize}(\mathbb{M})$ 
11:     $\mathbb{F} \leftarrow \mathbb{F} \cup \{\mathbb{M}, \text{OtherStatistics}(G)\}$ 
12:   return  $\mathbb{F}$ 

```

Although features have become unordered, it is nevertheless important to carefully curate them in order to achieve better classification results. Note that PGD is very efficient in counting motifs in graphs, and the dominant features from time series MVGs will be the probability distribution of motifs of different sizes:

Definition 3.4 (Motif probability distribution). Given a time series visibility graph G and the set of motifs \mathbb{M} , the motif probability distribution \mathbb{P}_G is the set of probabilities corresponding to each motif in \mathbb{M} .

Empirically, the distribution of connected and disconnected motifs vary greatly in graphs. It is thus desirable to calculate separately motif probability distributions depending upon motif connectivity. To that end, the motif probability distributions (MPDs) are calculated per motif size and connectivity. This essentially normalizes extracted motif features. Specifically, MPDs are normalized according to the following five groups (cf. Table 1): $\{\{M_{2_1}, M_{2_2}\}, \{M_{3_1}, M_{3_2}\}, \{M_{3_3}, M_{3_4}\}, \{M_{4_1}, \dots, M_{4_6}\}, \{M_{4_7}, \dots, M_{4_{11}}\}\}$. Finally, it is obvious that other graph features – e.g., graph density and assortativity coefficient – are independent of MPDs. As a result, no further curation for such features is needed.

3.2 Classification

When features are extracted, we can feed them into a generic classifier to learn from labeled samples and predict the class of unlabeled ones. We are in favor of most well-known and widely accepted and well optimized algorithms such as SVM, Random Forest and eXtreme Gradient Boosting (XGBoost) [8] for this task. Especially, as a highly optimized distributed gradient boosting library, XGBoost runs on major distributed environment. It has gained remarkable adoption since its inception and is well known for its performance in machine learning and data mining competitions.

Typical classification tasks involve learning models and selecting a performant estimator through the process of validation. Although in this study we have proposed a parameter-free method for feature extraction, it is still required to tune the hyper-parameters for generic classifiers. Note that hyper-parameters in machine learning refers to parameters that are external to the model and such values cannot be estimated from the training

data. As a result, they are often set using heuristics. For instance, the k in k NN classifier can be considered as a hyper-parameter, since “there is no analytical formula available to calculate an appropriate value” [22]. In order to tune hyper-parameters in our classifiers, we conduct cross-validation to evaluate the performance of estimators and apply grid search to find the most satisfactory estimator based on the cross entropy scores:

$$-\log P(\hat{y}|y) = -(y \log(\hat{y}) + (1 - y) \log(1 - \hat{y})) \quad (5)$$

where y is the ground truth, and \hat{y} is the probabilistic predictions by an estimator. Since datasets may be highly imbalanced, which will lead to degraded classification results, we can apply random oversampling techniques over the minority class and use stratified cross validation to preserve class balance when validating models.

4 EVALUATION

To evaluate our approach, we conduct experiments using a large number of publicly accessible datasets. We first introduce the datasets. Then we list and validate our heuristics, followed by creating an accurate classifier with stacked generalization. Next, we compare the accuracy and efficiency of our method with state-of-the-art approaches. Finally, we close this section with a case study and discussions.

4.1 Datasets

When validating our heuristics, we consider the most popular and largest open dataset for TSC: the UCR Time Series Classification Archive [9]. Specifically, we use a subset from the UCR archive that are more recent (added after the summer of 2015), which include datasets from various fields ranging from electrocardiograms (ECG) to intra-species image recognition data. These datasets have a uniform file format and consistent internal data structures, making it possible to conduct batch processing in a content-agnostic manner. Furthermore, datasets in this subset are generally larger in size, making it more reliable to evaluate the scalability of TSC algorithms.

When comparing our approach with state-of-the-art approaches, we take advantage of the UEA & UCR Time Series Classification Repository since it contains all datasets from the UCR archive. In addition, this repository also provides open source implementation for more than 18 TSC algorithms [3] and benchmarking results are publicly available from the repository website¹. We compare our results with relevant algorithms using the default train and test split from this repository.

4.2 Validating Heuristics

Before diving directly into MVG representations, it would be a prerequisite to validate our heuristics step by step. We summarize these heuristics below:

- (1) Motif statistics from VGs and HVGs can serve better during classification when combined with other graph features such as degree statistics.
- (2) Features from HVGs are more capable of capturing *local* characteristics while those from VGs are capable of capturing *global* characteristics. Combining features from both HVGs and VGs can help yield more accurate classification results.

¹<http://timeseriesclassification.com/>

- (3) Multiscale representations are able to reveal time series features at different scales, and a generic classifier is able to conduct feature selection and find important features to perform more accurate classification than using features without multiscale augmentation.

When validating these heuristics, we feed the features corresponding to each heuristic to an XGBoost classifier for 3-fold cross-validation and model selection. A set of hyper-parameters have been set for grid search, including the learning rate (three choices from 0.01 to 0.3), number of estimators (10 choices from 10 to 100), max tree depth (10 or 20). In order to prevent overfitting, the subsampling and column sampling hyper-parameters are both set to 0.5 to randomly collect half of the data instances and features to grow trees. To reduce the impact of random over sampling on minority classes and floating-point summation issues in parallel processing, all experiments have been repeated five times and average accuracy scores are calculated. Finally, all experiments are conducted on a Linux server with two Intel Xeon E5-2430 CPUs with a clock rate of 2.20GHz. With this setup, we illustrate step by step how experiments are setup and present the final classification results in Table 2.

4.2.1 Choosing Graph Features. We first investigate which graph features are helpful for extracting distinguishable information from time series. Specifically, we transform time series into UVGs consisting of both VG and HVG representations and try to extract MPDs as well as other features (density, assortativity and degree statistics) from these graphs. We are interested in finding out whether MPDs are sufficient for TSC and if extracting other statistic features from graphs are necessary. Next, we take advantage of XGBoost classifier to train on different feature sets and classify the test datasets. Columns A, B, C and D in Table 2 presents the classification error rates using HVG with only MPDs, HVG with MPDs and other graph features, VG with only MPDs and VG with all features. Comparison on the bottom of the table shows that including features such as density and assortativity coefficient indeed helps improving classification accuracy. For HVGs, including features other than MPDs increases classification accuracy in 32 datasets, while for VGs 29 datasets saw accuracy improvements. A Wilcoxon signed rank test with p -values $9.48e-7$ and $9.56e-5$ suggests that such improvement is indeed significant (both p -values < 0.05). Figure 3 shows the classification results in the form of scatter plots, where each point represent a dataset. Such results along with the Wilcoxon test indeed suggest that our Heuristic (1) is valid.

Figure 3: Comparison of classification error rates: using MPDs with or without other graph features.

4.2.2 VG and HVG. Next, it is necessary to show that graph features extracted from both VGs and HVGs are important. Recall that, intuitively, VGs are helpful for capturing global features while HVG can help locating local features. We separately test the distinguishing power of VGs and HVGs for time series in order to make sure that both can lead to satisfactory classification results.

Furthermore, we conduct experiments to investigate if combining VGs and HVGs can better capture both global and local features for time series and thus lead to more accurate classification.

Figure 4: Comparison of classification error rates: using HVGs, VGs or combining two together (denoted as UVG here).

Figure 4 illustrates the comparison of classification accuracy with VG and HVG features as well as combining both VG and HVG. The first scatter plot shows that for majority datasets, VG features can yield more accurate classification performance. However, it is still worth mentioning that HVG features can also outperform VG features in some specific datasets, possibly due to the reason that local features are more influential in such datasets. Moreover, it is obvious from the other two scatter plots in Figure 4 that combining both VG features and HVG features can greatly boost the classification accuracy. This is probably due to the excellent feature selection capability of XGBoost, so that the classifier is able to find out which features are more important during the training process. In addition, as shown in Table 2, using VGs outperforms HVGs in 30 datasets with a p -value of $3.09e-3$, suggesting VGs are capable of capturing more characteristics in time series. Finally, combining features from both VGs and HVGs yields more accurate results in 27 datasets with a p -value of $5.01e-3$, indicating significant improvement when combining two different types of graphs. As a result, the validity of our Heuristic (2) can be confirmed.

4.2.3 UVG, AMVG and MVG. Since we have demonstrated that taking advantage of both VG and HVG features can improve classification accuracy for UVG representations, now we can investigate whether Heuristic (3) holds, *i.e.*, if multiscale representations can help achieving even more accurate results. To visually inspect which representation suites best for TSC, we further draw scatter plots of the accuracy results in Figure 5. It is then obvious that AMVG and UVG (scatter plot on top) lead to similar classification accuracy, which suggests that AMVG can be good approximations for original time series data. Furthermore, the two scatter plots in the bottom of Figure 5 indeed confirm that MVG representations result in better classification performance, since almost all dots representing results from different datasets fall on the side of MVG.

Figure 5: Comparison of UVG, AMVG and MVG's error rates.

From Table 2, we can see that multiscale approximations outperforms uniscale time series in 19 datasets, with a Wilcoxon p -value of $0.8623 > 0.05$. As a result, AMVG representations are not statistically significantly different than UVGs. On the other

Table 2: Error rates of classifying 39 UCR datasets compared with 1NN-Euclidean and 1NN-DTW. Different heuristic combinations are taken into account. Bold-faced values indicate lowest error rates (including ties) for specific datasets in all experiments.

hand, MVGs outperform AMVG in 29 datasets with a p -value of $1.72e-4$ and MVGs are more accurate than UVGs in 30 datasets with a p -value of $8.74e-4$, suggesting that MVG representations indeed contribute significantly towards a more accurate feature extraction and TSC process. As a result, our Heuristic (3) is valid.

4.2.4 Summary of Heuristic Validation. Overall, all our heuristics are supported by experiment results and each heuristic contributes significantly to a more accurate TSC process. Table 2 also shows the comparison between our approach and Euclidean distance- as well as DTW-based nearest neighbor classification. Our approach outperforms 1NN-Euclidean in 26 datasets with a Wilcoxon p -value of 0.01 , suggesting MVG features with XGBoost is significantly more accurate than 1NN-Euclidean. Moreover, MVG appears to be in par with 1NN-DTW in terms of classification accuracy since 23 datasets are in favor of MVG with a p -value of 0.1638 . Next, we will try to build a more robust and accurate classifier using stacked generalization.

4.3 Stacked Generalization

Previously we have solely taken advantage of XGBoost for classifying time series with features extracted from graphs. However, it can also be interesting to investigate if other classifiers can achieve similar results. Besides, although modern classifiers such as XGBoost and RF are capable of efficiently conducting feature selection during training, we can still conduct feature selection processes and feed such *a priori* information to classifiers in order to achieve better classification accuracy. To that end, we propose feeding different sets of features to a collection of classifiers and then create a meta-classifier using stacked generalization (*a.k.a* stacking or blending) [41]. This meta-classifier will then hopefully generate better final predictions. In fact, a variant of this technique has led to winning the Netflix Prize with a reward of one million dollars [37].

Before building a meta-classifier with stacked generalization, we first make sure that features we previously extracted are suitable inputs for different classifiers such as RF and SVM. Generally, tree-based classifiers are not so sensitive to monotonic transformations of individual features. As a result, it is often not required

to have features scaled to similar magnitudes for RF and XGBoost. However, since SVM’s kernel functions (in an Euclidean space) are usually sensitive to different feature magnitudes, we use Min-Max scaling to transform each feature into range of zero and one. After that, we compare the classification performance of these three classifiers.

In order to evaluate the significance of the differences a generic classifier can incur, we take advantage of the Nemenyi test [12], which is a post-hoc test aiming for finding whether groups of data differ after a statistical test of multiple comparisons. This test can be illustrated by means of a critical difference diagram, where average ranks of all approaches are presented. Specifically, the location of vertical lines indicate the average ranking of an approach and bold lines (insignificance lines) indicate groups of approaches that are not significantly different. In this case, for one approach to be considered significantly better than another, its overall ranking has to be at least 0.5307 higher than its competitor. As shown in Figure 6, XGBoost performs slightly better than RF in general, and both are significantly more accurate than SVM. Such results are not surprising, since [13] have empirically tested hundreds of classifiers and concluded that RF produces the most accurate classification results. This study was conducted before the initial release of XGBoost, and the recent adoption momentum of XGBoost indeed suggests that XGBoost is great for yielding accurate classification results.

Figure 6: Critical difference diagram comparison of RF, SVM and XGBoost.

Now that generic classifiers can be used for graph features extracted from time series, we then set to investigate whether stacking can help further increase classification accuracy. We first stack top performing classifiers in each family before blending classifiers from different families. Specifically, we first select the top five most accurate classifiers from RF, SVM and XGBoost through cross validation. Then these five classifiers are stacked to produce a meta-classifier, which is used for producing final predictions. Finally, when stacking classifiers of different families, five classifiers from each family have been selected, thus the meta-classifier has been trained with 15 classifiers. Our algorithm is described in Algorithm 2.

Algorithm 2 Algorithm for creating an ensemble classifiers using stacked generalization.

Input: Training dataset $\mathbb{D} = \{\mathbb{X}_i, y_i\}_{i=1}^m$ ($\mathbb{X}_i \in \mathbb{R}^n$, $y_i \in \mathbb{Z}$)
Base classifiers \mathbb{H} (with different hyper-parameters)
Output: An stacked ensemble E

```

1: procedure BUILDSTACKINGENSEMBLE( $\mathbb{D}$ ,  $\mathbb{H}$ )
2:    $\mathbb{S} \leftarrow \text{CreateStratifiedKFolds}(\mathbb{D}, \text{cv}=3)$  ▷ 3-fold CV
3:    $\mathbb{E} \leftarrow \emptyset$  ▷ Best performing base estimators
4:   for all  $h \in \mathbb{H}$  do
5:      $H \leftarrow \emptyset$ 
6:     for all  $S = \{\mathbb{D}_{train}, \mathbb{D}_{validation}\} \in \mathbb{S}$  do
7:       TrainClassifier( $h, \mathbb{D}_{train}$ )
8:        $\hat{y} \leftarrow \text{Predict}(h, \mathbb{X}_{validation})$ 
9:       score  $\leftarrow -\log P(\hat{y}|y_{validation})$ 
10:       $H \leftarrow H \cup \{h, \text{score}\}$ 
11:    $H \leftarrow \text{arg sort}(H)$  ▷ Sort estimators by score
12:    $\mathbb{E} \leftarrow \mathbb{E} \cup \text{slice}(H, k)$  ▷ Select top- $k$  estimators
13:    $W \leftarrow \text{ComputeEstimatorWeights}(\mathbb{E})$  ▷ with logistic regression
14:    $E \leftarrow \sum_{i=1}^{|\mathbb{E}|} W_i \mathbb{E}_i$ 
15:   return  $E$ 

```

Our experiments show that, for RF and SVM, stacking their top performing classifiers indeed increases final classification. In the case of XGBoost, however, stacking its most accurate classifiers does not seem to significantly increase classification accuracy, since the classification results of stacked generalization is on par with those with a single most accurate classification during cross validation. It possibly indicates that XGBoost has already very good generalization capabilities. Finally, stacking most accurate classifiers from three different families can help achieving better classification accuracy than single best XGBoost classifier in most datasets. As a result, stacked generalization can indeed be helpful for further improving the performance of MVG.

Figure 7 demonstrates how stacked generalization can help boosting classification accuracy. It is straightforward that stacking XGBoost and SVM produces similar classification accuracy, while stacking top performers from all three families can be significantly more accurate than using a single family. As a result, we are confident that staked generalization is favorable for more accurate TSC.

Figure 7: Critical difference diagram comparison of stacking single family of classifiers versus all families of classifiers.

4.4 Accuracy Benchmarking

Finally, we compare our results with the state-of-the-art and relevant approaches. Table 3 presents the classification error rates as well as the running time statistics. Specifically, datasets in this experiment are from the UEA & UCR Time Series Classification Repository thanks to the many benchmarking results that are publicly available. Note that although names of the datasets used in this repository are exactly the same compared to our previous experiments, the similarity of their contents is not guaranteed. In fact, the training and testing datasets may have been swapped for a number of datasets. An obvious example is the FordA dataset, where in this experiment the training dataset and testing set are of size 1320 and 3601 respectively, while in our previous experiments the training set has 3601 samples and the testing test has 1320.

We compare our method MVG with five state-of-the-art approaches: two distance-based global similarity matching algorithms including Euclidean- and DTW-based nearest neighbor classification (1NN-ED and 1NN-DTW), and three local pattern matching algorithms including Learning Shapelets (LS) [15], Fast Shapelets (FS) [31] and SAX-VSM [36]. Among all five approaches, LS is recognized as the most accurate classifier [39] by the research community. However, LS is also known for its high computation complexity. We first compare the classification accuracy of different approaches in this section and then investigate MVG’s efficiency later in section 4.5.

Viewing the error rate comparison columns in Table 3, it is obvious that MVG is the most accurate classifier with 16 winning datasets. LS then follows MVG with 12 winning datasets. A Wilcoxon test between MVG and LS yields a p -value of $0.3421 > 0.05$, suggesting that MVG should not be considered significantly better than LS. SAX-VSM is ranked third with 10 winning cases. The Wilcoxon test again suggest that such difference is not statistically significant. However, MVG is indeed significantly more

Table 3: Classification error rates compared with five benchmark approaches and running time statistics (in seconds).

accurate than FS, 1NN-DTW and 1NN-ED. Moreover, scatter plots in Figure 8 shows that most of the points in each comparison are located away from the diagonal line, suggesting that MVG is indeed a very different approach when compared to the state-of-the-art. Having confirmed MVG’s excellent accuracy, we continue to investigate its runtime efficiency.

4.5 Efficiency

The pipeline of MVG consists of a feature extraction phase and a train-validate-test process. During the feature extraction process, time series are firstly transformed in to VGs and then features are extracted from such graphs. With optimization from [1], transforming time series of length n into VGs has a computation complexity of $O(n \log^2(n))$ and it can be effectively solved within $O(\log^2(n))$ time when taking full advantage of parallelization. Extracting motif features from VGs may be potentially expensive, fortunately PGD provides a fully parallel way of counting small motifs. For instance, counting graph cliques of size 4 – one of the most time consuming tasks in PGD – has a computation complexity of $O(m \cdot \Delta \cdot T_{max})$, where m is the number of 4-motifs (i.e., 11), Δ is the maximum degree and T_{max} is the maximum number of triangles incident to an edge and $T_{max} \ll \Delta$. PGD is hundreds of times faster than other motif counting algorithms:

counting motifs from a graph with more than 26,000 vertices can take only 0.01 seconds on a twelve-core commodity CPU [2]. Since other statistic features such as density, k -core, assortativity and degree statistics extracted from time series VGs are intentionally chosen to be simple metrics, collecting these features has a time complexity of $O(\max(|V|, |E|))$. Since we use a multiscale graph representation, ultimately graph generation has a mono-thread complexity of $O(n \log^3(n))$ and in parallel an $O(\log^3(n))$ time complexity. As a result, feature extraction per graph has a computation complexity of $O(\max(|V|, |E|) + m \cdot \Delta \cdot T_{max})$. The classification process leverages state-of-the-art classifiers that are widely used and well-optimized. Overall, the efficiency of MVG may be best illustrated when we compare our method against our benchmarking approaches.

Previous research [39] has shown that LS is extremely time consuming, and FS as an approximated approach can be 100X faster than LS. As a result, FS will be a good and strong baseline to which the running time of our approach can be compared. Thus we record the running time of FS and MVG and compare their efficiency. These experiments are conducted on a computer with Intel i7-4980HQ quad-core CPU clocked at 2.80GHz, 16GB memory and solid-state drive suitable for fast I/O. We use the

Figure 8: Comparison of classification accuracy with five state-of-the-art approaches in the form of scatter plots.

FS implementation by its original authors [31] with default parameters. Columns located on the right side of Table 3 shows the running time per dataset for MVG and FS. For MVG, running time for feature extraction and training are recorded separately and then summed. Overall, MVG completes faster than FS for 24 datasets. The total running time of FS for all 39 datasets amounts to 395075 seconds, which is more than 18 times that of MVG. A scatter plot of the running time is provided in Figure 9, obviously MVG can be up to 100X faster than FS, suggesting that it is indeed an efficient TSC approach. In addition, we note that FS appears to be time consuming with large datasets with time series of high dimensionality, while the running time of MVG remains reasonable as datasets grow larger. Furthermore, since we have experimented only on a quad-core commodity computer that is not really powerful in terms of parallel processing, the efficiency of MVG can be easily boosted by adding more computing cores. Overall, MVG can indeed be considered an efficient TSC approach.

Figure 9: Runtime comparison between FS and MVG.

4.6 Case Study

Although accuracy and efficiency are very important measurements for TSC approaches, it is also desirable for TSC methods to have comprehensible classification processes, so that users may gain extra insights into his/her time series data. Popular approaches based on shapelets and subsequences may have a natural advantage in classification comprehensibility. However, since features extracted in MVG are solely statistical, it can be difficult to locate exactly where a distinguishing subsequence lies in the original time series. However, for MVG it is still possible to understand which features have contributed most to correct classification. For instance, when feeding features to train an XGBoost classifier, it will assign weights to all the features. After ranking these features, we can also gain insights into the data. For instance, Figure 10 illustrates a scatter matrix plot for the test dataset of FordA showing ten most important features

learned by the classifier². Out of ten features, six are features from HVGs, which are created from the original series (T_0). VGs features from dimensionality-reduced approximations (T_2 and T_3) are also present. Moreover, it appears that most highly ranked graph features for this dataset are MPDs and assortativity, suggesting that statistics other than MPDs are indeed helpful. Finally, visually from the kernel density estimation it is obvious that some features alone – e.g., T_0 HVG $P(M4_4)$ – can already provide good classification guidelines, suggesting that it is feasible for MVG to present visually comprehensible cues regarding its classification decisions.

4.7 Discussions

Due to specific characteristics of VGs, obviously MVG may not be suitable for every TSC scenarios. For instance, VGs are agnostic of affine transformations in time series. That is, in applications where the absolute oscillation is more important, MVG is less likely to detect such characteristics. Furthermore, when dealing with non-stationary time series data where trends are very frequently found, MVG works best when trends are not the deciding factor since VGs may not be able to capture long-term monolithic trends. Since many graph features have been taken into account in MVG, we believe it can be robust in practical applications.

In addition to limitations inherited from VGs, our approach is more suitable for applications where the size of training datasets is larger, so that classification models can generalize better. In fact, when we review the classification accuracy of MVG, it seems that a majority of its winning datasets have either long time series or large training datasets. This is perhaps innate to the nature of statistics: sample size has to be sufficiently large to make accurate estimations. Based on running time comparison, MVG also scales well with large datasets, which can be an important advantage in the era of big data.

5 RELATED WORK

TSC is a major task in time series mining thanks to its wide application scenarios. As a consequence, there are a plethora of classification algorithms for TSC. Classical TSC approaches involve utilizing 1NN classification together with similarity measures specific to time series data, e.g., DTW [7] and its variants with lower bounding [33] and early abandoning techniques [30].

Another line of research transforms time series into texts and resort to text classification algorithms. For example, inspired by the well known *bag-of-words* approach, [27] proposes the Bag-of-Patterns approach for TSC. SAX-VSM [36] also takes advantage of bag-of-words approach and builds term frequency-inverse document frequency (*TF-IDF*) vectors in its training phase. It defines a similarity measure of two vectors (that are constructed

²To save space, we show more illustrations comparing original time series and important MVG features on project website. URL: <http://daoyuan.li/mvg/>

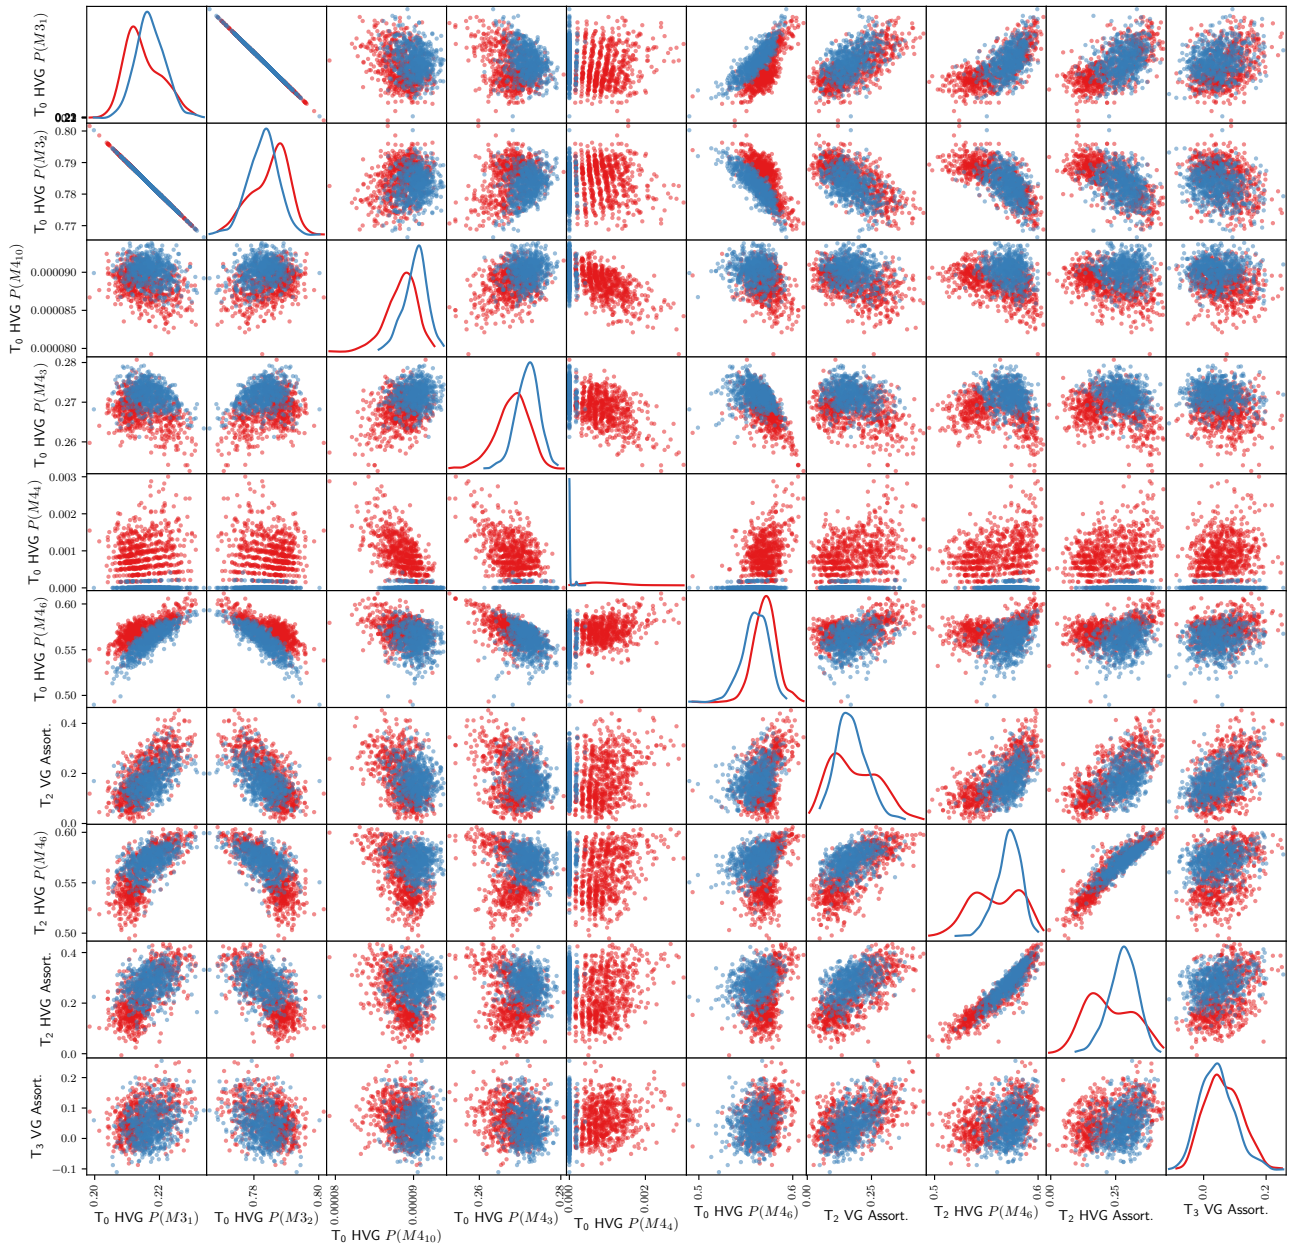

Figure 10: Scatter matrix of ten most important features for FordA's test dataset. Different point colors indicate different classes and the diagonal shows the Gaussian kernel density estimation for each feature.

from original series) based on their inner product. Both Bag-of-Patterns and SAX-VSM rely on SAX [26] for transforming time series into texts. A more recent work, Representative Pattern Mining (RPM) [39], also tries to classify time series by means of finding the most representative SAX-symbolized subsequences. Our previous work Domain Series Corpus (DSCo) [25] also transforms time series into texts and approximates TSC to a pseudo language detection problem. [35] invents another symbolic representation based on Fourier transform and proposes a bag-of-patterns approach named BOSS ensemble based on this symbolic representation method.

Recently, shapelet-based approaches are gaining popularity among the research community. A shapelet [44] is a single subsequence in time series that is representative of its class. However, these approaches [15, 16] are known for their high computation complexity. As we have demonstrated in this paper, FS [31] as

an approximated approach can also take long time to run. High computation complexity is also present for TSC approaches using deep neural networks [43]. Finally, [4] introduce an ensemble algorithm named Collective of Transformation-based Ensembles (COTE) – an ensemble of 35 different classifiers – that has shown to be very accurate but has a time complexity of $O(m^4 n^2)$, where m is the dimensionality of time series and n is the size of training dataset.

Although the concept of time series VGs has appeared for almost a decade, using it for TSC has just started picking up. Machine learning approaches taking advantage of VG and its variants are generally using artificially generated data [42] or EEG signals. Finally, graph kernel methods [21] can be used for evaluating graph similarity, which may potentially be used for TSC as well. Our approach transforms TSC into a graph classification [14] problem. Since we convert time series into

a set of graphs at different scales, we have not experimented generic graph classification algorithms. However, they are indeed interesting for future experiments.

6 CONCLUSIONS AND FUTURE WORK

This paper proposes a graph-based multiscale time series representation named MVG and a feature extraction method for TSC. MVG transforms time series into a collection of visibility graphs of various scales and feature extraction are conducted by investigating statistical graph features such as probability distributions of small motifs, assortativity as well as degree statistics. After a large scale evaluation with open datasets and comparison with a number of state-of-the-art TSC algorithms, our proposed approach appears to be both accurate and efficient: it can be more accurate than LS and up to $\sim 100X$ faster than FS.

In the future, we plan to further investigate other useful and efficient graph features – such as degree distribution entropy, centrality, bipartivity, *etc.* [11] – for MVG in order to further improve its accuracy. Currently we have only evaluated MVG with univariate time series data, we are also excited to investigate the possibility of adopting MVG for multivariate TSC.

ACKNOWLEDGMENT

The results of this study comes from an industrial collaboration project, the authors would like to thank Paul Wurth S.A. for supporting this project.

ABSTRACT

Online social networks (OSNs) embed a rich set of information that could be used in a few fields. Extensive research has been done on estimating graph properties such as counts of wedges and triangles in OSNs. While these graph properties which are defined based on the structural information only are useful at a coarse level, they are not sufficient in applications where finer-grained information is desired. In this paper, we study a problem of estimating a type of graph property, namely the count of edges, refined by the labels of the users, which are usually available in users' profiles, and serves as finer-grained information. Existing solutions for estimating graph properties pay no attention on users' labels and thus they are not suitable for many real world applications. We develop two algorithms for the problem, each of which samples a set of edges or nodes via a random walk process and construct estimators based on the sampled edges or nodes. Theoretical analysis on the accuracy guarantees of our algorithms and extensive experiments based on real datasets verify that our algorithms are superior over baseline algorithms.

1 INTRODUCTION

Online social networks (OSN) is very commonly used in real life and it embeds a rich set of information that would be useful in applications from different fields such as social community, marketing business, political campaigns, etc. People are interested in knowing some information of graph properties such as counts of wedges, triangles, cliques, and k -node structures etc. embedded in OSNs. In the literature, researchers have studied problems of estimating degree distribution [7, 14, 16], clustering coefficient [11], graph size [11, 13] and graphlet statistics [5, 21]. These graph properties are usually defined based on the structural information, e.g., a triangle is a triplet of three nodes which are connected with one another via links.

We notice that graph properties based on the structure information correspond to information at a coarse level only, which may not be sufficient in some applications. For example, if an education institution considers to introduce a new Spanish course in Hong Kong, the most important step is to determine whether there are enough potential users who are likely to take this course in Hong Kong. One simple but efficient way is to estimate the number of links/friendships between a user living in Hong Kong and another user living in Spain in OSNs. The reason is that if a

user has Spanish friends, then it is likely that he/she will be interested in learning Spanish. Another example is that estimating the number of links/friendships between a user living in China and another user living in Austria in an OSN is an indicator of how many people from Austria and those from China interact with each other. Such information is very useful for airlines in web marketing and advertising, e.g., it could be used for decision making about whether or not to launch a new flight route between China and Austria. Thus, graph properties refined by some feature/label information of users (which are available in user's profiles in many cases) correspond to finer-grained information and could be highly valuable in real world application.

Motivated by this, we propose to estimate graph properties refined by users' labels. In this paper, we focus on one type of graph properties, namely the number of edges with some target labels. Specifically, given two target labels, we say that an edge is a *target edge* if one node of the edge has one target label and the other node has the other target label. For example, in the example of estimating the number of links between users living in Spain and those living in Hong Kong, "Spain" and "Hong Kong" could be used as two target labels and an edge between a user living in Spain and another user living in Hong Kong corresponds to a target edge. Then, the problem studied in this paper is to estimate the number of target edges for two given target labels.

Existing solutions of estimating graph properties (based on the structural information only) do not pay any attention to users' labels and thus, they could not be used for our problem of estimating graph properties (based on both the structural information and the information of users' labels). Another branch of studies that is related to ours is labeled graph mining, such as graph classification [20], subgraph mining [3, 4, 9] and label prediction [24]. However, these solutions all assume full access to the graph, which is not true when dealing with OSNs as we do in this paper since OSNs are only accessible via provided APIs [11, 13].

To solve the problem of estimating the number of target edges, we develop two algorithms, namely, NeighborSample and NeighborExploration, both of which are based on a random walk on the graph and sample a set of edges or nodes. NeighborSample samples a set of k edges with k iterations, at each iteration it samples one edge by sampling a user via a random walk process and then sampling a neighbor of this user. NeighborExploration samples a set of nodes with k iterations via a random walk process and also explores all neighbors of each sampled node and records the number of target edges incident to the sampled node, if the sampled node involves a target label (with the purpose of sampling target edges with higher probabilities). Then, based on the

sample set, we construct unbiased estimators using some statistical techniques. For each estimator, we conduct some theoretical analysis on the relationship between the number of samples and the corresponding accuracy guarantees.

In summary, our main contributions are as follows. First, we propose to estimate graph properties refined by users' labels in OSNs, which, to the best of our knowledge, is the first attempt to do so. Second, we develop two algorithms for estimating the number of edges with target labels and provide theoretical analysis on the accuracy guarantees. Third, we conducted extensive experiments which verified that the algorithms developed in this paper are superior over baseline algorithms.

This paper is organized as follows. Section 2 reviews the related work. Section 3 provides some preliminaries and the problem definition. Section 4 introduces our proposed algorithms for estimating the number of edges with target labels. Section 5 presents the experiments and Section 6 concludes the paper and gives a few directions for future study.

2 RELATED WORK

In the literature, OSNs with restricted access and labeled graphs with full access are both popular topics, but to our knowledge, there has been no study about labeled graphs with restricted access, which we study in this paper.

A lot of work has been done on online social networks with restricted access and most existing work is based on random walk methods, which have been used for estimating degree distribution [7, 14, 16], clustering coefficients [11] and graph size [11, 13]. In [14], the authors introduced a non-backtracking random walk method, which is more efficient than traditional random walk for estimating degree distribution. In [11], the authors proposed simple but efficient sampling algorithms for estimating the clustering coefficient and the graph size via simple random walk. In addition, node pairs sampling in OSNs has also been studied in [22]. Recently, Chen et al. [5] proposed the state-of-the-art random walk based algorithms for graphlets statistics using the concepts of subgraph relationship graphs and expanded Markov Chain.

Labels in graph are widely used in many applications, which has attracted much attention from researchers and a considerable amount of work has been done on labeled graphs. Particularly, it has been studied in the area of subgraph mining a lot. In [9], the authors studied the problem of mining frequent neighbourhood pattern in labeled graphs and in [4], a method for mining significant connected subgraph in labeled graphs is proposed. Anchuri et al. consider the difference between labels as a cost and introduce an algorithm for mining approximate subgraph patterns with label cost [3]. Labels are also used in graph classification. In [20], the authors proposed an algorithm for classifying labeled nodes based on structural neighbourhood. Recently, Ye et al. [24] considered a new scenario where only very few vertices have labels compared to large amounts of unlabeled vertices, and proposed an algorithm which leverages the limited user information and friendship network wisely to infer the labels of unlabeled users in OSNs.

3 PRELIMINARIES AND PROBLEM DEFINITION

In this section, we first introduce some basic notations, and then give a formal definition of the problem.

An OSN is represented as an undirected graph $G(V, E)$, where a user corresponds to a node in V and a friendship between two users corresponds to an edge in E . For each user u in G , we denote u 's degree by $d(u)$, i.e., $d(u)$ corresponds to the number of u 's friends. Each user/node in V has a set of labels such as this user's gender, profession, living country etc. which could be found out in most cases by checking users' profile. For an edge (u, v) , we define its label as a pair of two labels, one is a label of u and the other is a label of v .

Let t_1 and t_2 be two target labels. We say that an edge (u, v) is a *target edge* if the edge has the pair of t_1 and t_2 as one of its labels, i.e., either u has t_1 and v has t_2 , or v has t_1 and u has t_2 . We say that (t_1, t_2) is the target edge label. Let F be the number of target edges. In this paper, we study the problem of estimating F with the following assumptions: (1) we have no full access to the graph $G(V, E)$ but only some limited access via APIs each of which can be used to retrieve the list of friends/neighbors of a given user; (2) the information of $|V|$ and $|E|$ is available as prior knowledge (this is reasonable since this information can be often obtained from the OSN owner's reports or Internet, and in case that such information is not publicly available, some existing methods such as [11] and [23] could be used to estimate $|V|$ and $|E|$, respectively).

We also derive the bound on the sample size which can achieve an (ϵ, δ) -approximation estimation of F . The \hat{F} which satisfies the following equation is an (ϵ, δ) -approximation estimation of F .

$$P[(1 - \epsilon)F < \hat{F} < (1 + \epsilon)F] \geq 1 - \delta \quad (1)$$

4 ESTIMATORS OF NUMBER OF EDGES WITH TARGET LABEL

We propose to estimate the number of edges with target labels by first sampling a set of edges or nodes and then constructing an (un-biased) estimator based on the set of sampled edges or nodes. In the following, we introduce two algorithms, one for sampling edges and the other for sampling nodes, both of which are based on a random walk on the graph. The first one, as presented in Section 4.1, is called *NeighborSample* and samples a set of k edges with k iterations at each of which it samples one edge by sampling a user via a random walk process and then sampling a neighbor of this user. The second one, as presented in Section 4.2, is called *NeighborExploration* and samples a set of nodes with k iterations via a random walk process and also explores all neighbors of each sampled node and records the number of target edges incident to the sampled node, if the sampled node involves a target label (with the purpose of sampling target edges with higher probabilities).

For each sampling algorithm, we use Hansen-Hurwitz estimator [10], Horvitz-Thompson estimator [12] and Re-weighted estimator [17] to estimate the number of target edges. Hansen-Hurwitz estimator and Horvitz-Thompson estimator are two simple and widely used estimator when samples are sampled with unequal probabilities, and Re-weighted estimator is an estimator based on the Hansen-Hurwitz estimator.

4.1 Estimation Based on NeighborSample

4.1.1 Sampling Process. NeighborSample samples a set S of k edges with k iterations. At each iteration, it samples an edge by sampling a user u via simple random walk first and then randomly picking one of u 's neighbors, says v (i.e., (u, v) corresponds to the edge sampled at this iteration). The pseudo-code of NeighborSample is presented in Algorithm 1.

Algorithm 1 NeighborSample

Require: an online social network $G(V, E)$ accessible via APIs

- 1: $S \leftarrow \emptyset$
 - 2: **for** $i: 1 \leftarrow k$ **do**
 - 3: Sample a user u_i via simple random walk
 - 4: Sample a neighbor v_i of u_i randomly
 - 5: $S \leftarrow S \cup (u_i, v_i)$
 - 6: **end for**
 - 7: **Return** S
-

Based on the sampling process, we construct two different estimators, one is based on the *Hansen-Hurwitz Estimator* and the other is based on the *Horvitz-Thompson Estimator*.

4.1.2 Hansen-Hurwitz Estimator. We define X_i ($1 \leq i \leq k$) to be the edge sampled at the i^{th} iteration of the sampling process. Consider the distribution of X_i . First, X_i could be any edge $(u, v) \in E$. Second, an edge (u, v) is sampled if and only if the following two events happen: (E1) u is sampled by the random walk (line 3 in Algorithm 1) and then v , as one of u 's neighbors, is picked (line 4 in Algorithm 1) and (E2) v is sampled by the random walk (line 3 in Algorithm 1) and then u , as one of v 's neighbors, is picked (line 4 in Algorithm 1). Third, the probability of event E1 is equal to $\frac{d(u)}{2|E|} \cdot \frac{1}{d(u)} = \frac{1}{2|E|}$ (the probability that u is sampled by the random walk is equal to $\frac{d(u)}{2|E|}$ according to the stationary distribution of a random walk [8, 18] and the probability that one specific neighbor of u is sampled is equal to $\frac{1}{d(u)}$) and so is that of event E2. Therefore, the probability that X_i corresponds to any edge (u, v) , denoted by $\pi(X_i = (u, v))$, is equal to $\frac{1}{2|E|} + \frac{1}{2|E|} = \frac{2}{2|E|} = \frac{1}{|E|}$, i.e., X_i corresponds to a uniform sample from the set of edges.

Now, consider $\frac{I(X_i)}{\pi(X_i)}$ which is also a random variable, where $I(X_i)$ is an indicator function and $I(X_i) = 1$ if X_i is one target edge, and 0 otherwise. We deduce that $E[\frac{I(X_i)}{\pi(X_i)}] = \sum_{X_i \in E} I(X_i) = F$. Based upon on this, we construct an estimator of F as $\frac{I((u_i, v_i))}{\pi(X_i = (u_i, v_i))} = |E| \cdot I((u_i, v_i))$, which could be verified to be unbiased. Since in each iteration, we can construct such an estimator, we use the average of these estimators as the final estimator, which is presented as follows.

$$\hat{F} = \frac{1}{k} \sum_{1 \leq i \leq k} |E| \cdot I(X_i) = \frac{1}{k} \sum_{1 \leq i \leq k} |E| \cdot I((u_i, v_i)) \quad (2)$$

This estimator corresponds to a Hansen-Hurwitz estimator [10].

Implementation. A straightforward implementation of the NeighborSample sampling process as shown in Algorithm 1 would perform k random walk processes. We note that performing a random walk process is costly since it needs to walk for some enough steps (which corresponds to the *mixing time* [6] of the random walk) in order to achieve the stationary distribution, where each walk from one user to one of her neighbors requires to issue an API call. Fortunately, we observe that the above estimator does not require to sample edges (u_i, v_i) ($1 \leq i \leq k$) independently, and thus we propose to sample all these edges using a *single* random walk process. Specifically, it performs a enough number of simple random walk steps first (i.e., the mixing time is achieved) and then continues to walk for k steps further, each via an edge. At the end, it picks those edges it walks through at the last k steps as the sampled edges. In this way, k edges are sampled via only a single random process and as could be verified, the probability that one sampled edge corresponds

to a specific edge in the graph is still equal to $\frac{1}{|E|}$ and thus the estimator constructed above is still valid.

Analysis. In this part, we derive theoretical results on the number of edges to sample in order to achieve some pre-set accuracy guarantee.

THEOREM 4.1. *Let $1 > \delta > 0$, $\epsilon \leq 1$ and $k \geq 1$. Sampling k edges in NeighborSample will return an (ϵ, δ) -approximation estimation of F by the Hansen-Hurwitz estimator, if*

$$k \geq \frac{\sum_{X \in E} |E| \cdot I(X) - F^2}{\epsilon^2 \cdot F^2 \cdot \delta}$$

PROOF. Since $F = E[\frac{I(X_i)}{\pi(X_i)}]$, if $\frac{1}{k} \sum_{i=1}^k \frac{I(X_i)}{\pi(X_i)}$ is an (ϵ, δ) -approximation estimation of $E[\frac{I(X_i)}{\pi(X_i)}]$, then \hat{F} is also an (ϵ, δ) -approximation estimation of F .

Let $Y = \frac{1}{k} \sum_{i=1}^k \frac{I(X_i)}{\pi(X_i)}$, then $E[Y] = F$ and $Var[Y] = \frac{1}{k} (E[\frac{I(X_i)^2}{\pi(X_i)^2}] - E[\frac{I(X_i)}{\pi(X_i)}]^2) = \frac{1}{k} \cdot \sum_{X \in E} \frac{I(X)}{\pi(X)} - F^2$ and $E[Y] = F$. By Chebyshev's inequality (see Appendix A), we obtain the bound of k for achieving (ϵ, δ) -approximation.

$$k \geq \frac{\sum_{X \in E} |E| \cdot I(X) - F^2}{\epsilon^2 \cdot F^2 \cdot \delta} \quad \square$$

4.1.3 Horvitz-Thompson Estimator. For each edge $e = (u, v) \in E$, we define a new indicator function $H(e \in S)$ such that $H(e \in S)$ is equal to 1 if e is sampled by the NeighborSample sampling process once or multiple times, and 0 otherwise. We define $Pr(e)$ as the probability that an edge e is sampled in at least one iteration of the NeighborSample sampling process, i.e., $e \in S$. Consider $Pr(e)$ for a specific edge e , we observe that the event that e is not sampled happens if and only if all following k events happen: e is not sampled in the i^{th} iteration for $1 \leq i \leq k$. Considering that the probability that each of these events happens is equal to $(1 - \frac{1}{|E|})$ and these events are independent, we know that the probability that e is not sampled in any of iterations is equal to $(1 - \frac{1}{|E|})^k$, which further implies that the probability that e is sampled in at least one of the iterations, i.e., $Pr(e)$, is equal to $1 - (1 - \frac{1}{|E|})^k$.

Then, we construct an estimator of F as follows.

$$\hat{F} = \sum_{e \in E} \frac{I(e)}{Pr(e)} H(e \in S) = \sum_{e \in E} \frac{I(e)}{1 - (1 - \frac{1}{|E|})^k} H(e \in S) \quad (3)$$

Next we show how this estimator is derived and that it is unbiased. Define $\{S_1, S_2, \dots, S_m\}$ as the collection of all possible sample sets each of which contains k edges from the edge set E . Let $P(S_i)$ be the probability that we get set S_i as the sample set in NeighborSample process. Let S be a random set from $\{S_1, S_2, \dots, S_m\}$, we have

$$\begin{aligned} E[\sum_{e \in E} \frac{I(e)}{Pr(e)} H(e \in S)] &= \sum_{j=1}^m P(S_j) \sum_{e \in E} \frac{I(e)}{Pr(e)} H(e \in S_j) \\ &= \sum_{e \in E} \frac{I(e)}{Pr(e)} \sum_{j=1}^m P(S_j) H(e \in S_j) \\ &= \sum_{e \in E} \frac{I(e)}{Pr(e)} Pr(e) = \sum_{e \in E} I(e) = F \end{aligned} \quad (4)$$

So the estimator $\hat{F} = \sum_{e \in E} \frac{I(e)}{Pr(e)} H(e \in S)$ is an unbiased estimator.

Implementation. Different from the case of the Hansen-Hurwitz estimator in Section 4.1.2, the Horvits-Thompson estimator requires that the edges sampled in different iterations are independent. With the implementation in Section 4.1.2, the edges sampled are not independent since the edge sampled at the current iteration is adjacent to the one sampled at the last iteration. To meet the independence requirement, we adopt an existing strategy [11], which is to use those vertices (and edges) which are

sampled far away from each other by a certain number r of steps in the random walk process, (in this way, every two sampled edges could be regarded as approximately independent sampled edges, and following [11], we set r as $2.5\%k$) in our experiments.

Analysis. In this part, we derive some theoretical results on the number of edges to sample in order to achieve some pre-set accuracy guarantee.

THEOREM 4.2. *Let $1 > \delta > 0$, $\epsilon \leq 1$ and $k \geq 1$. Sampling k edges in NeighborSample will return an (ϵ, δ) -approximation estimation of F by the Horvitz-Thompson estimator, if*

$$k \geq \max_{e \in E} \log \frac{I(e)^2 + B}{B} / \log \frac{1}{A(e)}$$

where $A(e) = 1 - \frac{1}{|E|}$ and $B = \delta \epsilon^2 \cdot F^2 / |E|$.

PROOF. Let $\pi_e = \frac{1}{|E|}$ be the probability of sampling edge e in one NeighborSample process. In [12], it has been proved that the variance of the Horvitz-Thompson estimator is

$$\begin{aligned} \text{Var}[\widehat{F}] &= E[\widehat{F}^2] - E[\widehat{F}]^2 \\ &= \sum_{e_1 \in E} \sum_{e_2 \in E} \frac{I(e_1)I(e_2)}{\Pr(e_1)\Pr(e_2)} E[H(e_1 \in S)H(e_2 \in S)] \\ &\quad - \sum_{e_1 \in E} \sum_{e_2 \in E} \frac{I(e_1)I(e_2)}{\Pr(e_1)\Pr(e_2)} E[H(e_1 \in S)]E[H(e_2 \in S)] \\ &= \sum_{e_1 \in E} \sum_{e_2 \in E} \frac{I(e_1)I(e_2)}{\Pr(e_1)\Pr(e_2)} \text{Cov}(H(e_1 \in S), H(e_2 \in S)) \end{aligned} \quad (5)$$

Since $\text{Cov}(H(e_1 \in S), H(e_2 \in S)) = \Pr(e_1, e_2) - \Pr(e_1)\Pr(e_2)$, where $\Pr(e_1, e_2) = \Pr(e_1) + \Pr(e_2) - (1 - (1 - \pi_{e_1} - \pi_{e_2})^k)$ for $e_1 \neq e_2$ and $\text{Cov}(H(e_1 \in S), H(e_2 \in S)) = \Pr(e_1)(1 - \Pr(e_1))$ for $e_1 = e_2$, so we have

$$\begin{aligned} \text{Var}[\widehat{F}] &= \sum_{e_1 \in E} \left(\frac{1 - \Pr(e_1)}{\Pr(e_1)} \right) I(e_1)^2 + \\ &\quad \sum_{e_1 \in E} \sum_{e_2 \in E, e_2 \neq e_1} \left(\frac{\Pr(e_1) + \Pr(e_2)}{\Pr(e_1)\Pr(e_2)} + \right. \\ &\quad \left. - \frac{\{1 - (1 - \pi_{e_1} - \pi_{e_2})^k\} - \Pr(e_1)\Pr(e_2)}{\Pr(e_1)\Pr(e_2)} \right) I(e_1)I(e_2) \end{aligned} \quad (6)$$

The second term in the right hand side of Equation (6) can be simplified as

$$\begin{aligned} &\sum_{e_1 \in E} \sum_{e_2 \in E, e_2 \neq e_1} \left(\frac{(1 - \pi_{e_1} - \pi_{e_2})^k}{\Pr(e_1)\Pr(e_2)} \right. \\ &\quad \left. - \frac{(1 - \pi_{e_1} - \pi_{e_2} + \pi_{e_1}\pi_{e_2})^k}{\Pr(e_1)\Pr(e_2)} \right) I(e_1)I(e_2) \end{aligned} \quad (7)$$

since $\pi_{e_1} = \pi_{e_2} = 1/|E| \geq 0$, it is obvious that $1 - \pi_{e_1} - \pi_{e_2} \leq 1 - \pi_{e_1} - \pi_{e_2} + \pi_{e_1}\pi_{e_2}$. As a result, the term 7 is also negative, so we can ignore this term. By Chebyshev's inequality (see Appendix A), we have

$$\sum_{e \in E} \left(\frac{(1 - \pi_e)^k}{1 - (1 - \pi_e)^k} \right) I(e)^2 \leq \delta \epsilon^2 \cdot F^2 \quad (8)$$

so if

$$\left(\frac{(1 - \pi_e)^k}{1 - (1 - \pi_e)^k} \right) I(e)^2 \leq \delta \epsilon^2 \cdot F^2 / |E| \quad (9)$$

holds for each $e \in E$, then Equation (8) also holds.

Define $A(e) = 1 - \pi_e$ and $B = \delta \epsilon^2 \cdot F^2 / |E|$, then we obtain the bound of k for achieving (ϵ, δ) -approximation.

$$k \geq \max_{e \in E} \log \frac{I(e)^2 + B}{B} / \log \frac{1}{A(e)} \quad (10)$$

□

4.2 Estimation Based on NeighborExploration

4.2.1 Sampling Process. NeighborExploration samples a set S of nodes with k iterations for a given integer k . At each iteration, it first samples a node by a random walk process and then explores *all* edges incident to u if u involves a target label. The

Algorithm 2 NeighborExploration

Require: an online social network $G(V, E)$ accessible via APIs
Require: a pair of two target labels t_1 and t_2

- 1: $S \leftarrow \emptyset$
 - 2: **for** $i: 1 \leftarrow k$ **do**
 - 3: Sample a user u_i via simple random walk
 - 4: **if** u_i has label t_1 or label t_2 **then**
 - 5: Explore all the neighbors of u_i and compute the number of target edges incident to u_i and we use function T to record the mapping from u_i to the number of target edges incident to u_i .
 - 6: **end if**
 - 7: $S \leftarrow S \cup u_i$
 - 8: **end for**
 - 9: **Return** S and function T
-

rationale of exploring all neighbors of the user u is that once we know that u has a target label, the probability that we can find a target edge incident to u would be relatively high since one of the two target labels has been covered already. The pseudo-code of NeighborExploration is presented in Algorithm 2.

4.2.2 Hansen-Hurwitz Estimator. We define a random variable Y_i to be the node sampled at i^{th} iteration of NeighborExploration sampling process. Y_i could be any user $u \in V$ and the probability that Y_i corresponds to a specific user u , denoted by $\pi(Y_i = u)$, is equal to $\frac{d(u)}{2|E|}$ which is based on the stationary distribution of a simple random walk. We define $T(Y_i)$ as the number of target edges incident to Y_i , which also corresponds to a random variable and could be computed when all neighbors of Y_i are explored after we sample Y_i in the random walk process.

Now, consider $\frac{T(Y_i)}{\pi(Y_i)}$ which is also a random variable. We deduce that $E[\frac{T(Y_i)}{\pi(Y_i)}] = \sum_{u \in V} T(u) = 2 \cdot F$. Based upon on this, we construct an estimator of F as $\frac{T(Y_i)}{2 \cdot \pi(Y_i)}$ which could be easily verified to be unbiased. Since in each iteration, we can construct such an estimator, we use the average of these estimators as the final estimator, which is presented as follows.

$$\hat{F} = \frac{1}{k} \sum_{1 \leq i \leq k} \frac{T(Y_i)}{2 \cdot \pi(Y_i)} = \frac{1}{k} \sum_{1 \leq i \leq k} \frac{|E| \cdot T(u_i)}{d(u_i)} \quad (11)$$

This estimator corresponds to a Hansen-Hurwitz estimator [10].

Implementation. Same as the case in Section 4.1.2, the estimator here does not require that the sampled nodes are independent. As a result, it can sample all nodes via a single random process by performing an enough number of simple random walk steps first (i.e., the mixing time is achieved) and then continuing to walk for k steps further. At each of the last k steps, it checks whether the current user u involves a target label. If so, it explores all edges incident to this user, and records $T(u)$.

Analysis. In this part, we derive some theoretical results on the number of nodes to sample in order to achieve some pre-set accuracy guarantee.

THEOREM 4.3. *Let $1 > \delta > 0$, $\epsilon \leq 1$ and $k \geq 1$. Sampling k nodes in NeighborExploration will return an (ϵ, δ) -approximation estimation of F by the Hansen-Hurwitz estimator, if*

$$k \geq \frac{\sum_{u \in V} \frac{2|E| \cdot T(u)^2}{d(u)} - 4F^2}{4\epsilon^2 \cdot F^2 \cdot \delta}$$

PROOF. Since $F = \frac{1}{2}E[\frac{T(Y_i)}{\pi(Y_i)}]$, if $\frac{1}{k}\sum_{i=1}^k \frac{T(Y_i)}{\pi(Y_i)}$ is an (ϵ, δ) -approximation estimation of $E[\frac{T(Y_i)}{\pi(Y_i)}]$, then \hat{F} is also an (ϵ, δ) -approximation estimation of F .

Let $X = \frac{1}{k}\sum_{i=1}^k \frac{T(Y_i)}{\pi(Y_i)}$, then $E[X] = 2F$ and $Var[X] = \frac{1}{k}(E[\frac{T(Y)^2}{\pi_Y^2}] - E[\frac{T(Y)}{\pi_Y}]^2) = \frac{1}{k} \cdot \sum_{u \in N} \frac{T(u)^2}{\pi_u} - 4F^2$. By Chebyshev's inequality (see Appendix A), we obtain the bound of k for achieving (ϵ, δ) -approximation.

$$k \geq \frac{\sum_{u \in V} \frac{2|E| \cdot T(u)^2}{d_u} - 4F^2}{4\epsilon^2 \cdot F^2 \cdot \delta} \quad (12)$$

□

4.2.3 Horvitz-Thompson Estimator. We define an indicator function $H(u \in S)$ such that $H(u \in S)$ is equal to 1 if u is sampled by the NeighborExploration sampling process once or multiple times, and 0 otherwise. S is the sample set obtained from the NeighborExploration sampling process. Then, we define $Pr(u)$ as the probability that a node u is sampled in at least one iteration of the NeighborExploration sampling process, i.e., $u \in S$. Consider $Pr(u)$ for a specific node u . We observe that the event that u is not sampled happens if and only if all following k events happen: u is not sampled in the i^{th} iteration for $1 \leq i \leq k$. Considering that the probability that one of these events happens is equal to $(1 - \frac{d(u)}{2|E|})$, and these events are independent, we know that the probability that u is not sampled in any of iterations is equal to $(1 - \frac{d(u)}{2|E|})^k$, which further implies that the probability that u is sampled in at least one of the iteration, i.e., $Pr(u)$ is equal to $(1 - (1 - \frac{d(u)}{2|E|})^k)$.

Then, we construct a Horvitz-Thompson estimator of the number of target edges as follows.

$$\hat{F} = \frac{1}{2} \sum_{u \in V} \frac{T(u)}{Pr(u)} H(u \in S) = \frac{1}{2} \sum_{u \in V} \frac{T(u)}{1 - (1 - \frac{d(u)}{2|E|})^k} H(u \in S) \quad (13)$$

This estimator could be verified to be unbiased similarly as it is done for the Horvitz-Thompson estimator based on Neighbor-Sample in Section 4.1.3.

Implementation. Also, the Horvitz-Thompson estimator requires that the nodes sampled in different iterations are independent. With the implementation in Section 4.2.2, the nodes sampled are not independent since the node sampled at the current iteration is adjacent to the one sampled at the last iteration. To meet the independence requirement, we use the same strategy introduced in 4.1.3, which is to use those nodes which are sampled far away from each other by a certain number r of steps in the random walk process, and we set r as $2.5\%k$.

Analysis. In this part, we derive theoretical results on the number of nodes to sample in order to achieve some pre-set accuracy guarantee.

THEOREM 4.4. *Let $1 > \delta > 0$, $\epsilon \leq 1$, and $k \geq 1$. Sampling k nodes in NeighborExploration will return an (ϵ, δ) -approximation estimation by the Horvitz-Thompson estimator, if*

$$k \geq \max_{y \in V} \log \frac{T(y)^2 + B}{B} / \log \frac{1}{A(y)}$$

where $A(y) = 1 - \pi_y$ and $B = 4\delta\epsilon^2 \cdot F^2 / |V|$.

PROOF. Let $\pi_y = \frac{d_y}{2|E|}$ be the probability of sampling node y in the random walk process. In [12], it has been proved that the

variance of the Horvitz-Thompson estimator is

$$Var[\hat{F}] = \frac{1}{4} \{ \sum_{y \in V} (\frac{1 - Pr(y)}{Pr(y)}) T(y)^2 + \sum_{y \in V} \sum_{z \in V, z \neq y} (\frac{Pr(y) + Pr(z)}{Pr(y)Pr(z)} - \frac{-\{1 - (1 - \pi_y - \pi_z)^k\} - Pr(y)Pr(z)}{Pr(y)Pr(z)}) T(y)T(z) \} \quad (14)$$

The second term in the right hand side of Equation (14) can be simplified as

$$\sum_{y \in V} \sum_{z \in V, z \neq y} (\frac{(1 - \pi_y - \pi_z)^k}{Pr(y)Pr(z)} - \frac{(1 - \pi_y - \pi_z + \pi_y \pi_z)^k}{Pr(y)Pr(z)}) T(y)T(z) \quad (15)$$

since $\pi_y = d_y / (2|E|) \geq 0$, it is obvious that $1 - \pi_y - \pi_z \leq 1 - \pi_y - \pi_z + \pi_y \pi_z$. As a result, term (15) is negative, so we can ignore this term. Then By Chebyshev's inequality (see Appendix A), we have

$$\sum_{y \in V} (\frac{(1 - \pi_y)^k}{1 - (1 - \pi_y)^k}) T(y)^2 \leq 4\delta\epsilon^2 \cdot F^2 \quad (16)$$

so if

$$(\frac{(1 - \pi_y)^k}{1 - (1 - \pi_y)^k}) T(y)^2 \leq 4\delta\epsilon^2 \cdot F^2 / |V| \quad (17)$$

holds for each $y \in V$, then Equation (16) also holds.

Define $A(y) = 1 - \pi_y$ and $B = 4\delta\epsilon^2 \cdot F^2 / |V|$, we can get the bound of k ,

$$k \geq \max_{y \in V} \log \frac{T(y)^2 + B}{B} / \log \frac{1}{A(y)} \quad (18)$$

□

4.2.4 Re-Weighted Estimator. Based on the NeighborExploration sampling process, the nodes are sampled with non-uniform probabilities, which is different from the case based on the NeighborExploration sampling process. This makes it possible to construct a *Re-weighted* estimator [17] as follows.

$$\hat{F} = \frac{\sum_{i=1}^k T(u_i) / d(u_i)}{2 \sum_{i=1}^k 1 / d(u_i)} \cdot |V| \quad (19)$$

Here, u_i corresponds to the user sampled via the random walk process in i^{th} iteration. It was known that the Re-weighted estimator can be interpreted using the *importance sampling* (IS) framework [17]. Specifically, instead of sampling nodes from the target distribution (i.e., the uniform distribution), the IS framework samples edges from a different and easily implemented trial distribution (i.e., the stationary distribution of a random walk process). According to the IS framework, the importance weight of a user u is given by $\frac{1/|V|}{d(u)/2|E|} \propto 1/d(u)$, which meets the definition in Equation (19), where $1/|V|$ corresponds to the probability based on the target distribution and $d(u)/2|E|$ corresponds the probability based on trial distribution.

Implementation. Same as the Hansen-Hurwitz estimator in Section 4.2.2, the Re-weighted estimator constructed here does not require that the nodes sampled are independent, and thus the implementation described in Section 4.2.2, which samples all nodes with one single random walk process, could be applied.

Analysis. In this part, we derive theoretical results on the number of nodes to sample in order to achieve some pre-set accuracy guarantee.

THEOREM 4.5. *Let $1 > \delta > 0$, $\epsilon \leq 1$ and $k \geq 1$. Sampling k nodes in NeighborExploration will return an (ϵ, δ) -approximation estimation of F the by the Re-Weighted estimator, if*

$$k \geq \max \{ 18 \frac{\sum_{y \in V} \frac{T(y)^2}{\pi_y} - 4F^2}{\epsilon^2 \cdot 4F^2 \cdot \delta}, 18 \frac{\sum_{y \in V} \frac{1}{\pi_y} - |V|^2}{\epsilon^2 \cdot |V|^2 \cdot \delta} \}$$

PROOF. Let Y be a random node sampled from one random walk step and $\pi_Y = \frac{d(Y)}{2|E|}$ be the probability of sampling node Y in the random walk process. Since $F = E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}] \cdot \frac{|V|}{2}$ and $\widehat{F} = \frac{E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}]}{E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}]} \cdot \frac{|V|}{2}$, if $E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}]$ is an (ϵ, δ) -approximation estimation of $E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}]$, then \widehat{F} is also an (ϵ, δ) -approximation estimation of F .

Assume that $E[\frac{T(Y)}{\pi_Y}]$ and $E[\frac{1}{\pi_Y}]$ are $(\epsilon/3, \delta/2)$ -approximation estimations of $E[\frac{T(Y)}{\pi_Y}]$ and $E[\frac{1}{\pi_Y}]$ respectively. Let $A = \frac{E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}]}{E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}]}$ and $B = \frac{E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}]}{E[\frac{1}{\pi_Y}]}$, then we have $P[A/B > \frac{1-\epsilon/3}{1+\epsilon/3}] > 1 - \epsilon, A/B < \frac{1+\epsilon/3}{1-\epsilon/3} > 1 + \epsilon \geq (1 - \delta/2)^2 > 1 - \delta$. So $E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}]$ is an (ϵ, δ) -approximation estimation of $E[\frac{T(Y)}{\pi_Y}]/E[\frac{1}{\pi_Y}]$.

Let $X = \frac{1}{k} \sum_{i=1}^k \frac{T(y_i)}{\pi_{y_i}}$ and $Z = \frac{1}{k} \sum_{i=1}^k \frac{1}{\pi_{y_i}}$. By Chebyshev's inequality in Appendix A, we have

$$Pr[|X - E[X]| > \epsilon/3 \cdot E[X]] \leq \frac{Var[X]}{(\epsilon/3 \cdot E[X])^2} \leq \delta/2 \quad (20)$$

$$Pr[|Z - E[Z]| > \epsilon/3 \cdot E[Z]] \leq \frac{Var[Z]}{(\epsilon/3 \cdot E[Z])^2} \leq \delta/2 \quad (21)$$

Since $E[X] = 2F, Var[X] = \frac{1}{k} (E[\frac{T(Y)^2}{\pi_Y^2}] - E^2[\frac{T(Y)}{\pi_Y}]) = \frac{1}{k} (\sum_{y \in V} \frac{T(y)^2}{\pi_y} - 4F^2), E[Z] = |V|$ and $Var[Z] = \frac{1}{k} (E[\frac{1}{\pi_Y^2}] - E^2[\frac{1}{\pi_Y}]) = \frac{1}{k} (\sum_{y \in V} \frac{1}{\pi_y} - |V|^2)$, we have

$$k \geq \max\left\{18 \frac{\sum_{y \in V} \frac{T(y)^2}{\pi_y} - 4F^2}{\epsilon^2 \cdot 4F^2 \cdot \delta}, 18 \frac{\sum_{y \in V} \frac{1}{\pi_y} - |V|^2}{\epsilon^2 \cdot |V|^2 \cdot \delta}\right\} \quad (22)$$

□

5 EXPERIMENTAL RESULTS

5.1 Experimental Set-up

Datasets. We used 5 real datasets which are publicly available and widely used in previous work [5, 11, 13] as shown in Table 1. In the experiment, we simulate the scenario where we only have accesses to the graphs via APIs. In each network, we remove the directions of edges, self-loops and multi-edges. We use the largest connected component for each network (since the method could be similarly run on other connected components) and the statistics of the largest connected components of networks are shown in Table 1.

In order to show the efficiency and effectiveness of our algorithms comprehensively, we use several types of labels to evaluate our algorithms. In Facebook and Google+, we use users' genders as node labels. In Pokec, we use users' locations as node labels. Such information can be obtained in the users' profiles in these networks. While in Orkut and Livejournal, the node degree is considered as the node label since we do not have the users' profiles in these two networks. Node degree contains structural information about the graph and in OSNs, it shows the number of friends that the user has. In order to simplify the discussion, all the labels are denoted by integers in the experiments.

Mixing Time. The mixing time of the Markov Chain is defined as the minimal length of the random walk in order to reach the stationary distribution. Following [2, 19], we define the mixing time of a Markov chain on G parameterized by a variation distance parameter ϵ as follows,

Definition 5.1. The mixing time parameterized by ϵ of a Markov Chain is defined as

$$T(\epsilon) = \max_i \min\{t : |\pi - \pi^{(i)}|_1 < \epsilon\} \\ = \max_i \min\{t : \frac{1}{2} \sum_{u \in V} |\pi(u) - [\pi^{(i)} P^t](u)| < \epsilon\} \quad (23)$$

where vector π is the stationary distribution and P is the transition matrix. Vector $\pi^{(i)}$ is the initial distribution concentrated at node i , i.e. the i -th element is 1 and all the other elements are 0. $[\pi^{(i)} P^t](u)$ is the u -th element in $\pi^{(i)} P^t$. $|\pi - \pi^{(i)}|_1$ is the total variation distance which is a distance measure of two probability distributions.

After testing, we find that when $\epsilon = 10^{-3}$ which is small enough, the mixing time of Facebook, Google+, Pokec, Orkut and Livejournal is 3200, 200, 100, 800 and 900 respectively which are not very large. So it is easy to achieve the stationary distribution quickly in our experiments. Note that the nodes or edges encountered in the random walk before the mixing time are not included in the sample set.

Table 1: Statistics of Datasets

Existing algorithm using General Maximum Degree Random Walk Algorithm on Edges	EX-GMD

Adaptations of Existing Algorithms. In addition to the two algorithms and their five corresponding estimators developed in this paper, we consider a few baseline methods adapted from an existing study [16]. In [16], the authors have summarized several common used algorithms which perform random walk on nodes to get unbiased estimation of the relative count of target nodes which has a particular degree. If we multiply this estimation by the total number of nodes, then we can obtain the estimation of the count of target nodes. Those existing methods cannot be applied directly to our problem, since our problem is to estimate the number of target edges instead of target nodes. However, we find that if we transform the original graph G into a new graph G' , then we can apply those existing algorithms in [16] on graph G' to get the estimation of the count of target edges in G . We first describe how to construct G' base on G .

Let $G = (V, E)$ be the given graph, we construct a new graph $G' = (H, R)$ based on G with the following properties,

- Each edge in G corresponds to a node in G' and all these nodes constitute the node set H in G' . Thus, we have $|H| = |E|$.
- Two nodes in H are connected by an edge in G' if and only if they share one common vertex of G and all these edges constitute R .

where V and E are node set and edge set in G , and H and R are node set and edge set in G' .

It is obvious that if we apply the existing algorithms in [16] on graph G' , then we can get the estimation of the count of target nodes in G' . Since each node in G' corresponds to an edge in G , counting the number of target edges in G is the same as counting the number of target nodes in G' .

In [16], three existing algorithms, Re-weighted method, Metropolis-Hastings Random Walk algorithm (MHRW), and Maximum Degree Random Walk algorithm (MDRW), are reviewed by the authors. Also, two new algorithms, Rejection-controlled Metropolis-Hastings Random Walk algorithm (RCMH) and General Maximum Degree Random Walk algorithm (GMD), are proposed by the authors. Two parameters, α and δ , are used to control the performance of RCMH and GMD, respectively. The authors suggested to set $\alpha \in [0, 0.3]$ and $\delta \in [0.3, 0.7]$, and in this paper, we adopt settings which give the best results.

The abbreviation of each tested algorithm is shown in Table 2, and all algorithms are implemented in C++, and we conducted experiments on a Linux machine with Intel 3.40GHz CPU.

Measurements. We adopt the *normalized root mean square error* (NRMSE) measure as our error measurement, which is defined as follows.

$$\text{NRMSE}(\hat{F}) = \frac{\sqrt{\mathbb{E}[(\hat{F}-F)^2]}}{F} = \frac{\sqrt{\text{Var}[\hat{F}] + (F - \mathbb{E}[\hat{F}])^2}}{F}, \quad (24)$$

Note that NRMSE captures both the variance and the bias of the estimator.

Objectives. The objectives of the experiments can be summarized as follows:

- (1) The diversity of the network types and corresponding label types serve to show that our methods sustain satisfactory performance across different domains.
- (2) The different types of labels in different networks have very different frequencies. This helps us to investigate the effect of target edge frequency on the accuracy of the estimation.
- (3) Another factor which can affect the accuracy is the sample size, we expect the accuracy to improve with more samples taken. Hence in our experiments, we vary the sample sizes and examine the impact.
- (4) A major objective is to compare our proposed methods with the baseline methods, which are outlined in Section 5.1. We aim to show that our proposed algorithms outperform these baseline methods.
- (5) Since we propose two algorithms, NeighborSample and NeighborExploration, it is of interest to compare the two and find out how they differ and how to choose between these algorithms depending on the given problem characteristics.

5.2 Comparison among algorithms with varying sample size

Firstly, we compare the estimation accuracies of different algorithms. We examine the NRMSE results of different algorithms

Table 3: The labels and their corresponding locations in Pokec

Label	Location
2	zilinsky kraj, kysucke nove mesto
13	zahranicie, zahranicie - australia
20	kosicky kraj, michalovce
24	trnavsky kraj, trnava
51	trnavsky kraj, skalica
86	bratislavsky kraj, bratislava - nove mesto
122	kosicky kraj, kosice - ostatne
135	banskobystricky kraj, dudince

while varying the sample size from $0.5\%|V|$ to $5\%|V|$. Each target edge label is represented in the form of (A, B) where A and B are two integers representing two node labels.

In Facebook and Google+, we use one target edge label (1, 2) (1 and 2 represent female and male respectively), while in Pokec, Orkut and Livejournal, we pick 4 different target edge labels to evaluate all algorithms. The results on Facebook are shown in Table 4. The results on Google+ are shown in Table 5. The results on Pokec are shown in Tables 6 - 9 (We use 4 target edge labels, (86,135), (2,51), (13,20), and (24,122). All these numbers represent locations using Slovak language, which are shown in Table 3). The results on Orkut are shown in Tables 10 - 13. The results on Livejournal are shown in Tables 14 - 17.

In these tables, each row shows the NRMSE of an algorithm with increasing sample size and each column shows the NRMSE of each algorithm for a fixed sample size. The target edge label, the count and the percentage count of the target edges are shown in the caption of each table. Each NRMSE value is calculated by averaging over 200 independent simulations.

In Pokec, Orkut and Livejournal, there are thousands of edge labels we can choose. We first order those edge labels in ascending order of the count of target edges and divide them into 4 parts with equal size, then we pick one target edge label from each part randomly. With this method, we can test our algorithms on both high frequency edge labels and low frequency edge labels.

Tables 18 - 22 show the bounds of number of samples needed to achieve an $(0.1, 0.1)$ -approximation based Theorem 4.1 - 4.5. However, from the experimental results in Tables 4 - 17, we find that the number of samples needed to achieve a good estimation is much less than the bound.

The best NRMSE results for each sample size are underlined and marked with bold font. The best NRMSE results and the corresponding algorithms are also summarized in Tables 23 - 26 when $5\%|V|$ API calls are used.

We summarize our findings as follows.

- (1) The best algorithm in each table is always one of our newly proposed algorithms (NeighborSample and NeighborExploration), demonstrating that our new algorithms outperform adaptations of existing algorithms.
- (2) Our algorithms give good estimation with low API cost. Tables 23 - 26 summarize the best algorithms and the corresponding NRMSE values of each tested label when only $5\%|V|$ API calls are used. The largest NRMSE is 0.209 and most of the NRMSE values are smaller than 0.1. Note that for some tested target labels, the number of target edges is relatively small compared with the total number of edges, while our algorithms can still obtain accurate estimations. This shows that our proposed algorithms are highly effective.
- (3) The NRMSE results of all algorithms decrease as the number of API calls increases, which means that our estimation

converges to the ground truth when more samples or API calls are used. This behavior is as expected.

- (4) In most of the cases, NeighborExploration returns the best estimations. However, NeighborSample outperforms NeighborExploration in the cases where the target edges constitute a larger proportion in the whole edge set. This is the case for the results of facebook and google+. This indicates that when the target edges are abundant, neighborhood exploration is not needed to boost the sampling probability for the target edges.
- (5) For the datasets of Orkut and Livejournal, we have multiple sets of results for edge labels with different frequencies. It is found that the NRMSE values for more frequent labels are generally smaller than those with less frequent labels. We have therefore conducted a more systematic study about the impact of the label frequency, to be reported in the next subsection.

5.3 Comparison among algorithms with varying relative count of target edges

We notice that in the same graph, for different target labels the best algorithms can be different. It turns out that the relative count of target edges ($F/|E|$) may also affect the performance of different algorithms. In order to study the relationship between the performance of different algorithms and the relative count of target edges, we measure the values of NRMSE for a range of $F/|E|$. The results for Orkut and Livejournal are plotted in Figure 1 and Figure 2. Each node in these figures corresponds a target edge label and the x-coordinate is the relative count of edges with this label and the y-coordinate is the NRMSE of the target edge count estimation when $5\%|V|$ API calls are used. Here, we only run experiments on two networks, Orkut and Livejournal, since the range of the relative count of target edges in Orkut and Livejournal is much larger than the ranges in other

networks, so the change of NRMSE is more obvious in these two networks when the relative count of target edges varies. The results of existing algorithms are not shown, since we have demonstrated that those algorithms are much less competitive in the previous experiments. Each NRMSE value is calculated by averaging over 200 independent simulations.

We summarize our results as follows.

- (1) In the same network, as the relative count of target edges increases, the NRMSE results of all algorithms decrease, which means that the estimation is more accurate. This is reasonable, since the probability of sampling target edges in random walk will be higher if there are more target edges in the networks, which will result in better estimations.
- (2) When the relative count of target edges changes the best algorithm may also be different. When the relative count of target edges is small, NeighborExploration algorithms outperforms NeighborSample algorithms and the difference is quite significant, but when the relative count of target edges is large enough, the results of NeighborExploration algorithms and NeighborSample algorithms are very close and the best algorithm will change from case to case.

We explain why our new algorithm NeighborExploration outperforms NeighborSample when the relative count of target edges is small as follows. In NeighborSample algorithms, the probability of sampling a target edge is $\frac{F}{|E|}$, since NeighborSample samples edges uniformly. However, our new algorithm, NeighborExploration, can find a target edge with probability $\frac{\sum_{u \in Q} d_u}{2|E|}$, where node set Q contains all nodes which is included in at least one target edges, since once we sample a node all target edges which contains this node will also be found. As a result, our new algorithm NeighborExploration can obtain target edges with a

6 CONCLUSION

In this paper, we propose to estimate the number of edges with target labels, which to the best of our knowledge corresponds to the first attempt to estimate graph properties refined by users' labels. To solve the problem, we developed two algorithms, namely NeighborSample and NeighborExploration, which samples a set of edges/nodes first and then constructs estimators based on the sampled edges/nodes. These two algorithms are suitable in different cases, e.g., NeighborExploration is better than NeighborSample when the fraction of edges with target labels is low. We also provide some theoretical results on the accuracy guarantees of the algorithms. We conducted extensive experiments which

**Figure 1: NRMSE vs. number of target edges in Orkut when 5%|V| API calls are used****Figure 2: NRMSE vs. number of target edges in Livejournal when 5%|V| API calls are used**

verified that the algorithms developed in this paper are superior over baseline methods.

There are a few directions for future study. For example, it would be interesting to estimate some other types of graph properties such as numbers of wedges and triangles refined by users' labels in OSNs.

A CHEBYSHEV’S INEQUALITY

Let X be a random variable with expectation $E[X]$ and variance $\text{var}(X)$. Then the Chebyshev’s inequality states that for any $t > 0$,

$$P(|X - E[X]| > t) \leq \frac{\text{var}(X)}{t^2} \quad (25)$$

Let \hat{X} be an estimator of $E[X]$, $t = \epsilon E[X]$ where $0 < \epsilon < 1$ and $0 < \delta < 1$, then we call \hat{X} an (ϵ, δ) -approximation of $E[X]$, if the following Chebyshev’s inequality holds.

$$P(|\hat{X} - E[X]| > \epsilon E[X]) \leq \frac{\text{var}(X)}{(\epsilon E[X])^2} \leq \delta \quad (26)$$

which shows that the probability of that \hat{X} is in the range $[(1 - \epsilon)E[X], (1 + \epsilon)E[X]]$ is larger than $1 - \delta$.

An Homophily-based Approach for Fast Post Recommendation on Twitter

ABSTRACT

With the unprecedented growth of user-generated content produced on microblogging platforms, finding interesting content for a given user has become a major issue. However due to the intrinsic properties of microblogging systems, such as the volumetry, the short lifetime of posts and the sparsity of interactions between users and content, recommender systems cannot rely on traditional methods, such as collaborative filtering matrix factorization. After a thorough study of a large Twitter dataset, we present a propagation model which relies on homophily to propose post recommendations. Our approach relies on the construction of a similarity graph based on retweet behaviors on top of the Twitter graph. Finally we conduct experiments on our real dataset to demonstrate the quality and scalability of our method. **Keywords:** Recommender System; Collaborative Filtering; Microblogging Systems

1 INTRODUCTION

During the last decade, several microblogging platforms have emerged such as Twitter, Pinterest, Instagram, Weibo or Tumblr. These platforms rely on the same paradigm: users follow each other's and share content. They have their specific audience and features but all have encountered unprecedented growth. This growth tends to make microblogging platforms overcrowded and users to encounter difficulties to keep up with all the available content. For instance, in 2017, 500 million messages were published every day on Twitter. Finding relevant messages to recommend in real time is a real challenge of prime interest for these platforms. Indeed, effectively recommending fresh publications leads to higher engagement from users which is crucial for a social media service [12].

Many recommendations methods have been proposed in the literature. Some works propose to extract features from items to recommend them to suitable users like [23]. However this approach provides poor results on microblogging platforms due to the short length of the messages (140 characters for a tweet), and a broad variety of content: video, picture, sound etc. Other methods based on collaborative filtering try to capture similarity between users based on "co-liked" items and to use this similarity to determine recommendations [30]. Among collaborative filtering methods, matrix factorization [20] and social trust models [25]

are very popular. If these methods provide relevant recommendations to end-users, they can not scale up with the huge amount of items produced by a platform like Twitter despite existing optimization techniques [26]. For instance the similarity matrix size will be of 1 000 billion of messages with millions of users, and will permanently grow up, so in addition to storage issues (even if this is a sparse matrix), it requires constant and costly computations.

To face this issue, Twitter has developed its own recommender system named *GraphJet* [32]. This method relies on a bipartite graph built on users interactions with messages and computes random walks. By starting these walks from a query user, it is possible to compute a list of personalized recommendation at low cost [32]. However, due to its random walk-based computations, *GraphJet* tends towards recommending mostly popular messages. Even if many users tends to focus on popular tweets, this approach reduces chances to recommend more specific content with similar interests in the neighborhood.

Based on a thorough analysis of a real Twitter dataset of 2.2M users extracted in 2015, with a special focus on the homophily concept, we propose in this article an original approach which achieves a good trade-off between relevance, scalability and freshness of recommendations. Our intuition is that recommendation relevance can be enhanced by understanding how people with similar profiles are interconnected. Our proposal relies on *SimGraph*, a similarity graph which links users with relevant-based edges based on common retweets, along with a scalable propagation model.

In a nutshell, the main contributions of this work are:

- (1) a micro-blogging analysis which focuses on retweets and homophily characterization;
- (2) a novel method to drastically reduce the cost of collaborative filtering methods relying on homophily and the construction of a similarity graph *SimGraph*
- (3) a convergent and scalable propagation algorithm enhancing recommendations with transitivity along with optimization techniques;
- (4) a thorough experimental comparison between *Collaborative Filtering*, *GraphJet*, a *Bayes Inference Model* and *SimGraph*, focusing on recommendation quality, processing time and robustness over time.

The rest of the paper is organized as follows. Section 2 is a review of the related works. Section 3 provides a thorough analysis of a Twitter dataset with a focus on homophily, which leads to our similarity graph and propagation model in Section 4. Our optimized propagation algorithm is presented in Section 5

and compared to other solutions in experiments in Section 6. Finally, Section 7 concludes the paper.

2 RELATED WORK

Since their appearance in the beginning of the 1990s at Xerox [11], recommender systems have been extremely popular and are used to recommend a large variety of objects such as : music [29], movies [27], news [9], recipes [8], etc. Different types of recommending methods emerged: content-based, collaborative filtering, graph-based, bipartite networks or deep learning.

Content-based methods aim at describing both profiles and items in order to provide recommendation [23]. The strength of content-based methods lies in the capacity to provide recommendations without requiring any feedback from users by extracting tendencies of collected data. In the context of microblogging, the content itself is poor with small-size tweets, links or multimedia, even if some works on Twitter targeted this approach [18]. However, content-based models generally suffer from overspecialized recommendations [1].

Collaborative Filtering (*CF*), on the opposite, combines both content and user interactions in order to produce recommendations. *CF* is generally represented as a matrix resolution problem and provides relevant recommendation. Lot of works focus on sparseness [19], on scalability [26] and on cold-start problems [2]. Matrix factorization methods transform both user and item vectors to a latent factor space, where similarities between items and users are generated by lower-dimensional hidden factors. However in the Twitter context, matrix factorization is not scalable due to the matrix size and continuous growth, but also it does not allow to consider the freshness of the recommended items.

Some other proposals exploit the social network and weight edges to quantify correlations between users. Jiang et al. [17] mix the social network with individual preferences into a matrix factorization model and improve recommendations. A broad range of social recommender systems have a similar approach like [33]. In Jamali et al. [16], authors present *SocialMF* to also enrich matrix factorization with the network of users. However the size of the Twitter matrix (more than 100 billions values) and its high growth (500 millions of messages/day) make these methods hard to exploit. Many works on trust networks have been done with explicit information, like in SoRec [24] on Epinion¹ producing and factorizing probabilistic matrices. However, the relationships between users on microblogging platforms is very heterogeneous and can carry many different meanings. Consequently it can not be really considered as a trust relationship.

The bipartite network model is another popular approach in recommendation systems. For instance Twitter proposes in [32] *GraphJet*, a random walk approach on user and post graph. Even though this method is particularly efficient, it only focuses, for scalability purposes, on the freshness of interactions. In our point of view, *GraphJet* by missing to exploit older interactions reduce the complexity of users profiles. Moreover, we will see in the experiments that this solution mainly addresses the hot-topic recommendations.

There exist also other works on Twitter for recommending hashtags [10] or users [6], or for filtering messages in the timeline [34]. But very few address the post recommendation problem.

Finally, deep learning methods on huge datasets such as Twitter [28] or Youtube [7] process neural networks to connect many dimensions such as similarity matrix, content features,

# nodes	2.2M
# edges	325.5M
# tweets	3,002M
avg. out-deg.	57.8
avg. in-deg.	69.4

user feedback. Even if the efficiency of such systems is promising, it faces scalability and dynamicity challenges for microblogging platforms. As a matter of facts, it currently uses past content to extract interesting items from user timelines but does not support real-time recommendation of posts from the whole network.

3 MICROBLOGGING ANALYSIS

We introduce here the main characteristics of our Twitter dataset and the different experiments we performed to characterize user behaviors. We discuss the main results of our data analysis and their implication for our recommendation model.

To build our dataset we first extracted a connected component from the graph from Kwak et al. [21]. Then for each node of this subgraph we updated every information in 2015 thanks to the Twitter API². More precisely, for each account we collected the incoming edges (followers), outgoing edges (followees) and all the tweets published by the associated account. Observe that due to the API limit we only retrieved the last 3,200 messages (maximum) for each account. Table 1 summarizes the main features of the dataset. With more than 2 million users and 3 billion messages we have a mean number of 1,375 published tweets per user. The original Kwak connected component contained 125M of edges, so its connectivity has almost doubled in 6 years. The average path length for our graph is 3.7 which is very close to the 4.1 found by Kwak et al. (Figure 1). Likewise, the diameter (longest shortest path between two nodes) for their graph is 18 which is very close to the one we obtained (15). We also observed that our

¹<http://www.epinions.com/>

²<https://dev.twitter.com/rest/public>

Figure 2: Distribution of the number of retweets per tweet

in/out-degree distributions (*i.e.* number of followers/followees per user) are close to the ones found in previous Twitter graph characterizations like [22, 35]. We conclude that we succeed in building a representative subgraph of Twitter along with the associated tweets published by the different accounts.

Based on our representative dataset we perform a set of experiments to analyze the retweet activity.

3.1 Retweet characterization

Our objective is to recommend relevant tweets to users. Retweet is the mean to express interest for a piece of information, which can indifferently be positively or negatively perceived. The study of tweet propagation through retweets is consequently of primary interest.

3.1.1 Retweet behavior. First, we analyzed the popularity of the retweet behavior. Figure 2 shows the number of retweets for a given message. A large majority of messages are never retweeted ($\approx 90\%$ of the tweets), or only a few times, with barely 2-3 retweets ($\approx 2\%$). Very popular messages are extremely rare: messages with more than 50 retweets represent less than 0.005%. These results are consistent with the study of Kwak [21] which underlines that a very large majority of the messages are never retweeted or retweeted only once. From a recommender system point of view, tweets which are retweeted more than 4-5 times must get a significant weight since they are popular. Observe that the network itself promotes the propagation of this type of messages (social network effect). However being able to recommend a recent tweet with a small number of retweets (less than 5) is a real challenge. This is one of the objective of our proposal.

When analyzing whether retweeting is a common behavior, we observe that only a small number of users produce many retweets (see Figure 3). The majority of users perform between 10 and 100 retweets. The average number of retweets per user is 156 while the median is 37.5 and we observe the traditional power law distribution where few people gather all the retweets. From the point of view of recommender systems, the main difficulty lies in users with very few retweets (or even none) who represent a large part of the users (a quarter of users have never retweeted). For these users, methods which rely on collaborative filtering would be unable to provide recommendations.

Figure 3: Number of retweets per user

Figure 4: Lifetime of a tweet

3.1.2 Lifetime of a tweet. Recommender systems must avoid recommending a tweet which is “outdated”, *i.e.* which won’t be propagated anymore because it no longer interests anyone. We study here the lifetime of a tweet that we measured as the time span between the publication of the initial message and the last time it was retweeted. Only messages which were retweeted at least once are considered in this experiment. The results are shown in Figure 4. We observe that a large part of the messages “die” (so are no longer retweeted) before reaching one hour (40%). 90% of the messages die before 72h (three days). It’s very uncommon for a message to be retweeted beyond that point. Therefore our results differ from the ones reported by Kwak et al. [21] which notice that 10% of the retweet activity takes place one month after the publication of the message. Indeed, Twitter still was, in 2009, a recent system and less content was created, thus it was more easy to retweet messages older than a few weeks. In 2017, with more than 500 million new tweets published every day, freshness of the tweets has become a central criterion of propagation.

We conclude from this analysis that users mainly share fresh information and the tweets to consider in our recommender system are the messages that reach at least 2 retweets. Moreover, even for these messages, we do not need to compute their score after 72h because after this limit they become irrelevant for recommendation.

3.2 Homophily study

Collaborative filtering methods rely on a list of *similar* users to determine recommendations. We study in this section the evolution of similarity scores between users with respect to their distance in the Twitter network. We adopt a Jaccard similarity measure with a slight adjustment to take into account the popularity of the tweet as advised by Breese et al. in [4]: the less popular a retweeted post by two users is, the closer these users are. The rationale for relying on retweets to measure the similarity between users, as explained before, is that retweets are the only way a user expresses explicitly an interest about a piece of information published.

Definition 3.1 (User similarity measure). The similarity of two users is defined as:

$$sim(u, v) = \frac{\sum_{i \in L_u \cap L_v} \frac{1}{\log(1+m(i))}}{|L_u \cup L_v|} \quad (1)$$

where $sim(u, v)$ stands for the similarity score between a user u and a user v . L_u is the profile of user u estimated through the set of all the tweets he retweeted. $m(i)$ is the popularity of the tweet, measured here as the number of times it has been retweeted.

Based on this measure we study the homophily between users. Homophily corresponds in social media to the tendency for people to be connected with people sharing the same interest. This effect has been studied on demographic dimensions (age, gender, political orientation) for example by Colleoni [5] or Zamal [37]. They show how one could predict a user demographic based on his neighborhood. Topical homophily also has been studied by Lerman [15], that shows how people who are topically more similar are also more likely to be connected. Bhattacharya et al. [3] present similar results. With our analysis we study the homophily phenomenon in a different perspective.

Because of computation costs, we limited our study to 2,000 users randomly selected from our dataset, checking that they retweeted at least a defined number of posts. For each of these users, we computed the length of the shortest path connecting them to all other users. The results are shown in Table 2. We see that only 5.96% of user pairs display a similarity score over 0 and are directly connected through the network. However this small number of users pair presents the highest mean similarity score with 0.0056. When exploring at distance 2, to reach the followees of the followees, we note that the mean similarity score of 0.0021 is still higher than the average value (0.0019), and they represent almost 38% of the user pairs. Most of the users (51%) with a similarity score not null are at distance 3 from each other. However their similarity score is lower, 0.0017. Moreover, we observe that, according to the topology of the Twitter network (Figure 1), a distance of 3 corresponds almost to the entire network.

Table 3 completes this experiment by studying the link between position in the Top- N of most similar users and their distance to the user. For each of the 2,000 users from the previous experiment, we collect the 5 users with the highest similar scores. We then compute the average shortest distance between a user

Distance	Nb of users	Perc.	Average similarity
1	19,163	05.96%	0.0056
2	121,857	37.91%	0.0021
3	166,633	51.84%	0.0017
4	12,070	03.76%	0.0018
5	297	00.09%	0.0016
6	6	00.01%	0.0019
Impossible	1,396	00.43%	0.0023

Table 2: Evolution of the similarity score through distance in the network

Rank	Average Distance	Distances distribution (%)			
		1	2	3	4
1	1.65	53.30	28.20	16.65	1.45
2	1.78	43.70	34.50	20.50	1.05
3	1.88	37.99	36.04	24.37	1.35
4	1.97	33.18	36.99	27.68	1.70
5	1.99	32.01	37.93	28.20	1.56

Table 3: Link between distance in the network and position in the Top- N ranking

and each user from his Top-5. We observe that the user at first rank, *i.e.*, the most similar user, is directly connected to the user in 53% of the cases. The average score decreases when going down in the user rank. For instance the user ranked at the fifth position is directly connected to the user in only 32% of the cases. This study of the top-5 reveals that when considering users at a distance 1 added with users at distance 2 we capture 70-80% of the most similar users.

From this experiment we conclude that relying on the "strong" homophily, *i.e.* direct connection between users, is not enough because they represent a very small subset of the set of similar users. On the other hand we observe a "soft" homophily corresponding to users having a good similarity score but located at distance 2. These users which represent around 37% of users with a not null similarity scores, must consequently be considered by recommender systems to determine meaningful recommendations.

4 OUR MODEL

Based on our previous analysis we propose a propagation model relying on homophily to build post recommendation. Our approach relies on the construction of a similarity graph on top of the Twitter graph. The basic idea is to exploit the fact that highest similar users are at a distance lower or equal to 2. Thus we can use an exploration of the network to drastically reduce the amount of computed similarities.

4.1 Similarity graph

Our experiments about the homophily enlighten that the natural homophily in Twitter, which is translated by a "follow" link, is not sufficient to detect users of interest while considering all nodes at a distance up to 2 allows to capture most similar users. So, we decide to perform a 2-hop exploration from each node (user) in the Twitter graph. The set of reachable nodes for a node u is named the 2-hop neighborhood, denoted $\mathcal{N}_2(u)$. Then we compute for each node v in $\mathcal{N}_2(u)$ the similarity score of v with all the nodes from $\mathcal{N}_2(u)$. For each node w with a similarity greater

	SimGraph
Nb of nodes	1,149,374
Nb of edges	4,950,417
Mean Similarity Score	0.0078
Mean out-degree	5.9
Diameter	21
Mean smallest path	7.5

Table 4: SimGraph characteristics

than a chosen threshold τ , we create an oriented edge $e(u, w)$ in our similarity graph.

So formally the definition of the similarity graph is:

Definition 4.1 (Similarity graph). Consider the Twitter graph $G(V, E)$ where V denotes the set of vertices and E the set of edges, and a given similarity threshold τ . The similarity graph $SimGraph(V', E')$ is defined as:

$$\begin{cases} V' \subseteq V \\ e(u, v) \in E' \Rightarrow u \in V \wedge v \in N_2(u) \wedge sim(u, v) \geq \tau \end{cases}$$

We report in Table 4 the main characteristics of the similarity graph for our Twitter dataset. First, we observe that around half of the users from the original Twitter dataset are not present in the similarity graph. The reason is that many users either don't retweet any message or nobody has retweeted the same messages as this user. This issue is very close to cold-start problems and we won't address in this paper the issue of recommending tweets for users who are not present in the similarity graph.

However, we could consider an approach similar to the one used in *GraphJet* [32] using the neighborhood's computed recommendation of cold start nodes to partially solve this issue. Therefore it seems possible without too much effort to recommend items also for cold-start users.

Another characteristic of the similarity graph is a more uniform in-degree distribution than the original graph, with few nodes having a large number of incoming edges. This property is particularly interesting since in the opposite situation it would have led to some users gathering all the influence in the similarity network. Paths between two nodes in our similarity network are now much longer than the original Twitter network since the diameter of the similarity graph is now 21 and the average smallest path was doubled from 3.7 to 7.5. We observe that we are still in a small world network context according to the definitions expressed in the work of Schnetler [31]. Basically, this construction of a similarity graph, relying on 2-hop exploration in the Twitter graph could be seen as a dimension reduction process.

4.2 Propagation Model

The sparsity of user interactions on data is generally considered a major bottleneck for a successful execution of a collaborative filtering recommender system. As we've seen before, in microblogging context, this sparsity issue is important. In their work, Huand et al. [14] use transitivity in a collaborative filtering model to fight the sparsity problem. Considering a similar approach, we propose a propagation model on top of our similarity graph. Propagation is an efficient way to face the sparsity since it allows to transmit content from a user u to a user v while there exists no link (*i.e.*, edge in the underlying graph) between them. Intuitively we consider that if a user w has interests similar to u

Figure 5: SimGraph smallest path

leading to several retweets, the content from u that we recommend to w should also be recommended to v if v is similar to w .

The only action we can collect to capture interests from a user for a tweet is the retweet action to share a piece of information. Consequently we assume here that liking a tweet is similar to sharing it (retweet). Therefore the words "like" and "retweet" are interchangeable. We estimate the sharing probability, *i.e.* the probability that a user u likes a tweet t as:

Definition 4.2. Sharing probability The probability that a user u likes (and shares) a tweet t is:

$$p(u, t) = \frac{\sum_{v \in F_u} p(u \leftarrow v, t)}{|F_u|}$$

where F_u denotes the set of influential (similar) users for u (*i.e.*, those connected by outgoing edges in the similarity graph) and $p(u \leftarrow v, t)$ is the probability that u likes t determined consistently by the behavior of his influential user v . This probability is estimated as:

$$p(u \leftarrow v, t) = p(v, t) \times sim(u, v)$$

Example 4.3. Consider the similarity graph of Figure 6 with 5 nodes (u, v, w, x, y). An edge $u \rightarrow v$ expresses the fact that v is an influential user of u . Edges values correspond to the similarity score $sim(u, v)$. Assume that user x liked/shared the tweet t_1 , so the probability that x like t_1 is $p(x, t_1) = 1$. Consequently the score of $p(w, t_1)$ is:

$$p(w, t_1) = \frac{\sum_{v \in F_w} p(w \leftarrow v, t)}{|F_w|} = \frac{0 \times sim(w, y) + 1 \times sim(w, x)}{2} = 0.25$$

However since $p(w, t_1)$ changes, all probabilities which depend on the value of $p(w, t_1)$ must be updated in turn.

5 PROPAGATION ALGORITHM

We introduce in this section our propagation algorithm which allows to recommend new content to users based on their similarity. We also present its convergence property and optimizations.

Figure 6: Example of similarity graph

5.1 Iterative algorithm

We perform our iterative propagation algorithm each time a tweet t is retweeted. We discuss different optimizations in Section ?? which exploit our observations regarding the popularity and the lifespan to avoid performing the propagation for each retweet.

So assume that we have a similarity graph $SimGraph = (V, E)$ with V the set of vertices and E the set of edges, and that a tweet t is retweeted by a user. Algorithm 1 presents our propagation algorithm. We denote by D the set of users that have already retweeted t . For each $v \in D$, the probability $p(v, t)$ is consequently 1 (line 3). For all other users $u \in V \setminus D$ we consider that the initial probability to retweet this tweet is $p(u, t) = 0$ (line 4). During an iteration, we compute for all the users u in $V \setminus D$ the probability $p(u, t)$ based on the probabilities from his followees, i.e. $p(v, t)$ for all $v \in F_u$ (line 10). So for iteration k we compute our probabilities based on the those which were computed at iteration $k - 1$. Observe that users $v \in D$ have a probability of 1 which is not re-computed during the iterative algorithm. The algorithm stops when no probabilities change during an iteration (line 7).

Algorithm 1: Propagation algorithm

input : Similarity graph $SimGraph = (V, E)$, a tweet t and a set of users D who retweet it

output: the set of vertices with their retweet probability

```

1 Initialization;
2 foreach u in V do
3   if u ∈ D then p(u, t) = 1;
4   else p(u, t) = 0;
5 end
6 convergence = false;
7 while convergence = false do
8   convergence = true;
9   foreach u in V \ D do
10    p'(u, t) = (∑_{v ∈ F_u} p(v, t) × sim(u, v)) / |F_u|
11    if p(u, t) ≠ p'(u, t) then convergence = false;
12    p(u, t) = p'(u, t);
13  end
14 end
15 Return ∀u ∈ V, p(u, t);

```

Example 5.1. Consider our previous example in Figure 6. After that user x liked/shared the tweet $t1$, we propagate this action on the similarity graph and we first update the score of $p(w, t)$ since x is an influential user of w . Since the value of $p(w, t)$ changed and is now 0.25 we must update in a second iteration the probability

of the users influenced by w , so here only u .

$$p(u, t1) = \frac{\sum_{v \in F_u} p(u \leftarrow v, t)}{|F_u|} = \frac{0 \times sim(u, v) + 0.25 \times 0.5}{2} = 0.0625$$

Since there is no users influenced by u the algorithm stops.

Therefore this algorithm produces for an incoming tweet a probability score for every users in the propagated sub-graph. Then, the recommendations of a user is based on the top- k tweets sorted on probability. We will study in Section 6.2 the impact of the size (k) on the quality of the recommendations compared to competitors.

5.2 Linear system formulation

Consider we have n users (u_1, u_2, \dots, u_n) in the similarity graph, our propagation model consists in resolving the following linear system with n equations:

$$\begin{cases} a_{11}p_{u_1} + a_{12}p_{u_2} + \dots + a_{1n}p_{u_n} = b_1 \\ a_{21}p_{u_1} + a_{22}p_{u_2} + \dots + a_{2n}p_{u_n} = b_2 \\ \dots = \dots \\ a_{n1}p_{u_1} + a_{n2}p_{u_2} + \dots + a_{nn}p_{u_n} = b_n \end{cases}$$

which can be written under a matrix product $Ap = b$ with:

- vector b which is the initial state vector, with $b_i = 1$ if u_i has retweeted (shared) the message and 0 otherwise;
- vector p is the solution vector, containing the probabilities after propagation of any user to like the tweet;
- the similarity matrix A which is defined as:
 $\forall i \leq n, \forall j \leq n,$

$$a_{i,j} = \begin{cases} 1 & \text{if } i = j \\ \frac{-sim(u_i, u_j)}{|F_{u_i}|} & \text{if } (u_i, u_j) \text{ is an edge in the } SimGraph \\ 0 & \text{otherwise} \end{cases}$$

5.3 Convergence property

Incremental resolution methods such as Jacobi, Gauss-Seidel or successive over-relaxation (SOR) can be used to solve such a linear system $Ap = b$. A necessary and sufficient condition to ensure convergence for this incremental resolution method is that the matrix A is diagonally dominant. This condition is fulfilled here because $\forall u, v \ sim(u, v) \leq 1$, so $\sum_{j \neq i} |a_{ij}| < \frac{1}{|F_u|} \times \sum_{j \neq i} 1 = 1$. Since $|a_{jj}| = 1$, we conclude that $|a_{jj}| \geq \sum_{j \neq i} |a_{ij}|$ for all i , so A is diagonally dominant.

Considering the Jacobi method of resolution, the convergence speed is bound by the matrix norm $\|A\|$. However, this value is dependent of the matrix's values, and therefore cannot be known theoretically. We conducted an experimental study on our dataset and show that the convergence of our model is bound to $\|A\| = 0.91$ - the worst case scenario. The unpredictable or bad convergence speed of our model led us to apply several optimizations to guarantee a fast convergence and therefore a fast computation.

5.4 Propagation algorithm optimizations

We propose and test several optimizations for the propagation algorithm which significantly improve its performance.

Propagation thresholds. A first optimization consists in setting a static threshold β to decide whether a score updated at an iteration k should be transmitted to the followees at the iteration

$k + 1$. So when $p(u, t)^n - p(u, t)^{n-1} < \beta$ the user u does not propagate its score to his followees for any following iteration.

We extend this traditional approach by proposing a dynamic threshold based on our analysis about the evolution of the tweet popularity and its lifespan. Indeed the probabilities computation for a popular message requires a long time in order to reach convergence. Moreover, this tweet is likely to be sent to a large part of our similarity network. Oppositely, a tweet which has not been retweeted many times because it has just appeared in the system leads to faster computations. Most recommender systems focus on already-popular tweets. So, by setting a dynamic threshold which favors tweets less popular because they have just appeared, we could recommend them earlier than other recommender systems, and at lower computing costs. Precisely we define our dynamic threshold $\gamma(t)$ for a tweet t as:

$$\gamma(t) = \frac{(m(t))^p}{k^p + (m(t))^p}$$

where $m(t)$ denotes the popularity of the message t which can be measured as the number of retweets, for instance. k and p are fixed parameters and are superior to 0, they are used to fit properly the distribution of popular items. Basically $\gamma(t)$ is bounded between $[0, 1]$ and close to 0 when few people have shared t , and close to 1 when the message is considered popular. However other dynamic thresholds could be considered.

Postponed computation. We propose another optimization based on the time frame update. It consists in starting the propagation process not at each time a new retweet happens on a message but after time interval δ depending on the account activity. For instance, assume that a message is very popular with dozens of retweets per minute. We could decide to wait 10 minutes before executing the propagation computation. On the opposite a very unpopular message can wait few hours before launching the propagation process.

6 EXPERIMENTS

We evaluate the *SimGraph* model along with our propagation algorithm. We first detail the experiment protocol used with our *Twitter* dataset to measure the quality of generated recommendations. Then we present our different results and compare them with other recommendation methods.

6.1 Experimental Setup

Our experiments are performed on a Linux machine with 512GB of RAM memory and 80 Intel(R) Xeon(R) CPU E7-4830 v2 @ 2.20GHz. We use Java Openjdk 1.8 for all our implementations. To compare our method with several baseline solutions, we implement a *Bayes* Inference Model used for recommendation [36], a standard collaborative filtering method (*CF*) [13] and *GraphJet* algorithm [32] which is currently used by *Twitter*. The rationale for the choice of these different competitors is that our method could be seen as a combination of probabilistic and collaborative filtering approaches. Regarding the Bayesian inference model we tweak it slightly to consider only the binary feedback of *Twitter* (liking or doing nothing) instead of ratings from 1 to 5. Moreover due to computational issues it is necessary to define a threshold in the Bayesian probabilities computation to stop the costly process. The implementation of the *GraphJet* method is based on *Twitter* source code³. All experiments are performed on the real *Twitter* dataset introduced in Section 3.

³<https://github.com/twitter/GraphJet>

Figure 7: Recall Capacity for 1500 users

To measure the quality of the recommendations on our dataset, we compare the recommendations of the different methods with real observations. To achieve this, we consider retweets of messages which were retweeted at least twice. They constitute a set of 132, 389, 409 sharing actions for these messages that we ordered on time. We split the set in two: the first 90% of actions (the oldest retweets) compose the training set and the last 10% the test set. While the former set is used to train the four methods, the latter one allows to check the recommendations with real retweets. Note that the test set captures 66 days of retweets from the users in our dataset. Then we randomly select 500 users with less than 100 retweets (*low-active users*), 500 users with more than 100 retweets but less than 1,000 (*moderate-active users*) and finally 500 users with more than 1,000 retweets (*intensive users*). Combined, they constitute a set of 1,500 users used to compare the results of the different methods. We consider that a message is a *hit* if it is recommended to a user *before* he actually interact with the message (retweet/like). This prediction task can be seen as a quality measure.

6.2 Quality of the recommendations

Number of recommendations. Figure 7 displays the average number of recommendations proposed by the different recommender systems with respect to the maximum number of daily recommendations for each user (i.e. the size of the top- k recommendations). We observe that *Bayes*, *GraphJet* and *SimGraph* present similar behavior, capped between 50 and 70 recommendations per day and user. Only *CF*, with a linear growth, is capable of providing a high number of recommendations for any user with this maximum of 140 recommendations. There are several possible explanations for this. First, *CF* by relying on every similarity scores possible between pair of users is independent of the network. Therefore the scope of candidate items to be proposed is very large. Second, *Bayes* and *SimGraph* which rely on propagation methods could theoretically compute a prediction score for any message to almost any user. The fact that their curve is not linear seems to be a direct consequence of using thresholds during the propagation. We could argue that our threshold values are well chosen since 50 recommendations a day per user

Figure 8: Number of hits for 1500 users

Figure 10: Number of hits for 500 *medium* users

Figure 9: Number of hits for 500 *small* users

Figure 11: Number of hits for 500 *big* users

remains sufficient. Finally, *GraphJet* is limited by the low connectivity and the slow activity of small users. In fact, the total number of possibilities offered to small users is limited to their neighborhood.

Retweet prediction. A prediction corresponds to a hit in the test dataset when the recommendation of a message happens *before* it is effectively retweeted/shared in the dataset. Figure 8 plots the total number of hits for the combined set of 1,500 users with respect to the number of recommendations proposed to a user per day. This experiment is refined by different sets of users on Figure 9 (low-active users), Figure 10 (moderate-active users) and Figure 11 (big users). We observe that the results are globally stable among the different sets of considered users.

The main difference between types of users (small, medium, big) comes from the bounds of the number of hits. In fact, the total number of retweets/share is higher for big users and therefore the probability to have a hit. But interestingly, users' behavior is identical for medium and big users. According to small users, since the total number of retweets is low, the probability to find a

hit grows up quickly for all approaches but a threshold is reached faster.

We note that the *CF* model has a linear evolution in the combined set of 1500 users, so it is better suited for applications proposing a high number of recommendations. But as we saw in Figure 7 this model also proposes the largest number of recommendations which leads to a constant but low precision score of 0.0001% (*i.e.*, it proposes a lot of noise). For instance, when limiting to a top-30 for recommendations, *CF* gets 5,685 hits while *Bayes* and *GraphJet* get respectively 3,564 and 2,541 hits. *SimGraph* outperforms them with a total number of 8,509 hits at top-30. However, this number of hits is limited for small users with a stabilization of 700 hits for $k > 80$. It is due to the fact that those users do not retweet much and cannot statistically lead to much more hits.

SimGraph outperforms other approaches, *e.g.* *GraphJet* by a factor of 3.5, for any $k < 200$. For very large values of k , *CF* slightly outperform our method *Simgraph*. Similarly to *CF*, *SimGraph* does not rely directly on the underlying network and

Figure 12: Popularity of hits

focuses on similarities which quickly provides good results based on users interests. But, thanks to the similarity graph and transitivity, our solution succeeds in providing new recommendations coming from other kinds of interests, different from the ones observed in the user profile, based on proximity where *CF* fails.

Popularity of the hits. We now focus on how popular the recommendations are in each solution which led to some hits. It helps to identify their scope of accuracy. Figure 12 shows that *GraphJet*'s random walks mainly generate hits on popular messages with an average number of retweets equals to 113 for each hit. Indeed, the most popular a message is, the more often the random walk will reach it. Therefore, *GraphJet* naturally is more inclined to recommend popular items.

On the contrary, the Bayesian model recommends less popular messages: for the hits it produced there were only 6 retweets on average. Thus, it produces more "local" recommendations, due to the probability computation on top of the underlying network. Observe however that the messages popularity decreases with the size of the top- k , in order to provide more recommendations *Bayes* will find items that are even less popular.

Collaborative filtering approaches, *CF* and *SimGraph*, present a more balanced result with respectively 35 and 23 retweets for a recommended tweet. These systems recommend both popular and more dedicated messages. Observe that at first *CF* will propose less popular items due to relying on strong similarities far in the network while *SimGraph* will propose more popular items. The curve will then intersect around top-70.

Hits comparison. Figure 13 displays the amount of hits in common between *SimGraph* and other methods. It shows the ratio σ of common hits, i.e. :

$$\sigma(\text{competitor}) = \frac{\text{hits}(\text{SimGraph}) \cap \text{hits}(\text{competitor})}{\text{hits}(\text{competitor})} \quad (2)$$

We notice first that the ratio of common hits does not evolve more than 10% for each method. Except for *CF* that proposes less popular retweet at the beginning (see Figure 8) and more popular ones then, which levels up the number of common hits.

On the contrary, *GraphJet* focuses mainly on popularity at the beginning and shares less similarity between users, but then

Figure 13: Parts of hits that are included in SimGraph

Figure 14: F1 Scores over number of recommendations

after 40 recommendations this intersection reaches a bound due to a more diversified set of recommendations in *SimGraph*.

The Bayesian method shares more similarities between hits with more than 50% which means that our method predicts retweets of tweets with various popularity: popular tweets like *GraphJet*, but also less popular tweets like *CF* and not-popular like *Bayes* based on the network.

F1 Measure. Figure 14 plots the F1 score for each method, according to the hits obtained over the number of daily recommendations per user. Except *Bayes*, methods peak around the same size of $k = 15$, which seems to be a good number of recommendation per day. *GraphJet* by doing less hits for same amount of recommendation leads to a lower score when combining precision and recall. *CF* proposes too many recommendations even with better precision obtains a similar F1 score as *Bayes* that proposed less recommendations but with more hits. Finally, *SimGraph* gives a really good compromise, with both popular and

similar in the neighborhood, of recommendations of tweets. Overall on this task, *SimGraph* performs 4 times better than *GraphJet* and 2 times better than *Bayes* and *CF*.

6.3 Performances

Processing time. We compare now processing time for the different methods. Results are presented in Table 5. We observe that *CF* has the highest initialization time with almost 9s per user, since it requires to compute the similarities between all pairs of users, so theoretically $|V|^2 \approx 1.3 \times 10^{12}$ computations. Oppositely *Bayes* has the lowest initialization time with 10ms per user to initialize all probabilities. For *SimGraph*, the initialization consists in exploring for each user his neighborhood up to distance 2 (BFS exploration) and to compute similarities for each user found during the exploration to build the similarity graph. For each user, using this method requires 311ms to determine its most similar users. *GraphJet* only relies on the Twitter and retweets graph and does not need any initialization.

According to the message processing time, all the methods were implemented in a multi-thread way on a 70 cores parallelization process. We can observe that *Bayes* takes around 1 second to compute the recommendation scores for a given message due to graph exploration. Oppositely *CF* is able to compute very quickly the different recommendations (0.5ms per message) based on the pre-computed similarities. *SimGraph* requires 38ms to compute the recommendation score of a message to users based on our iterative propagation algorithm. *GraphJet* is user-centric and computes top- k recommendations for a given user, and not a set of users to recommend a given message. Computing k recommendations for a given user requires 14ms.

To compare performances of the different algorithms we measure the total time for processing both the initialization and the recommendations, for each user for *GraphJet* or for each of the 13.2 million incoming messages during the test dataset for other methods. For *GraphJet* we perform the computation periodically, here we chose every 5 hours. Note that the test period extends over 66 days. It results that *Bayes* is the most expensive method with 51.22h of total computation. *CF* is also expensive with 41.01h of computation mainly for the pre-processing. *GraphJet* provides much faster recommendations (4.2h). *SimGraph* is a good trade-off with an initializing time by node of 311ms and an average time per message of 38ms leading to a total computation time of 3.41h. We see that both the *Bayes* and *CF* methods suffer of very long computation time, making them hard to use in a real life scenario.

Notification time. This experiment illustrates the benefit of the different methods regarding the notification time. In other words, we want to study how much time in advance a recommended tweet will be presented to the user before the actual interaction. Remember that according to our study in Section 3, a tweet has a short lifespan. We compute for each hit the difference between the time when the recommendation was performed and the time when the user perform the retweet in the test dataset. In Figure 15, we see that *GraphJet* is very stable and permits to predict a hit 80,000s (around 22 hours) in advance on average. *GraphJet*'s tendency to recommend popular items makes it more efficient on this task, having more opportunities to predict such messages before. Interestingly the *CF* curve is correlated with the average popularity of the item predicted in Figure 12. Recommending dedicated items long time in advance is a difficult task therefore, and naturally the average advance time increases for *CF* and

Figure 15: Average advance time before real retweets (in s)

Figure 16: Number of hits with several updating strategies

can predict recommendations before *GraphJet* for very large k values. Indeed *CF* benefits from not having to wait for a message to propagate through the network to compute a recommendation score, therefore can predict popular items long time in advance. Following the same conclusion that predicting dedicated messages long time in advance is a difficult task, it fully explain why *Bayes* and *SimGraph* can only predict iterations 17h in advance on average since they have to wait for more signals.

Graph update. Microblogging platforms such as Twitter are permanently in motion. Each retweet/like performed impacts some changes of similarity scores and consequently impacting recommendations computation and quality. Keeping structures up to date to fit the shift of users' interest is a very difficult task. Therefore an efficient updating strategy is crucial to make our recommendation model robust to network and retweet evolutions. *GraphJet* is a very suitable solution in real life because, by avoiding any initialization step, it continuously stays updated no matter the amount of new information published. However, as

	init. (per user)	init total time	time (per message)	total time (70 cores //)	total time
		1,149,374 users		13,238,941 Tweets (Trial period)	init + recos
Bayes	10ms	0.04h	975ms	51.22h	51.26h
CF	8,583ms	39.40h	0.5ms	0.02h	41.01h
SimGraph	311ms	1.41h	38ms	2.00h	3.41h
	init. (per user)	init total time	time (per user)	total time (70 cores //)	total time
		1,149,374 users		1,149,374 users * 66 days (Trial period)	init + recos
GraphJet	0ms	0h	14ms	4.2h	4.2h

Table 5: Initialization and recommendation time (in ms)

we saw in Figure 8 the gain in hits prediction with our method *SimGraph* is substantial enough to inquire how we can keep this increase of accuracy while dealing with incremental updates. We study the impact of computing our recommendations based on an outdated similarity graph and the outcome of using different updating strategies. For this experiment we assume that *SimGraph* was built at the beginning of the test dataset (after 90% of the retweets). We plot in Figure 16 the number of hits obtained for the last 5% of the retweets (half of the 10% trial). We compare four approaches:

- from scratch, where the graph is totally rebuilt after 95% of the retweets, from the original graph,
- old *simgraph*, where we keep the exact same *SimGraph* that the one computed at 90%,
- *crossfold*, where we apply our similarity graph construction on the previous old *simgraph* instead of the twitter graph,
- *SimGraph* update, where we update similarity scores on the similarity graph built at 90%

As expected re-building from scratch the similarity graph at 95% allows to get the best predictions. This strategy is also the most expensive one with similar computation cost as the ones expressed in Table 5. Surprisingly old *SimGraph* and *SimGraph* update have almost the exact same results, indicating that the topology of the computed network has a more important impact than the weight computed on the edges. The *crossfold* strategy is very promising because it fits almost perfectly with the from scratch strategy while cutting drastically computation cost. Indeed, the *crossfold* strategy perform a BFS at distance 2 on the already computed similarity graph to search for new influential users that weren't considered during the first *SimGraph* computation. This method both increases the density of the graph while updating the weight edges. These results enlighten the possibility to follow the evolution of users by incrementally computing a *SimGraph* on top of the previous iteration and avoid computing things from scratch.

7 CONCLUSION

We propose in this paper *SimGraph*, a scalable recommendation model based on a similarity graph which exploits homophily for propagation of probabilities. We study the homophily impact between users on the network. This indicate that homophily is a good property to find quickly users of high similarities and therefore drastically reduce the computation cost of such operation. We find that applying transitivity on those similarities reduces the sparsity efficiently with a fast convergent model thanks to optimization technics. We propose a propagation model in order to compute on-demand relevant recommendations for an incoming post. Our experiments enlighten that our method outperforms

other approaches for recommendation computations, but also provides more hits than the competitors for a lower number of recommendations blending popular and more confidential items. We also demonstrate how *SimGraph* can be updated at low cost, showing its usability in real world scenarios.

As future works, we intend to enhance our similarity graph by analyzing content of the tweets with entity recognition. In fact, our similarity is based on common retweets between users and can be improved by creating "topic tweets" by merging similar tweets. This will make users likely to be similar in the similarity graph and therefore enhance results for small users. We also plan to break "information bubbles", since recommended information is generally originated from the same sub-part of the graph. We are currently working on the identification of bubbles in our twitter graph based on both the network topology and tweet topics. Then we will propose a complementary score for recommendations by escaping from information locality from a bubble to another.

ABSTRACT

Selection algorithms usually score individual items in isolation, and then select the top scoring items. However, often there is an additional diversity objective. Since diversity is a group property, it does not easily jibe with individual item scoring. In this paper, we study set selection queries subject to diversity and group fairness constraints. We develop algorithms for several problem settings with streaming data, where an online decision must be made on each item as it is presented. We show through experiments with real and synthetic data that fairness and diversity can be achieved, usually with modest costs in terms of quality.

Our experimental evaluation leads to several important insights in online set selection. We demonstrate that theoretical guarantees on solution quality are conservative in real datasets, and that tuning the length of the score estimation phase leads to an interesting accuracy-efficiency trade-off. Further, we show that if a difference in scores is expected between groups, then these groups must be treated separately during processing. Otherwise, a solution may be derived that meets diversity constraints, but that selects lower-scoring members of disadvantaged groups.

1 INTRODUCTION

Diversity is desired in many contexts, ranging from results of a Web search to admissions at a university. As algorithms are increasingly used to make decisions, there is growing interest in algorithms that can produce diverse results. Indeed, fairness and diversity are central to responsible data science practice [7, 17].

Diversity is a set concept: it makes no sense to talk about an individual item as being diverse. Fairness is less clearly a set concept; nevertheless, fairness is often stated with respect to some comparison standard, usually a group [5, 12, 19]. For example, in the context of racial discrimination, we frequently refer to under-represented minorities, which is a set construct, with fairness requiring proportional representation.

Most algorithmic decision-making is based on the individual: typically, a score is assigned to an individual item based on its attributes. However, since fairness and diversity are set concepts, they can only be guaranteed as part of a set selection procedure.

In this paper, we show how we can guarantee fairness and diversity in set selection. We begin by developing a simple general problem statement in Section 2, to maximize *utility* subject to a set of *diversity constraints*. We show that our problem formulation covers a wide range of fairness and diversity requirements. We then solve this problem in two settings. In Section 3, we present a baseline algorithm that make the assumption that all items are available before any selections have to be made. Then, in Section 4

we develop algorithms that decide whether to accept, reject or defer an item in an online manner, as the items are presented. We refer to this variant as the Diverse K -choice Secretary Problem.

Algorithms of Section 4 constitute the main technical contribution of this paper. These algorithms build upon a rich body of work on the Secretary Problem [8, 11, 14] — selecting the maximum element in a randomly-ordered sequence of N elements, and on its K -choice variant — selecting K elements out of N [4].

In Section 5, we show experimentally that the online algorithms of Section 4 produce solutions that both meet the diversity requirements and are very close to the baseline algorithm of Section 3 in terms of utility. Further, we demonstrate that theoretical guarantees on solution quality of online algorithms are conservative on real datasets. These algorithms start by observing the scores of the items in the stream without accepting any items, to develop a quality estimate; this is known as the warm-up period. We show that an interesting quality-efficiency trade-off can be achieved by tuning the length of the warm-up period. Finally, we show that if a difference in scores is expected between groups, then these groups must be treated separately during processing. Otherwise, a solution may be derived that meets diversity constraints, but that results in selecting lower-scoring members of historically disadvantaged groups.

We discuss related work in Section 6 and conclude in Section 7.

2 PROBLEM DEFINITION

The basic problem setting is that we have a set of items, each with associated attributes. From this set, we wish to select K items to maximize a utility score (to be defined below) subject to diversity constraints (also to be defined below). The items in the set may be presented to us together or one at a time.

We obtain the utility score for a set of K selected items as the sum of scores of each individual selected item. The *score* of an item may be pre-computed and stored as a physical attribute, or it may be computed on the fly, and possibly even be obtained as the result of an expensive scoring algorithm. In all cases, all we require is that we eventually have a single scalar score value for each item. The score is sometimes called the *utility score* or *utility value* in the literature.

The basic top- k problem is to choose K items with the highest score. That is, for any item j in the top- k , and any other item q not in the top- k , we have $s_j \geq s_q$, where s_q is the score of item q . This is equivalent to saying we choose $K \geq 0$ items such that $\forall k \in [0, K][\text{argmin}_{j \in [0, K]}(s_j)]$ is maximized. This is further equivalent to saying $\sum_{j \in [0, K]} s_j$ is maximized. We will use this last definition, since with added diversity constraints these three definitions are no longer equivalent, and the first two may not be appropriate.

Having described the utility maximization problem above, let us now turn to fairness and diversity constraints. Among the attributes associated with items, we assume that one discrete-valued attribute is of particular concern. We call this the *sensitive*

*This work was supported in part by NSF Grants No. 1741047 and 1464327.

†This work was supported in part by NSF Grants No. 1250880 and 1741022.

attribute. Our notions of fairness and diversity are defined with respect to the value of this sensitive attribute.

In practice, there may be multiple sensitive attributes, rather than just one. In this case, we could consider each independently, by making minor appropriate modifications to all statements below. If combinations of multiple attributes are of concern, or if dependencies between the sensitive attributes need to be captured explicitly, we could represent such combinations as a single (Cartesian product) attribute of concern. For example, if both race $\in \{W, B, H\}$ and gender $\in \{M, F\}$ are sensitive attributes, we could combine these into a single attribute of cardinality 6.

If a sensitive attribute is not discrete-valued, or takes on too many discrete values, then we can bucketize the attribute value into a finite number of discrete buckets. Attributes such as age and salary are often treated this way in practice for many applications. In fact, sensitive attributes may also have associated privacy concerns, and so may need to be converted to noisy histograms, e.g., to enforce differential privacy.

We further assume that the dataset is partitioned on the value of the sensitive attribute. That is, each item is associated with exactly one value of the sensitive attribute. For example, a person of mixed race should not be listed as having both White and Black as values for the race attribute: rather this value should be set to an appropriate single value, such as "White-Black-Mixed".

Let there be d distinct values of the sensitive attribute. Our requirement is to choose k_i elements for each distinct value $i \in [1..d]$, with each $k_i \in [0, K]$, and $\sum_i k_i = K$. Of course, this begs the question of what the k_i values should be. We next consider several notions of fairness and diversity and show how to capture these within this framework.

Fairness by proportional representation (of values of the sensitive attribute). Suppose that the number of items N is known, as is the number of items n_i in each sensitive category $i \in [1..d]$. Then, proportional representation requires that the desired size K of the selected set be prorated among the d categories. That is $k_i = K * n_i / N$. We call the right hand side of this equation $proportion_i$, for convenience.

A difficulty we run into is that k_i must be an integer: an item in some category is either selected or it is not. Thus, fractional values do not make sense, yet $proportion_i$ is not always an integer. We can round $proportion_i$ to the nearest integer to determine each k_i , hoping to return K items in total. But we may end up with rounding errors resulting in violation of $\sum_i k_i = K$. To avoid this, it is reasonable to provide some flexibility in choosing the value of each k_i , using the formula $\lfloor proportion_i \rfloor \leq k_i \leq \lceil proportion_i \rceil$, where $\lfloor . \rfloor$ is the floor function and $\lceil . \rceil$ is the ceiling function.

Even weaker constraints are often acceptable in practice. For example, in a class of 821 students, and with a binary assignment of the gender attribute, we may desire to see 410 students of one gender and 411 of the other. However, it is unlikely that an institution would be accused of discrimination if they admitted 407 women and 414 men. Generally, it is acceptable to set thresholds on the relative representation of different categories. This idea is a generalization of the 80% rule of disparate impact [10].

Another potentially appropriate fairness metric is the normalized difference: the mean difference normalized by the rate of positive outcomes, which in our case corresponds to being selected among the top- k . Another is the elift ratio: the ratio of positive outcomes for the historically disadvantaged demographic group over the general group. A ratio of 1 indicates no discrimination, while a ratio below 0.8 has been construed as discrimination by

US courts. These and other proportional representation metrics can be found in a recent survey by Zliobaite [19].

Coverage-based diversity. A popular measure of diversity is coverage [7]: is there representation for every category in the selected set? Whether this is possible depends on how K , the number of items selected in total, compares to d , the number of categories of items. If $d \geq K$, then each $k_i \leq 1$. We cannot get full coverage, but by not choosing 2 from any category, we make sure to include a representative from as many categories as possible. If $d \leq K$, then each $k_i \geq 1$. Since K is large enough in this case, we can have multiple items from each category as long as we make sure that we have at least one from each category.

To avoid "tokenism" — selecting a single representative of each category, we may want to specify coverage diversity in terms of a larger minimum number per category. For example, we may require that there be at least 5 members of each race in the selected set. Such a choice would typically be made only if $5d \leq K$, and our requirement becomes that each $k_i \geq 5$.

Summarizing the scenarios considered above, we can state the specific diversity or proportionality constraint of interest as $floor_i \leq k_i \leq ceil_i$, where $floor_i$ and $ceil_i$ are integers that are determined, for each i , based on the particular constraint of interest. This formulation allows us to treat combinations of sensitive attributes (represented by a single Cartesian product attribute) in a way that captures attribute dependencies. For example, we can derive the constraint for the number of female candidates of a minority race to be higher or a lower than what would result from $proportion_{female} \times proportion_{minority}$.

The general statement of our problem is as follows:

Diverse Set Selection Problem Statement: Given N items, each with an associated utility score and an identified sensitive attribute, for each value i of the sensitive attribute, choose k_i items such that the summation utility of the selected set is maximized, subject to $floor_i \leq k_i \leq ceil_i$ and subject to $\sum_i k_i = K$. The $floor_i$ and $ceil_i$ values depend on the specific constraint to be applied. These values are computed prior to the optimization problem, and are assumed to be given.

All N items may be given together; we call this the static case and study it in Section 3. Alternatively, the items may arrive one at a time; we call this the online case and study it in Section 4.

The standard cost-metric in the top- k problem is the number of items examined: ideally, this should be much less than N . We carry over this metric to our problem domain as well. This metric, which we call *walking distance* (it is sometimes called *depth* in the top- k literature), is a simple surrogate for the incurred CPU cost, and has the advantage of being independent of the implementation and of the execution environment. We will discuss in Section 4 that walking distance relates to solution utility in the online case, and so is more informative than wall-clock time.

Another standard top- k cost metric is *buffer size*: the in-memory storage cost for running the algorithm. We do not present experimental results on buffer size, but note that all algorithms proposed here use buffers of constant size, under the assumption that K and $\sum_i ceil_i$ are constants.

Finally, as we shall see when we get to the online algorithms, we cannot always get the best answer if we are required to decide for each item on the spot. An *accuracy* metric we develop will reflect how close the online solution comes to the true optimum. We note that this optimum is the best we can do subject to the

Figure 1: An illustration of the static scenario. $N = 12$ items, labeled a through l, belong to one of two classes, blue and red. The goal is to select $K = 3$ items subject to $1 \leq k_{blue} \leq 2$ and $1 \leq k_{red} \leq 2$. Items arrive in score-sorted order, with scores ranging from 9 down to 1.

diversity or fairness constraints: a higher score may be possible without these constraints. We describe all metrics in Section 5.3.

3 THE STATIC PROBLEM

In this section, we solve the problem for the case when we have access to all items. We call this the *static* case. In the next section, we will turn to the online (streaming) case.

In the traditional set up for the top- k problem with multi-attribute criteria, the problem setting assumes that we have items sorted by attributes of interest, with our ranking criterion being some monotone aggregation function of these attribute values (e.g., weighted sum). We proceed down the sorted list(s), stopping when we can predict that an unseen item cannot possibly be included in the selected set [9].

In our problem setting, item scores are precomputed, and so we consume a single list of items, sorted by decreasing score. But we have a more complex selection criterion: Diversity constrains each k_i , the number of items with a value i for the sensitive attribute, to $floor_i \leq k_i \leq ceil_i$.

Recall that d is the number of distinct values of the sensitive attribute. Let us define $required = \sum_{i=1}^d floor_i$. For our set of floor and ceiling constraints to be feasible, we must have $required \leq K$. The difference $K - required = slack$, represents the total slack that we have to choose items after all floor constraints are satisfied. To return a set of items with the highest utility (total score), we are best off filling the slack with items of highest utility, unconstrained by sensitive attribute value, as long as the number of items per category does not exceed the respective ceiling constraint. We use this observation in Algorithm 1. We illustrate the algorithm with an example.

Example 3.1. Consider the score-sorted list of items in Figure 1. $N = 12$ items are partitioned into $d = 2$ categories (blue and red), with 6 items per category. The goal is to select $K = 3$ items, with between 1 and 2 items per category. That is, $floor_{red} = floor_{blue} = 1$ and $ceil_{red} = ceil_{blue} = 2$.

We process items in order, left-to-right. At step 1, blue item a is accepted to meet the $floor_{blue}$ constraint. Among the remaining 2 items that will be accepted, one must be red, to meet the $floor_{red}$ constraint, and the other can be of either color. At step 2, blue item b is encountered and accepted. At this point, only one item remains to be accepted, and it must be red. At step 3, blue item c is skipped. Finally, at step 4, red item d is accepted, meeting the $floor_{red}$ constraint, and selecting the required $K = 3$ items. The algorithm terminates after consuming 4 items.

Let us now consider the pseudocode of Algorithm 1. As illustrated in Example 3.1, the algorithm accepts an item if the floor constraint of its category has not been met (line 7), or if the ceiling constraint of its category has not been met and some

Algorithm 1 Diverse top- k selection from a sorted list.

Require: List of items I sorted by score,
number of items to select K , number of categories d ,
constraints $floor_i \leq k_i \leq ceil_i$ for each $i \in [1 \dots d]$.
{Initialize the output list L .}

- 1: $L = \emptyset$
{Initialize the counts of per-category selected items C .}
- 2: $C = [k_1 = 0, \dots, k_d = 0]$
{Compute the slack value s .}
- 3: $slack = K - \sum_{i=1}^d floor_i$
- 4: **while** $|L| < K$ **do**
- 5: $x = getNextItem(I)$
- 6: $i = category(x)$
- 7: **if** $k_i < floor_i$ **then**
- 8: $L \leftarrow x$
- 9: $k_i = k_i + 1$
- 10: **else if** $(k_i < ceil_i) \wedge (slack > 0)$ **then**
- 11: $L \leftarrow x$
- 12: $k_i = k_i + 1$
- 13: $slack = slack - 1$
- 14: **end if**
- 15: **end while**
- 16: **return** L

slack remains (line 10). Algorithm 1 terminates once K items are selected.

In general, we only have inequality constraints on each of the k_i values. However, note that in the special case that for each i , $floor_i = ceil_i$, we have the value of each k_i determined exactly. In this case, once the floor constraints are met for each category, we will have selected K items in total, since $K = \sum_i k_i = \sum_i floor_i$.

Algorithm 1 never examines any item with score lower than the smallest score included in the selected set. In this sense, the number of items examined is optimal — there is no way to examine fewer items if we proceed strictly in score order. This optimality result holds even though the worst case number of items examined is still N .

Besides the computational cost, we have one additional important notion of goodness to consider: that of the utility score. It is straightforward to establish the following Theorem.

THEOREM 3.2. *Algorithm 1 produces a solution that has the highest possible utility score, subject to the given constraints.*

Even though Algorithm 1 is optimal, subject to the diversity constraints, in general it will return K items with the combined utility score that is lower than would be possible in the absence of these constraints. This cost of diversity was illustrated in Example 3.1: we skipped item c although accepting it would maximize utility, but would result in selecting all items from the same category, blue. We will quantify the cost of diversity experimentally in Section 5 (Figure 7).

4 THE ONLINE PROBLEM

In practice, even though a set has to be selected, not all items in the set may be available for evaluation at once. Rather, they may appear one at a time, with a decision to be made on the specific item instantaneously. For example, we may wish to hire a diverse set of employees. However, each hiring decision may have to be made individually on each job applicant when the job application arrives. The order of arrival of applications is not, in general, determined by the quality of the applicants. More generally, we

have to classify each *individual* item, as presented, into one of two buckets: “selected” or “not selected,” subject to the utility and diversity criteria in our problem statement, for the selected *set*. Such situations motivate us to consider an online scenario, which is sometimes referred to as streaming.

Returning to the hiring example, we note that, while the quality of an applicant may be unknown ahead of the job interview, it is reasonable to assume that the number of applicants, both over-all and in each demographic category (e.g., by race, gender or some other sensitive attribute) can be known ahead of time, because these properties are declared by the applicants. The classic Secretary Problem and its variants, described next, and our proposed solution presented in the remainder of this section, rely on this information.

4.1 Background and Problem Statement

The problem of designing an online algorithm to optimize the probability of selecting the maximum element in a randomly-ordered sequence has been studied extensively [8, 11, 14], and is traditionally known as the Secretary Problem. In this problem, the goal is to hire one secretary from a pool of N candidates, where N is known, and candidates arrive in random order. When a candidate is interviewed, the decision must be made to hire or reject the candidate, and this decision is irreversible. It was shown by Lindley [14] and by Dynkin [8] that the optimal hiring strategy is to interview $m = \lfloor \frac{N}{e} \rfloor$ candidates without making any offers (this is called the *warm-up period*), and make an offer to the first candidate who is better than the best of the first m candidates (or accept the last candidate if no better candidate is seen). This strategy yields the best candidate with probability $\frac{1}{e}$, and is said to have *competitive ratio* e . Further, this is the best such strategy for the Secretary Problem, *i.e.*, with the highest competitive ratio [11].

A generalization of the Secretary Problem called the K -choice Secretary Problem is stated as follows: design an online algorithm for picking K out of N non-negative numbers presented in random order, to maximize their expected sum. While a straightforward extension of the Secretary Problem is natural here (with the same length of warm-up, $\lfloor \frac{N}{e} \rfloor$, remembering the scores of the K highest-scoring candidates), the exact optimal competitive ratio for this problem is not known for $K > 1$. This quantity is known to lie between $1 + c\sqrt{k}$ and $1 + C\sqrt{k}$ for some pair of constants $c < C$ [3].

Another interesting variant is the Poset Secretary Problem: If the elements of the permutation (candidates) are only partially ordered, how to maximize the probability of returning a maximal element in the poset? The incomparable elements present the main challenge: many simple modifications of the total order algorithm to handle incomparable elements were shown to have vanishing success probabilities [13].

In this section, we state, and then present a solution to, the online variant of the Diverse Set Selection Problem of Section 2:

Diverse K -choice Secretary Problem Statement: Design an online algorithm for picking K out of N items, each with an associated non-negative utility score and an identified sensitive attribute, presented in random order. Select items to maximize their expected sum, subject to diversity constraints of the form $floor_i \leq k_i \leq ceil_i$ for each value i of the sensitive attribute, and subject to $\sum_i k_i = K$.

Figure 2: An illustration of the online scenario. $N = 12$ items belong to one of two classes: blue and red, with $n_{blue} = n_{red} = 6$. The goal is to select $K = 3$ items subject to $1 \leq k_{blue} \leq 2$ and $1 \leq k_{red} \leq 2$.

4.2 Online Algorithm

We now present Algorithm 2 that solves the Diverse K -choice Secretary Problem. The basic idea of this algorithm is to solve d K -choice Secretary Problems [4] *in parallel*, one for each category, to satisfy the per-category *floor* constraints. But that in itself is not enough: we also have to run a category-insensitive K -choice Secretary algorithm to select the remaining items, subject to *ceiling* constraints.

Algorithm 2 relies on the estimates of the number of items per category in the stream (n_i represents the estimate of the number of items from category i), and guarantees that diversity constraints are met if these estimates are accurate. We now illustrate Algorithm 2 with an example.

Example 4.1. Consider the stream of items in Figure 2. $N = 12$ items are partitioned into $d = 2$ categories, with 6 items per category: $n_{red} = n_{blue} = 6$. Like in Example 3.1, the goal is to select $K = 3$ items subject to $1 \leq k_{blue} \leq 2$ and $1 \leq k_{red} \leq 2$. In contrast to Example 3.1, items arrive in random order.

To start, we compute the lengths of the per-category warm-up periods: $r_{blue} = \lfloor \frac{n_{blue}}{e} \rfloor = 2$ and $r_{red} = \lfloor \frac{n_{red}}{e} \rfloor = 2$. Therefore, we will consider, and discard, 2 items in each category before accepting any items in that category. As we consider the warm-up items, we record $floor_{blue} = 1$ highest blue item score, and $floor_{red} = 1$ highest red item score in the respective per-category threshold heaps T_{red} and T_{blue} .

Similarly, we compute the length of the category-independent warm-up period $r = \lfloor \frac{N}{e} \rfloor = 4$. The number of items we will accept irrespective of their category membership corresponds to the difference between K and the sum of the floor constraints, and is 1 in our example. (We called this quantity *slack* in Algorithm 1.) Therefore, we will record the score of the highest-scoring item (of any category) among the first $r = 4$ items in the threshold heap T , setting $T = \{8\}$ (the score of item d).

The warm-up period for the blue category will terminate at step 3, after items a and c are considered, with $T_{blue} = \{6\}$. At step 4, a blue item d is encountered, with score 8, higher than $getMinElement(T_{blue}) = 6$, and this item is accepted.

The warm-up period for the red category will terminate at step 5, after items b and e are considered, with $T_{red} = \{4\}$ (score of b). We will reject the next red item, g, because its score is lower than $getMinElement(T_{red})$, and will accept the following red item i at step 9 to satisfy $floor_{red}$.

We are also looking to accept an item with a score higher than $getMinElement(T) = 8$ from any category, as long as its ceiling constraint is not exceeded. However, because i (score 9) was used to satisfy $floor_{red}$, which takes precedence, no such item is encountered. To return K items, we must accept the last item in the stream, l with score 5.

We terminate with the output $\{d, i, l\}$, with utility $8+9+5 = 22$. This is only slightly lower than the best possible utility of 24.

Algorithm 2 Diverse K -choice Secretary Algorithm

Require: Stream of items I , total number of items to select K , input size N , number of categories d , constraints $floor_i \leq k_i \leq ceil_i$ and number of items per category n_i for $i \in [1 \dots d]$.
{Initialize the output list L .}

- 1: $L = \emptyset$
{Initialize the array of counts of per-category selected items C .}
- 2: $C = [k_1 = 0, \dots, k_d = 0]$
{Initialize counts of per-category seen items M .}
- 3: $M = [m_1 = 0, \dots, m_d = 0]$
{Compute the length of per-category warm-up.}
- 4: $R = [r_1 = \lfloor \frac{n_1}{e} \rfloor, \dots, r_d = \lfloor \frac{n_d}{e} \rfloor]$
{Initialize d MinHeaps, one per category, $T_1 \dots T_d$.}
- 5: **for** $i=1 \dots d$ **do**
- 6: $T_i = \text{MinHeap}(floor_i)$
- 7: **end for**
- 8: $slack = K - \sum_{i=1}^d floor_i$
{Compute the length of category-independent warm-up.}
- 9: $r = \lfloor \frac{N}{e} \rfloor$
{Initialize a category-independent heap T .}
- 10: $T = \text{MinHeap}(slack)$
- 11: **while** $|L| < K$ **do**
- 12: $x = \text{getNextItem}(I)$
- 13: $i = \text{category}(x)$
- 14: **if** $\sum_i m_i < r$ **then**
- 15: $T \xrightarrow{\text{offer}} x$
- 16: **end if**
- 17: **if** $m_i < r_i$ **then**
- 18: $T_i \xrightarrow{\text{offer}} x$
- 19: **else if** $((k_i < floor_i) \wedge (\text{score}(x) > \text{getMinElement}(T_i))) \vee$
 $(n_i - m_i == floor_i - k_i)$ **then**
- 20: $\text{deleteMinElement}(T_i)$
- 21: $L \leftarrow x$
- 22: $k_i = k_i + 1$
- 23: **else if** $(\sum_i m_i \geq r) \wedge (\text{score}(x) > \text{getMinElement}(T) \wedge$
 $(k_i < ceil_i) \wedge (slack > 0))$ **then**
- 24: $\text{deleteMinElement}(T)$
- 25: $L \leftarrow x$
- 26: $k_i = k_i + 1$
- 27: $slack = slack - 1$
- 28: **else if** $(k_i < ceil_i) \wedge (\text{numFeasibleItems}() == K - |L|)$
 then
- 29: $L \leftarrow x$
- 30: $k_i = k_i + 1$
- 31: $slack = slack - 1$
- 32: **end if**
- 33: $m_i = m_i + 1$
- 34: **end while**
- 35: **return** L

In Example 4.1, we happen to satisfy both floor constraints (at steps 4 and 9) before accepting a category-independent item at the end of the stream. Note, however, that this may not be the case in general. For example, we could have accepted a blue item with a score higher than 8, had one been encountered at steps 5, 6, 7, or 8 – any time after $floor_{blue}$ is met.

Processing of item d in Example 4.1 illustrates that different streams (per-category and category-independent) are consumed

in parallel: d is part of the category independent warm-up (where it is discarded but its score is recorded in T), and it is also part of the post-warm-up stream for the blue category, where it is accepted, since its score exceeds $\text{getMinElement}(T_{blue})$.

Let us now consider the pseudocode for Algorithm 2. The algorithm uses a MinHeap data structure to keep track of the top- K elements seen thus far. We need one for each category (denoted T_i and initialized on line 6 with capacity $floor_i$), and an additional one for the extra elements after the floor constraints have been met (denoted T and initialized on line 10 with capacity $slack$). Each per-category heap T_i stores the best $floor_i$ scores seen among the first r_i items of category i . If $floor_i > r_i$, then T_i will store the first $floor_i$ elements observed, together with $floor_i - r_i$ elements of value -1 . Heap T is initialized similarly, storing the best $slack$ scores seen among the first $r = \lfloor \frac{N}{e} \rfloor$ items, irrespective of category.

During the warm-up period, an item x is not accepted (not added to L) irrespective of its score, but rather is offered to the relevant per-category heap (on line 18) or to the category-independent heap (on line 15). Note that the same item x may be offered to its per-category heap and to the category-independent heap during warm-up.

An item of category i is added to the output after the warm-up period if $floor_i$ is not yet satisfied and either (a) the item has a sufficiently high score or (b) we are at the end of the stream for category i (line 19). The latter condition is evaluated by comparing the number of items remaining in the stream ($n_i - m_i$) to the number of items still required for i ($floor_i - k_i$).

An item is also added to the output if its score is sufficiently high according to the category-independent estimate and there is sufficient slack to meet all outstanding floor constraints (line 24). Note that Algorithm 2 uses the slack mechanism in a similar way as Algorithm 1.

Finally, an item is added to the output if it is *feasible*: accepting it would not violate the ceiling constraint for its category, and if exactly $K - |L|$ feasible items remain in the input. We compute the number of feasible items (line 28) as a sum of $n_j - m_j$ (the number of items that remain on the stream in category j) over all feasible categories (those in which $ceil_j - k_j > 0$).

This final set of conditions (line 28) is required to ensure that exactly K items are returned by Algorithm 2. Asserting that exactly $K - |L|$ feasible items remain in I relies on the estimates of the number of items in each category.

Optimality. Algorithm 2 specifies per-category lengths of the warm-up period on line 4. What is the competitive ratio of this algorithm? To reason about this, let us first consider the K -choice Secretary Problem, a generalization of the Secretary Problem where $K \geq 1$ rather than 1 item is to be chosen in an online manner. Recall from Section 4.1 that, when $K = 1$, the optimal competitive ratio is e , and it is achieved with a warm-up period of length $\lfloor \frac{N}{e} \rfloor$ [8, 14]. For $K > 1$, it is known that competitive ratio is no worse than e under the same warm-up period length [4], but the optimal competitive ratio is not known [3].

Our problem setting, and its solution presented in Algorithm 2, differ from the generalized K -choice Secretary Problem in that we are receiving items from multiple distinct categories. Algorithm 2 treats items that belong to different categories as different sub-streams of a common stream, and is guaranteed to have a competitive ratio no less than e for selecting $floor_i$ items in each category, by an immediate application of the result of Babaioff et al. [4]. The remaining $slack$ items are selected from the common

stream (subject to floor and ceiling constraints), and will have a competitive ratio no less than e (subject to the same constraints).

We will empirically compare the quality of the result returned by Algorithm 2 to that of the static algorithms of Section 3 in Section 5.4. We will also consider the impact of warm-up period length on accuracy in that section.

Impact of per-category warm-up on utility. An important point to note is that, by estimating scores on a per-category basis rather than for the entire set of items at once, Algorithm 2 accommodates the case when score is not independent of category membership. Consider an example in which there are two categories A and B , and where, for all pairs of items $a \in A, b \in B, \text{score}(a) < \text{score}(b)$. Suppose further that a and b occur in the input in approximately equal proportion. Then, if a common heap T of size K is maintained for both categories during warm-up (with $K < \lfloor \frac{N}{e} \rfloor$), T will contain scores of some K items from B , and so it will be the case that, at any point in time, $\forall a \in A, \text{getMinElement}(T) > \text{score}(a)$. As a result, an online algorithm will accept a subset of B with a high combined score, and it will accept floor_A items from A that appear at the end of the stream. This represents the worst case for category A in terms of utility. We validate this claim experimentally in Section 5.4.

4.3 Online Algorithm with a Deferred List

In a true on-line setting, a decision must be made whether to accept or to reject an item once it is seen. In practice, it may be acceptable to keep a waiting list of modest size. For example, college admissions work this way.

We now introduce Algorithm 3, an optimized version of Algorithm 2 that will often return a set of K items of higher utility, subject to diversity constraints. This is accomplished by introducing per-category deferred lists D_i of bounded size. We now give an intuition behind this algorithm using an example.

Example 4.2. Consider again the stream of items in Figure 2. $N = 12$ items are partitioned into $d = 2$ categories, with 6 items per category: $n_{red} = n_{blue} = 6$, and arrive in random order. The goal is to select $K = 3$ items subject to $1 \leq k_{blue} \leq 2$ and $1 \leq k_{red} \leq 2$. We now highlight the differences in the processing of this input when a deferred list is allowed, as compared to that of Example 4.1 (Algorithm 2).

We conduct a warm-up period of length 2 for each category, storing $\text{floor}_{blue} = \text{floor}_{red} = 1$ highest score in each $T_{blue} = \{6\}$ and $T_{red} = \{4\}$. In contrast to Example 4.1, we do not conduct a category-independent warm-up period (there is no T).

Also in contrast to Example 4.1, items encountered during the warm-up period are not immediately discarded, but rather are placed into per-category deferred lists D_{blue} and D_{red} , which maintain up to $\text{ceil}_{blue} = 2$ and $\text{ceil}_{red} = 2$ items, respectively. Even beyond the warm-up period, we consider the scores of all encountered items, and always keep 2 best items of the appropriate category seen so far in each D_{blue} and D_{red} . Note that D_{blue} and D_{red} are MinHeaps, which we denote by sorting the elements in the order of increasing score.

In our example, $D_{blue} = \{c, a\}$ at step 3 (end of warm-up for blue), $D_{blue} = \{a, d\}$ at step 4 (d has a higher score than c and replaces c), and $D_{red} = \{e, b\}$ at step 5 (end of warm-up for red). We continue processing until a sufficient number of items post the warm-up period is seen (1 post-warm up item in each category in our example) and once there are at least K items in the union of deferred lists. We continuously update the

Algorithm 3 Diverse K -choice Secretary Algorithm with a deferred list

Require: Stream of items I , total number of items to select K , input size N , number of categories d , constraints $\text{floor}_i \leq k_i \leq \text{ceil}_i$ and number of items per category n_i for $i \in [1 \dots d]$.

{Initialize the output list L .}

- 1: $L = \emptyset$
- {Initialize i deferred lists D_i of capacity ceil_i for each category.}
- 2: **for** $i=1 \dots d$ **do**
- 3: $D_i = \text{MinHeap}(\text{ceil}_i)$
- 4: **end for**
- {Initialize the list of counts of per-category selected items C .}
- 5: $C = [k_1 = 0, \dots, k_d = 0]$
- {Initialize the list of counts of per-category seen items M .}
- 6: $M = [m_1 = 0, \dots, m_d = 0]$
- {Compute the length of per-category warm-up.}
- 7: $R = [r_1 = \lfloor \frac{n_1}{e} \rfloor, \dots, r_d = \lfloor \frac{n_d}{e} \rfloor]$
- {Initialize d MinHeaps, one per category, $T_1 \dots T_d$.}
- 8: **for** $i=1 \dots d$ **do**
- 9: $T_i = \text{MinHeap}(\text{floor}_i)$
- 10: **end for**
- {Initialize the number of unsatisfied categories u .}
- 11: $u = d - \sum_{i=1}^d \mathbb{1}[\text{floor}_i == 0]$
- {Initialize the total number of deferred items w (for “waiting”).}
- 12: $w = 0$
- 13: **while** $(u > 0) \vee (w < K)$ **do**
- 14: $x = \text{getNextItem}(I)$
- 15: $i = \text{category}(x)$
- 16: **if** $m_i < r_i$ **then**
- 17: $T_i \xleftarrow{\text{offer}} x$
- 18: **else if** $(k_i < \text{ceil}_i) \wedge (\text{score}(x) > \text{getMinElement}(T_i))$ **then**
- 19: $k_i = k_i + 1$
- 20: $\text{deleteMinElement}(T_i)$
- 21: **if** $(\text{floor}_i > 0) \wedge (k_i == \text{floor}_i)$ **then**
- 22: $u = u - 1$
- 23: **end if**
- 24: **end if**
- 25: $D_i \xleftarrow{\text{offer}} x$
- 26: $m_i = m_i + 1$
- 27: $w = \sum_i |D_i|$
- 28: **end while**
- 29: $W = \text{MaxHeap}(w)$
- 30: $W \leftarrow \bigcup_i D_i$
- 31: Invoke Algorithm 1 on W (sorted by score), compute L .
- 32: **return** L

per-category deferred lists as we process, evicting lower-scoring items and keeping 2 highest-scoring items in each category.

In our example, the algorithm terminates after step 9 (item i), with $D_{blue} = \{a, d\}$ and $D_{red} = \{b, i\}$. The union of these lists is then passed to Algorithm 1, which returns $\{a, d, i\}$, with combined utility 23. Per Example 4.1, this utility is 1 point higher than of executing Algorithm 2 on this input.

We will illustrate experimentally in Section 5.4 that Algorithm 3 usually returns a set of K items of higher utility than Algorithm 2. Note, however, that Algorithm 3 may sometimes

return items of lower combined utility, because it may terminate sooner than Algorithm 2.

We now describe Algorithm 3 in detail. To start, set u (unsatisfied) to the number of categories with $\text{floor}_i > 0$. Add the first ceil_i items to D_i irrespective of their score, then maintain no more than ceil_i items in D_i , replacing the lowest-scoring item $y \in D_i$ with item x if $\text{score}(y) < \text{score}(x)$.

A category becomes satisfied once floor_i items in D_i have a sufficiently high score (post warm-up). If a sufficient number of high-scoring items cannot be found, we satisfy floor_i by adding the required number of items of category i from the end of its stream.

The algorithm stops consuming its input once all unsatisfied categories become satisfied (i.e., once $u == 0$) and the total size of all D_i is at least K . Note that, even after a category i is satisfied, we can still add item x to D_i (while waiting for the remaining categories to be satisfied), if x happens to have a higher score than the lowest-scoring item currently in D_i .

Having filled the deferred lists, the algorithm will first add floor_i items from each D_i to the output list L , and will then fill the remaining slack positions with the highest-scoring items from the remaining deferred lists, irrespective of their scores. Algorithm 1 can be invoked for this purpose, with $I = \bigcup_i D_i$.

Note that when Algorithm 1 is invoked on line 31, it is invoked on input W , a sorted list whose size is bounded by $\sum_i \text{ceil}_i$. We assume that $\text{ceil}_i \ll |I|$. In fact, setting any ceil_i higher than K is not meaningful. Further, since K is commonly treated as a constant, then $\sum_i \text{ceil}_i$ can also be treated as such.

5 EXPERIMENTAL EVALUATION

In this paper, we have introduced diversity and fairness constraints into set selection queries under several different settings. Most importantly, we have introduced two streaming algorithms. For all our algorithms we are interested in evaluating the cost of introducing a diversity or fairness constraint in terms of the lower utility achieved. For streaming algorithms, we are further interested in how well we manage to satisfy a group constraint and make a group selection, while being forced to make decisions regarding individual items as they are presented.

5.1 Experimental Datasets

Our experimental evaluation is conducted on both real and synthetic datasets. The real data gives us a sense for what would happen in a real scenario, while the synthetic data let us vary parameters to dive deeper into understanding "what if" questions.

Forbes Richest. We selected two Forbes Richest People lists from 2016: US Richest with 400 individuals (<https://www.forbes.com/forbes-400/list/>) and World's Richest with 526 individuals (<https://www.forbes.com/billionaires/list/>). Both lists are naturally ranked by net worth. We used gender as the sensitive attribute in the US list, with a break-down of 27 female vs. 373 male individuals ($d = 2$ categories). We used country as the sensitive attribute in the World list, creating separate categories for US (197 individuals), Germany (44), China (43), Russia (25), and assigning the remaining 217 individuals to the category "other", resulting in $d = 5$ categories.

NASA Astronauts. This dataset is available at <https://www.kaggle.com/nasa/astronaut-yearbook/data> and consists of 357 astronauts, with their demographic information. We ranked this

dataset by the number of space flight hours, and assigned individuals to categories based on their undergraduate major. A total of 83 majors are represented in the dataset, we assigned 9 most frequent - Physics (35), Aerospace Engineering (33), Mechanical Engineering (30) etc, to their individual categories, and combined the remaining 141 individuals into the category "other", resulting in $d = 10$ categories.

Pantheon. This dataset is a ranking of 11,341 individuals based on the popularity of their biographical page in Wikipedia, and is available at <http://pantheon.media.mit.edu/rankings/people/all/all/-4000/2010/H15>. Individuals in the dataset include historical and present-day figures, and are described with name, gender, birth year, place of birth, and occupation. Occupation is aggregated into a set of $d = 8$ cultural domains (<http://pantheon.media.mit.edu/methods>), which we use as the sensitive attribute to state diversity constraints.

Synthetic data. We also used synthetic data in our experiments, in cases where it was important to control dataset composition and assignments of scores to items in particular categories. Synthetic datasets consisted of three attributes: identifier of a tuple, value of the sensitive attribute and score. Additional details about specific datasets will be given as appropriate.

In our discussion, we will find it convenient to use the term *balanced* to describe datasets in which different categories are represented in the same proportion. For example, a dataset in which diversity is stated with respect to gender is balanced if about 50% of the individuals in the input are male and about 50% are female.

5.2 Diversity Constraints

Recall that our algorithms are designed for diversity constraints stated in terms of size limits on each category. The specific constraints chosen can implement different notions of diversity or fairness as discussed in Section 2. We explore several families of constraints, generated using the procedure described below, after a brief discussion of requirements on the constraints.

A single per-category constraint of the form $\text{floor}_i \leq k_i \leq \text{ceil}_i$ is satisfiable if $\text{floor}_i \leq n_i$, where n_i is the number of items in category i in the input. While it is not incorrect to set $\text{ceil}_i > n_i$, this will not lead to sensible subset selection in practice, and will make satisfiability of a set of constraints more cumbersome to state. For these reasons, we also require that $\text{ceil}_i \leq n_i$.

A set of per-category constraints is *satisfiable* if two conditions hold: $\sum_{i=1}^d \text{floor}_i \leq K$ and $\sum_{i=1}^d \text{ceil}_i \geq K$.

We use several measures of diversity, listed below, to generate a set of per-category constraints of the form $\text{floor}_i \leq k_i \leq \text{ceil}_i$ for a given selected set size K and number of categories d . We generate constraints that are satisfiable individually and as a set, as discussed above. In what follows, we assume that each category i is represented in the input dataset, that is, that $n_i \geq 1$.

Minimum: (Cover as many categories as possible.)

If $K \geq d$, set $\text{floor}_i = \text{ceil}_i = 1$ for all d categories. Next, compute $r = K - d$. If $r > 0$, assign the remaining r positions in the top- K to a random category j by setting $\text{ceil}_j = \text{ceil}_j + r$. Select category j from among categories in which $n_j \geq \text{ceil}_j + r$.

If $K < d$, assign $\text{floor}_i = \text{ceil}_i = 1$ to a random set of K out of d categories, and $\text{floor}_i = \text{ceil}_i = 0$ to the remaining $d - K$ categories.

Figure 3: Accuracy of Algorithm 2 as function of walking distance, for different warm-up period lengths. Forbes US Richest, $K = 4$, $N = 400$ items, diversity on gender ($d = 2$), with average constraints $\text{floor}_i = \text{ceil}_i = K/d$.

Figure 4: Accuracy of Algorithm 3 as function of walking distance, for different warm-up period lengths. Forbes US Richest, $K = 4$, $N = 400$ items, diversity on gender ($d = 2$), with average constraints $\text{floor}_i = \text{ceil}_i = K/d$.

Average: (Select equal numbers from each category.)

If $K \geq d$, set $\text{floor}_i = \text{MIN}(\lfloor K/d \rfloor, n_i)$ and $\text{ceil}_i = \text{MIN}(\lceil K/d \rceil, n_i)$ for all d categories. Next, compute $r = \sum_{i=1}^d \text{ceil}_i$. If $r < K$, assign the remaining r positions in the top- K to a random category j by setting $\text{ceil}_j = \text{ceil}_j + r$. Select category j from among categories in which $n_j \geq \text{ceil}_j + r$.

If $K < d$, set constraints as in **minimum** above.

Proportion: (Select equal proportions from each category.)

Recall that N denotes the size of the input.

If $K \geq d$, set $\text{floor}_i = \lfloor K * n_i / N \rfloor$ and $\text{ceil}_i = \lceil K * n_i / N \rceil$.

If $K < d$, set constraints as in **minimum** above.

Relaxed average: Let integer t denote the tightness threshold.

If $K \geq d$, set constraints as in **average** above. Next, set $\text{floor}_i = \text{MAX}(\text{floor}_i - t, 0)$ and $\text{ceil}_i = \text{MIN}(\text{ceil}_i + t, n_i)$.

If $K < d$, set constraints as in **minimum** above.

Relaxed proportion: Let integer t denote the tightness threshold.

If $K \geq d$, set constraints as in **proportion** above. Next, set $\text{floor}_i = \text{MAX}(\text{floor}_i - t, 0)$ and $\text{ceil}_i = \text{MIN}(\text{ceil}_i + t, n_i)$.

If $K < d$, set constraints as in **minimum** above.

Note that in balanced datasets, average and proportion constraints are equivalent, as are relaxed average and relaxed proportion (for the same tightness threshold t).

5.3 Metrics

Recall that Algorithms 2 and 3 both consume the input one item at a time, and decide whether to accept or reject an item when it is encountered. Algorithm 3 differs from Algorithm 2 in that it can place an item on the deferred list, and decide after it has considered all feasible items which of these to accept. For a given input (a fixed set of items received in some fixed order), Algorithms 2 and 3 will stop consuming the input at some point. We refer to this point — the number of items considered from the input stream, as the *walking distance*, and use it as our primary measure of efficiency. This measure is sometimes called *depth* in the top- k literature.

In several experiments with online algorithms, we quantify the relationship between algorithm efficiency and accuracy. To quantify accuracy, we use an intuitive normalized measure that compares the scores of the K retrieved items with the best possible K scores, subject to diversity constraints. Based on our statement of optimality in Theorem 3.2, we use scores returned by Algorithm 1 as the gold standard.

To make accuracy insensitive to shifts in the score distribution, we subtract the minimum observed score from each value. For example, suppose that the lowest net worth of any individual

Figure 5: Per-category accuracy of Algorithm 2 as a function of K , on a balanced synthetic dataset of size $N = 10,000$ with average constraints. Category A items in the input have strictly lower scores than category B items. A common warm-up period leads to lower accuracy for both categories compared to per-category warm-up periods, and places items in category A at a particular disadvantage.

was 100, that $K = 2$ individuals were selected, with scores 225 and 200, and that the two highest-scoring individuals in the dataset, subject to diversity constraints, have scores 300 and 250, respectively. Then accuracy is computed as $\frac{(225-100)+(200-100)}{(300-100)+(250-100)}$.

5.4 Experimental Results: Online Algorithms

The most important question we are interested in is how well our streaming algorithms do despite being forced to meet set-oriented constraints while making decisions on individual items one at a time. The way the streaming algorithms are stated, they guarantee that the diversity constraints will be met, but do not guarantee optimality of utility score. We measure this in terms of accuracy, as described above.

The one parameter we can control in the streaming algorithms is the length of the warm-up period. Therefore, we start by presenting the relationship between warm-up period length and accuracy of the online algorithms of Section 4. To show this relationship, we will consider Figures 3 and 4, where 400 US Richest individuals (see Section 5.1 for dataset description) were randomly permuted, and where a diversity constraint was specified over the binary gender attribute, with $2 \leq k_F \leq 2$ and $2 \leq k_M \leq 2$ (a tight average constraint) and with $K = 4$. Each point in these figures corresponds to an execution of the relevant algorithm on a random permutation, with 100 executions per experiment (note that points may coincide). Other datasets in our experiments exhibited a similar trend.

We see that Algorithm 3 gets very high accuracy, often equaling the gold standard, if given enough warm up. Algorithm 2 also does not do too badly in terms of accuracy, though Algorithm 3 does substantially better.

Walking distance takes on values between K (output size) and N (input size). Walking distance is made up of two parts: length of the warm-up period during which an on-line algorithm is estimating item scores, and post-warm-up, during which an algorithm is able to accept items. In both Algorithms 2 and 3, the per-category warm-up period has length $\lfloor \frac{N_i}{e} \rfloor$ for category i , while the total

warm-up period length is the sum of per-category warm-up period lengths, and of $\lfloor \frac{N}{e} \rfloor$ for the category-independent warm-up.

Consider Figures 3a and 4a, which show the overall accuracy as a function of walking distance for Algorithms 2 and 3, respectively. Note that accuracy of Algorithm 2 varies significantly at walking distance 400 – the case when all N items were consumed from the stream. This effect is so pronounced that in Figure 3a the over-all trend in accuracy is decreasing, due exclusively to this end-of-stream effect. In contrast, Algorithm 3 is not forced to accept items from the end of the stream, and so its accuracy strictly increases as a function of walking distance.

We do not have explicit control of the post-warm-up walking distance (because we must return a valid set of results – K results that meet the diversity constraints). However, we can impact walking distance by changing the length of the per-category warm-up periods, set to $\lfloor \frac{N_i}{e} \rfloor$ by default. These settings provide a strong theoretical guarantee, but can be conservative in practice, particularly for Algorithm 3 (the deferred list variant). Figures 3b and 3c show accuracy when warm-up is abbreviated to a quarter and a sixteenth of the optimal for Algorithm 2, and Figures 4b and 4c correspond to Algorithm 3. Observe that reducing warm-up period length introduces a trade-off between walking distance (efficiency) and accuracy, and that accuracy is often comparable to that which results from the full warm-up period, but at a lower efficiency cost.

In the next experiment we demonstrate the importance of having per-category warm-up periods. Recall that Algorithm 2 considers, and rejects, $\lfloor \frac{N_i}{e} \rfloor$ items in each category before accepting any items. This warm-up period allows the algorithm to form an expectation on the score of an item. Suppose now that $K = 2$, that there are two categories A and B in the input, and that diversity constraints are such that exactly one item per category is to be selected. Further, suppose that scores of A-items are strictly lower than scores of B-items. If a common (rather than a per-category) warm-up period were used by the algorithm, with a common MinHeap of score thresholds T , then

(a) NASA Astronauts, $N = 357$, $K = 30$, $d = 10$.

(b) Forbes World Richest, $N = 526$, $K = 20$, $d = 5$.

Figure 6: Accuracy of Algorithm 3 under different diversity constraints, at $1/8$ warm-up.

Figure 7: The cost of diversity: quality of the selected set is lower, in absolute terms, when items of a lower score must be included to satisfy diversity constraints. Synthetic datasets with $N = 10,000$, $d = 2$, under average constraints. Item scores are drawn from Gaussian distributions with the same standard deviation but different means (μ_A and μ_B).

T would contain the highest-scoring B-items that were encountered during warm-up. Since A-item scores are lower than B-item scores, no post-warm-up A-item will have a score that exceeds $\text{getMinElement}(T)$. This would force the algorithm to walk down the end of the stream in all cases (impacting performance), and to accept the very last A-item from the stream (impacting accuracy for category A).

To illustrate this point, we generate a synthetic dataset of $N = 10,000$ items in two categories, A and B, with a balanced breakdown — 5,000 A-items and 5,000 B-items, and with category-dependent scores. Scores of A-items are drawn uniformly at random from the $[0, 0.5)$ range, while scores of B-items are drawn uniformly at random from $[0.5, 1)$. We vary K between 2 and

100, and impose a (tight) average diversity constraint, setting $\lfloor \frac{K}{2} \rfloor \leq k_F \leq \lfloor \frac{K}{2} \rfloor$ and $\lfloor \frac{K}{2} \rfloor \leq k_M \leq \lfloor \frac{K}{2} \rfloor$.

Figure 5 shows box-and-whiskers plots in which accuracy is presented as a function of K (see Section 5.3 for a description of how accuracy is computed). Observe that that accuracy for category A is lower than accuracy for category B in all cases when a common threshold is used (see Figure 5a). This is in contrast to the per-category threshold case in Figure 5b, where accuracy is comparable across the two categories.

Let us now compare performance of Algorithm 3 under different diversity constraints. Figure 6 presents accuracy as a function of walking distance, with warm-up period of length $\frac{1}{8}$ of the theoretically optimal (so, $\lfloor \frac{n_i}{8 * d} \rfloor$ per category), for two real datasets: NASA Astronauts ($N = 327$, $d = 10$ and $K = 30$) and the World’s Richest ($N = 526$, $d = 5$, $K = 20$). We also experimented with other real datasets, and with different values of K and warm-up period lengths, and present here results that are representative.

The average relaxed constraint (purple line in Figure 6) uses $t = \lfloor 0.3 * k \rfloor$ as the threshold (see Section 5.3 for a description of this and other constraints) and is easier to satisfy than the tight constraints, leading to somewhat lower walking distance. This difference was somewhat less pronounced in Figure 6a than in Figure 6b, and is sensitive to the variation in dataset composition (how balanced the categories are) and to the value of K .

In our final experiment with online algorithms, we quantified the impact of warm-up period length on the variance in accuracy. We generated a synthetic dataset with $N = 10,000$ items and with $d = 2$ categories. We requested that $K = 10$ items be returned by Algorithms 2 and 3, subject to proportion constraints.

Scores of A-items were drawn uniformly at random from $[0, 0.5)$, while scores of B-items were drawn from $[0.5, 1)$. (Note that we executed per-category warm-up in both algorithms, and so differences in scores between A and B do not impact accuracy, as we saw in Figure 5.) We generated three such datasets, with A constituting 10%, 25% and 50% of the over-all dataset. For Algorithm 2, we observed, as expected, that higher variance in accuracy occurs when A appears in the dataset in lower proportion: variance was 0.080 for 10% proportion, 0.075 for 25% proportion and 0.019 for 50% proportion. Variance did not differ significantly for Algorithm 3.

(a) NASA Astronauts, $N = 357$, $d = 10$.

(b) Pantheon, $N = 11,341$, $d = 8$.

(c) Forbes World's Richest, $N = 526$, $d = 5$.

(d) Forbes US Richest, $N = 400$, $d = 2$.

Figure 8: Walking distance of Algorithm 1 in proportion to N , as a function of K , for different diversity constraints.

5.5 Experimental Results: Static Algorithm

In this experiment we quantify the cost of imposing diversity constraints, in terms of a normalized measure we call *quality*: the sum of score of the diverse top- K divided by the sum of scores of the “vanilla” (category-agnostic) top- K . Figure 7 presents box-and-whiskers plots that quantify this cost of diversity as a function of K for two synthetic datasets, each of size N , with $d = 2$ categories represented in equal proportion, and with average diversity constraint. In the both datasets, item scores were drawn from per-category Gaussian distributions, with different means but the same standard deviations. The dataset presented in green had means of A-scores and of B-scores close to each other ($\mu_A - \mu_B = 0.1$), while in the dataset presented in blue, these distributions were further apart ($\mu_A - \mu_B = 0.5$). As expected, the cost of diversity is higher in the latter case, since items of lower scores (in absolute terms) must be included into the result to satisfy diversity constraints.

In our final experiment we use real datasets to support the claim that, while Algorithm 1 may walk to the end of the input in the worst case, this rarely happens in practice. Figure 8 presents walking distance of Algorithm 1 as a function of K for different diversity constraints, for the NASA Astronauts, Pantheon, Forbes World's Richest, and Forbes US Richest datasets. A value of 1 on the y -axis denotes that the algorithm walked to the end of the list (that is, walking distance equals N). We observe that this does not occur often, particularly for lower values of K .

6 RELATED WORK

There is considerable work on diverse top- k , starting with [2, 16], see also [18] (Sections 5.1, 5.6 and 6) for a survey. The work proposed here differs from prior work in that we consider a family of diversity constraints that can express coverage-based (rather than distance-based) diversity [7], and can also be used to compute

several fairness metrics — those based on proportional representation. To the best of our knowledge, diversity in combination with utility has not been considered in a fully online setting.

In [16] a generic method is proposed to extend top- k algorithms with a diversity criterion that is based on pair-wise similarity. The problem is formulated as: given a user-defined pair-wise similarity function $sim(s_i, s_j)$, and a user-defined similarity threshold τ , return the highest-scoring set of k items such that $sim(s_i, s_j) \leq \tau$. When describing top- k methods, they refer to incremental methods (generate results in decreasing order of scores, stop once k results were generated) vs. bounding methods (generate results in some order, stop once the top- k are among the results, Fagin’s TA is in this category).

More recently, diversity-aware top- k for pub/sub queries over text streams was considered in [6]. There, diversity is a pair-wise measure based on document similarity in the top- k (max-sum), quality is measured as the relevance of a document to a user’s query, and there is additionally a per-document recency score that is appropriate for a stream of Twitter messages or Facebook status updates, and is based on an exponential decay function.

Another related line of work is [1], where max-sum diversity is maximized subject to a constraint on a variant of coverage-based diversity. The problem is posed as a partition matroid, a local search algorithm is proposed, and it is shown that it achieves a 0.5 approximation of the optimal solution.

Selection of diverse set results in an online setting is studied in [15]. The authors consider selection of subsets of items that are simultaneously diverse along multiple dimensions. For example, for program committee selection it is desirable to achieve coverage of topics, geographic diversity and gender diversity. The paper proposes and analyzes several diversity objectives and proposes heuristic and dynamic programming methods. The most important difference between our method and that of [15] is that they do not explicitly handle utility.

In [16] a set of diverse top- k items is determined that maximizes the total score of the K selected items, subject to a pair-wise diversity constraint. The problem is modeled by representing the items as vertices in a graph, and by including an edge between vertices s_i and s_j if their similarity is above a user-specified threshold τ . A diverse set K is the independent set of a graph — a set of vertices in which no two vertices are adjacent. This formulation can accommodate the coverage diversity version of our problem: Include an edge between two vertices if they belong to the same category, then identify an independent subset of size d that maximizes the total score. If $d < k$, we add $k - d$ vertices that maximize the total score. The algorithmic contributions of [16] are in (1) determining when the set of $k' > k$ items is sufficient to compute the true diverse top- k , and (2) efficiently identifying the independent set of a graph for a fixed k (finding an independent set of a graph is NP-hard).

7 CONCLUSIONS

Diversity and group fairness are important objectives in algorithmic decision-making. Since most algorithms are designed to score or classify items individually, it is not easy to support these objectives. In this paper, we showed how we can continue to select items individually and meet desired diversity and group fairness constraints, while paying a very small utility cost.

We demonstrated experimentally that the theoretically-motivated setting for warm-up period length can be conservative in practice.

In our future work, we will investigate the interaction between expected (or observed) score variance and warm-up period length.

Further, we demonstrated that different categories must be treated separately in score estimation, to achieve comparable accuracy irrespective of expected score, and ultimately afford comparable opportunity to members of different groups.

ABSTRACT

The performance of modern geo-distributed database applications is increasingly dependent on remote access latencies. Systems that cache query results to bring data closer to clients are gaining popularity but they do not dynamically learn and exploit access patterns in client workloads. We present a novel prediction framework that identifies and makes use of workload characteristics obtained from data access patterns to exploit query relationships within an application’s database workload. We have designed and implemented this framework as Apollo, a system that learns query patterns and adaptively uses them to predict future queries and cache their results. Through extensive experimentation with two different benchmarks, we show that Apollo provides significant performance gains over popular caching solutions through reduced query response time. Our experiments demonstrate Apollo’s robustness to workload changes and its scalability as a predictive cache for geo-distributed database applications.

1 INTRODUCTION

Modern distributed database systems and applications frequently have to handle large query processing latencies resulting from the geo-distribution of data [11, 13, 41]. Industry reports indicate that even small increases in client latency can result in significant drops in both web traffic [20] and sales [3, 30]. A common solution to this latency problem is to place data closer to clients [38, 39] using caches, thereby avoiding costly remote round-trips to datacenters [27]. Static data, such as images and video content, is often cached on servers geographically close to clients. These caching servers, called *edge nodes*, are a crucial component in industry architectures. To illustrate this, consider Google’s datacenter and edge node locations in Figure 1. Google has comparatively few datacenter locations relative to edge nodes, and the latency between the edge nodes and datacenters can be quite large. Efficiently caching data on these edge nodes substantially reduces request latency for clients.

Existing caching solutions for edge nodes and content delivery networks (CDN) focus largely on static data, necessitating costly round trips to remote data centers for requests relying on dynamic data [21]. Since a majority of webpages today are generated dynamically [5], a large number of requests are not satisfied by cached data, thereby incurring significant latency penalties. We address this concern in Apollo, a system that exploits client access patterns to intelligently prefetch and cache dynamic data on edge nodes.

Figure 1: Google’s datacenter and edge node locations [21].

3. SELECT ... FROM ORDER_LINE, ITEM
   WHERE OL_I_ID = I_ID and OL_O_ID = @O_ID

```

Figure 2: A set of motivating queries in TPC-W’s Order Display web interaction. Boxes of the same colour indicate shared values across queries.

Database client workloads often exhibit query patterns, corresponding to application usage patterns. In many workloads [1, 10, 42], queries are highly correlated. That is, the execution of one query determines which query executes next and with what parameters. These dependencies provide opportunities for optimization through predictively caching queries. In this paper, we focus on discovering relationships among queries in a workload. We exploit the discovered relationships to predictively execute future dependent queries. Our focus is to reduce the response time of consequent queries by predicting and executing them, caching query results ahead of time. In doing so, clients can avoid contacting a database located at a distant datacenter, satisfying queries instead from the cache on a closer edge node.

As examples of query patterns, we consider a set of queries from the TPC-W benchmark [42]. In this benchmark’s Order Display web interaction, shown in Figure 2, we observe that the second query is dependent upon the result set of the first query. Therefore, given the result set of the first query, we can determine the input set of the second query, *predictively execute* it, and *cache* its results. After the second query has executed, we can use its result set as input to the third query, again presenting an

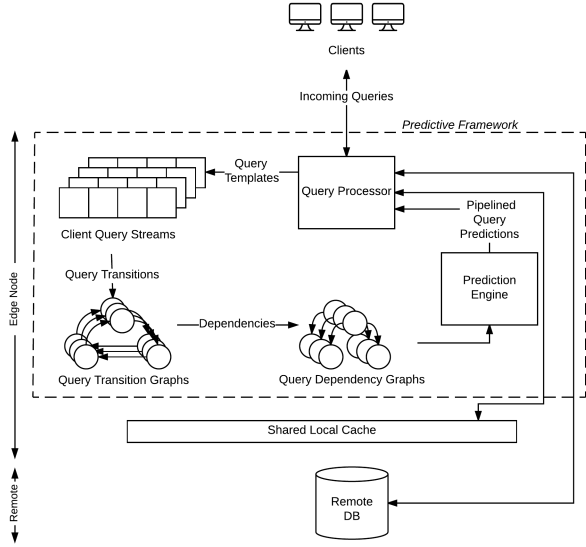

Figure 3: Query flow through components of the predictive framework.

opportunity for predictive caching. Similar scenarios abound in the TPC-W and TPC-C benchmarks, such as in the TPC-W Best-Seller web interaction and in the TPC-C Stock level transaction. Examples that benefit from such optimization, including real-world applications, have been previously described [10].

In this paper, we propose a novel prediction framework that uses a query-pattern aware technique to improve performance in geo-distributed database systems through caching. We implement this framework in Apollo, which uses a query transition graph to learn correlations between queries and to predict future queries. In doing so, Apollo determines query results that should be cached ahead of time so that future queries can be satisfied from a cache deployed close to clients. Apollo prioritizes common and expensive queries for caching, eliminating or reducing costly round-trips to remote data without requiring modifications to the underlying database architecture. Apollo’s ability to learn allows it to rapidly adapt to workloads in an online fashion. Apollo is designed to enhance an existing caching layer, providing predictive caching capabilities for improved performance.

The contributions of this paper are threefold:

- (1) We propose a novel *predictive* framework to identify relationships among queries and predict consequent ones. Our framework uses *online learning* to adapt to changing workloads and reduce query response times (Section 2).
- (2) We design and implement our framework in a system called Apollo, which predictively executes and caches query results on edge nodes close to the client (Section 3).
- (3) We deploy and extensively test Apollo on Amazon EC2 using the TPC-W and TPC-C benchmark workloads to show that significant performance gains can be achieved for different query workloads (Section 4).

2 PREDICTING QUERIES

A client’s database workload is comprised of a stream of queries and the transitions between them. These queries are synthesized into the *query transition graph*, which is at the core of our predictive framework. From this query transition graph, we discover

query relationships, dependencies and workload characteristics for use in our predictive framework. The predictive framework stores query result sets in a shared local cache, querying the remote database if a client submits a query for which the cache does not have the results.

Figure 3 gives a high level overview of how incoming queries are executed, synthesized into the query transition graph, and used for future query predictions. Incoming queries are routed to the query processor, which retrieves query results from a shared local query result cache, falling back to a remote database on a cache miss. Query results are immediately returned to the client and, together with their source queries, are mapped to more generalized *query template* representations (Section 2.1). These query templates are placed into per-client queues of queries called query streams, which are continuously scanned for relationships among executed queries. Query relationships are synthesized into the query transition graph and then used to detect query correlations, discovering dependencies among executed queries and storing them in a dependency graph. This dependency graph is used by the prediction engine to predict consequent queries given client queries that have executed.

Although we focus on geographically distributed edge nodes with remote datacenters, Apollo can also be deployed locally as a middleware cache. Our experiments in Section 4 show that both deployment environments benefit significantly from Apollo’s predictive caching.

Next, we discuss the abstractions and algorithms of our predictive framework, describing how queries flowing through the system are merged into the underlying models and used to predict future queries.

2.1 Query Templates

Using a transition graph to reason about query relationships requires a mapping from database workloads (queries and query relationships) to transition structures (query templates and template transitions). We propose a formalization of this mapping through precise definitions, and then show how our model can be used to predict future queries.

Queries within a workload are often correlated directly through *parameter sharing*. Motivated by the Stock Level transaction in the TPC-C benchmark, consider an example of parameter sharing in which an application executes query Q_1 to look up a product ID followed by query Q_2 to check the stock level of a given product ID. A common usage pattern is to execute Q_1 , and then use the returned product ID as an input to Q_2 to check that product’s stock level. In this case, Q_2 is directly related to Q_1 via a *dependency* relationship. Specifically, Q_2 relies on the output of Q_1 to execute.

We generalize our model by tracking relationships among query templates rather than among parameterized queries. Two queries Q_1 and Q_2 have the same query template if they share the same statement text barring constants that could logically be replaced by placeholders for parameters values (“?”). Each query template is represented by a node in the query transition graph.

Below is an example of two queries (Q_1, Q_1') and their corresponding templates (Qt_1, Qt_1'):

```

 $Q_1$ : SELECT C_ID FROM CUSTOMER WHERE C_UNAME = 'Bob' and C_PASSWD = 'pwd'
 $Qt_1$ : SELECT C_ID FROM CUSTOMER WHERE C_UNAME = ? and C_PASSWD = ?

```

```

Q1: SELECT C_ID FROM CUSTOMER WHERE C_UNAME =
'Alice' and C_PASSWD = 'pwd2'
Q1': SELECT C_ID FROM CUSTOMER WHERE C_UNAME =
? and C_PASSWD = ?

```

Note that although the above two original queries differ, their query templates are the same. Therefore, a node's transitions in the transition graph are based on query relationships from both Q_1 and Q_1' .

2.2 Query Template Relationships

To find query template relationships, we implement the transition graph as a frequency-based Markov graph, constructing it in an online fashion. We exploit the memory-less property of Markov models to simplify transition probability computations — transition probabilities are based solely on the previous query the client executed.

We monitor incoming queries, map them to query templates and calculate template transition probabilities. In particular, for any two templates Q_{t_i}, Q_{t_j} , we create an edge from Q_{t_i} to Q_{t_j} if Q_{t_j} is executed after Q_{t_i} . We store the probability of Q_{t_j} executing after Q_{t_i} on this edge, and refer to it as $P(Q_{t_j}|Q_{t_i})$. If this probability is larger than some configurable threshold τ , we say Q_{t_j} is related to Q_{t_i} .

The τ parameter serves as a configurable confidence threshold for query template relationships. More concretely, the τ parameter provides the minimum required probability for Q_{t_j} executing after Q_{t_i} to infer that they are related. By choosing τ appropriately, we can limit the predictive queries executed after seeing Q_{t_i} to only those that are highly correlated to it. In doing so, we ensure that our predictions have a high degree of accuracy and avoid inundating the database with predictive executions of unpopular queries.

$P(Q_{t_j}|Q_{t_i})$ is too broad to capture fine-grained query template relationships. Given enough time, almost all of the query templates in a workload could be considered related under the above definition. Two templates should not be considered related if there is a significant time gap between them, thus motivating a temporal constraint. Furthermore, by placing a temporal restriction on the relationship property, we reduce the time needed to look for incoming related templates. Consequently, we define a configurable duration, Δt , which specifies the maximum allowable time separation between related query templates.

Definition 2.1. For any two query templates Q_{t_i}, Q_{t_j} , in which Q_{t_j} is executed T time units apart from Q_{t_i} , if $P(Q_{t_j}|Q_{t_i}; T \leq \Delta t) > \tau$ for some threshold parameter $\tau \in [0, 1]$, we consider Q_{t_j} to be a related query template of Q_{t_i} .

To learn a transition graph representing $P(Q_{t_j}|Q_{t_i}; T \leq \Delta t)$, we map executed queries to query templates and place them at the tail of per-client queues called query streams. Since each client has its own stream and transition graph, we avoid expensive lock contention when updating the graphs and computing transition probabilities.

Algorithm 1 runs continuously over client query streams, updating their corresponding transition graphs. Intuitively, the algorithm scans the query stream, looking for other query templates that executed within Δt of the first query template, adding counts to their corresponding edges and afterwards incrementing the vertex count indicating number of times the template has been seen. To calculate the probability of $P(Q_{t_j}|Q_{t_i}; T \leq \Delta t)$, we take the edge count from Q_{t_i} to Q_{t_j} and divide by the vertex count for Q_{t_i} . To use

Algorithm 1 Query Transition Graph Construction

Input: $(Q_{t_1}, t_1), (Q_{t_2}, t_2), \dots$, an infinite stream of incoming query template identifiers and their execution timestamps,
 Δt , a fixed time duration,
 $G = (V, E)$, a directed graph, initially empty,
 $w_v : V \rightarrow \mathbb{N}$, vertex counters indicating the number of times we have seen the vertex, initially all zero,
 $w_e : V \times V \rightarrow \mathbb{N}$, edge counters indicating the number of times we've seen the outgoing vertex followed by the incoming vertex within Δt , initially all zero.

```

i ← 1
loop
  if ti + Δt > now() then
    wait until now() > ti + Δt
  end if
  V ← V ∪ {Qti}
  wv(Qti) ← wv(Qti) + 1
  j ← i + 1
  loop
    if tj > ti + Δt then
      // too far apart in time
      break
    else
      E ← E ∪ {(Qti, Qtj)}
      we(Qti, Qtj) ← we(Qti, Qtj) + 1
    end if
    j ← j + 1
  end loop
  // advance forward in stream
  i ← i + 1
end loop

```

the variables directly from Algorithm 1, the probability that query template Q_{t_j} executes within Δt of a query template Q_{t_i} is given by $\frac{w_e(Q_{t_i}, Q_{t_j})}{w_v(Q_{t_i})}$. Per Definition 2.1, if this probability exceeds τ then Q_{t_j} is considered related to Q_{t_i} .

The choice of the Δt parameter can impact prediction efficacy. If Δt is too high, it is possible that relationships will be predicted where there are none; if Δt is too low, we may not discover relationships where they are present. Although the choice of Δt is workload dependent, some indicators aid us in choosing an appropriate value, such as query arrival rate. If $P(Q_{t_j}|Q_{t_i}; T \leq \Delta t)$ is high for a fixed Q_{t_i} and many different Q_{t_j} , then either Q_{t_i} is a common query template with many quick-executing related query templates, or Δt is set too high. If this holds for many different Q_{t_i} , then Δt can be decreased. A similar argument holds for increasing Δt . We discuss selection of Δt and τ values for various workloads in Section 4.7.

A key property of our model is that it uses online learning to adapt to changing workloads. As new query templates are observed, query template execution frequencies change, or query relationships adjust, the transition graph adapts to learn the changed workload. Moreover, online learning precludes the need to undergo expensive offline training before deployment. Instead, our model rapidly learns client workloads and takes action immediately.

2.3 Parameter Mappings

Predictive query execution requires a stronger relationship between queries than the transition graph provides. In addition to queries being related, they must also exhibit a dependency relationship.

To provide predictive execution capabilities, we record the output sets of query templates and match them with the input sets of templates that we have determined are related based on the transition graph. We then confirm each output column to input variable mapping over a verification period, after which only the mappings present in every execution are returned.

As a concrete example, consider the TPC-W queries from Figure 2. We will refer to the query template for the first query as Qt_1 and the template for the second query as Qt_2 . In the first stage of tracking, we observe which query templates have executed within Δt of Qt_1 . Once Qt_1 has executed enough times (according to the verification period), we begin to construct mappings among the query templates. After Qt_1 finishes an execution, we record its output set. When any of Qt_1 's related query templates (in this case assume only Qt_2) are executed, we record their input sets. We then check if any column's result in Qt_1 's output set maps to the input parameters of Qt_2 . If they do, we record the matching output columns with their corresponding input argument position. If the *same* mappings are observed across the verification period, we infer that these mappings always hold.¹ If a query template has mappings for every one of its input arguments from a set of prior templates, we can predict a query by forwarding parameters from its prior template's result sets as soon as they are available. In this case, we say the query template is a candidate for predictive execution given its prior query templates' result sets. Similarly, we discover mappings between Qt_2 and Qt_3 and use them to execute Qt_3 given Qt_2 's result set.

2.4 Pipelining Query Predictions

Parameter mappings among query templates enable predictive execution of queries as soon as their input sets are available via prior template execution. It may be the case that the prior query templates are also predictable, forming a hierarchical tree of dependencies among templates. We exploit these relationships by *pipelining* query predictions. Pipelining uses result sets from predictively executed queries as input parameters for future predictions, thereby enabling predictions several steps in advance.

Figure 4: An example of pipelining within a dependency hierarchy. The arrows represent a mapping from a prior query template's output set to the consequent query template's input set.

Figure 4 illustrates how pipelining can be used to form extended chains of predictive executions using the TPC-W example from Figure 2. Qt_1 has a mapping to Qt_2 , which in turn has a mapping

¹If future executions disprove a mapping, we will mark that mapping invalid and preclude the template from predictive execution if its dependencies are no longer met.

to Qt_3 . If Qt_1 is executed, we can forward its result set as input with which to predictively execute Qt_2 . Once Qt_2 has also been executed, we can predictively execute Qt_3 . As such, Qt_2 is *fully defined* given the result set of Qt_1 , and Qt_3 is fully defined given the result set of Qt_2 . We formalize the notion of fully defined queries:

Definition 2.2. A fully defined query template (FDQ) Qt_j has all of its inputs provided by some set, possibly empty, of prior query templates $Qt_{i_1}, Qt_{i_2}, \dots, Qt_{i_k}$ where each Qt_{i_m} ($\forall m \in [1, k]$) is either:

- (1) a fully defined query template, or
- (2) a dependency query template, required to execute Qt_j .

Per Definition 2.2, both Qt_2 and Qt_3 are FDQs, but Qt_1 is simply a dependency query. This definition captures the dependency-graph nature of FDQs — each node in this graph corresponds to a query template, with inbound and outbound edges corresponding to inbound and outbound parameter mappings, respectively. The transition graph induces the dependency graph but is stored and tracked separately. By keeping the dependency graph separate, we reduce contention on it. Once the dependency graph matches the current workload, it will not need to be modified until the workload changes.

Algorithm 2 Core Prediction Algorithm

```

Input: executed query template  $Qt$ 
  record_query_template( $Qt$ )
  new_fdqs = find_new_fdqs( $Qt$ )
  rdy_fdqs = mark_ready_dependency( $Qt$ )
  rdy_fdqs = rdy_fdqs  $\cup$  new_fdqs
  ordered_fdqs = find_all_runnable_fdqs(rdy_fdqs)
  for all rdy_fdq  $\in$  ordered_fdqs do
    execute_fdq(rdy_fdq)
  end for
  
```

Discovering new FDQs, managing FDQ dependencies, and pipelining predictions comprise the main routine of the predictive framework. The engine executes Algorithm 2 after the execution of a client-provided instance of query template Qt . The engine records Qt 's result set and input parameters in the query transition graph (Section 2.3), looks for parameter mappings, and records discovered dependencies in the dependency graph. This query template is then marked as executed so that FDQ pipelines that depend on its result set can proceed. Any queries that are determined ready for execution given the result of this query (and previously executed queries) are then executed, forwarding parameters from their dependent queries' result sets. The dependencies are then reset, waiting for future invocations with which to predict queries. The dependency graph is stored as a hash map with edges between dependent queries, allowing Apollo to quickly determine which FDQs are ready for execution given an executed query.

Always defined query templates (ADQs) are a subset of FDQs, requiring that all of their prior query templates (recursively) are FDQs. They comprise an important subclass of fully defined queries since their dependencies are *always* satisfied; they can be executed and cached at any time. As a concrete example, "SELECT COUNT(*) FROM shopping_cart" is an ADQ because all of its input parameters (the empty set) are always satisfied.

It follows from Definition 2.2 that an FDQ is an ADQ if and only if all of its inputs are provided by ADQs. Consequently, ADQ

hierarchies are discovered by recursively checking the dependency structure of the FDQ.

3 APOLLO

In this section, we present Apollo, our system that implements the predictive framework described in Section 2. Apollo is a system layer placed between a client application and the database server. Application clients submit queries to the Apollo system, which then interacts with the database system and cache to return query results.

Apollo uses Memcached [19], a popular industrial-strength distributed caching system, as the query result cache. Each executed read-only query has its result set placed in Memcached, which employs the popular Least Recently Used (LRU) eviction policy. With predictive caching enabled, Apollo also places predictively executed query results into the cache, increasing the number of cache hits and thereby overall system performance. Apollo’s predictive engine operates in a *complementary* manner where queries are passed unchanged through to the cache and database, preserving the effective workload behaviour. Apollo executes predicted queries and caches them ahead of time, reducing response times through correlated query result caching.

Since Apollo is implemented in the Java programming language, we use the JDBC API to submit queries to the remote MySQL [33] database. The JDBC API [32] makes Apollo database agnostic and therefore portable, allowing MySQL to be easily swapped for any other JDBC compliant relational database system.

To efficiently track query templates within Apollo, we identify queries based on a hash of their constant independent parse tree. A background thread processes the SQL query strings placed into the query stream, parsing and then hashing them into a 64-bit identifier. All parameterizable constants are replaced by a fixed string, and therefore share the same hash code. Thus, queries with the same text modulo parameterizable constants have the same hash.

Hashes can be computed efficiently and are used internally to refer to query templates. Apollo uses them to look up nodes in the transition graph, and to find statistics and parameters we have stored for each query template. Hash collisions are very rare due to the length of the hash and common structures that SQL statements share. Due to the complementary nature of Apollo, query template hash collisions are guaranteed not to introduce incorrect system behaviour.

3.1 Prediction Engine

When a client submits a query, it has its results retrieved from the local cache or executed against the remote database, then placed into Apollo’s *query stream* and evaluated by the prediction engine. Background threads use the query stream to construct the transition graph described in Section 2, processing executed queries into query templates. The core prediction routine from Section 2.4 is then invoked: new FDQs are discovered from the underlying transition graph, the dependency graph is updated, and future queries are predicted using pipelining. We now detail each of these subroutines, showing how these operations are carried out efficiently.

Algorithm 3 shows how new FDQs are discovered. First, the transition graph is consulted for all related query templates (templates with inbound edges from Qt_i) since these are the templates that may have new mappings from Qt_i ’s result set. Qt_i itself is also

checked since it may be an ADQ (if it has no input parameters). For each query template Qt_j that has no recorded dependency information in the dependency graph, the transition graph is checked to see which templates have mappings to them. If each of Qt_j ’s input parameters are satisfied by its prior query templates then by Definition 2.2 we know that it is an FDQ. An FDQ structure is constructed for Qt_j and its dependencies are recorded in the dependency graph. For efficiency, we represent the dependency graph as a hash map from dependency query templates to dependent templates and their full dependency list. Therefore, determining newly satisfied FDQs can be performed quickly with simple lookup operations.

Algorithm 3 find_new_fdqs

Input: a query template Qt_i
Output: a set of newly discovered FDQs

```

queries_to_check = get_related_queries( $Qt_i$ )
queries_to_check = queries_to_check  $\cup$  { $Qt_i$ }
new_fdqs = {}
for all  $Qt_j \in$  queries_to_check do
  if !already_seen_deps( $Qt_j$ ) then
    p_mappings = get_prior_query_mappings( $Qt_j$ )
    if have_enough_mappings( $Qt_j$ ) then
      fdq = construct_fdq( $Qt_j$ , p_mappings)
      unresolved_deps = get_dependencies(fdq)
      add_to_dep_graph(unresolved_deps, fdq)
      mark_seen_deps(fdq)
      new_fdqs = new_fdqs  $\cup$  {fdq}
    end if
  end if
end for
return new_fdqs

```

Apollo ensures that there exists only one instance of an FDQ hierarchy throughout the system so that mapping updates affect both the FDQ and any FDQ structures that contain it. To do so, we track the FDQs that the system has constructed before, returning a previously constructed FDQ if applicable. During FDQ construction, dependency loops are detected and returned as dependency queries in an FDQ hierarchy. If all children of an FDQ are tagged as ADQs, or if an FDQ has no parameters and no children, then it is tagged as an ADQ and stored for use during cache reload (Section 3.4.2). Dependency queries are marked as unresolved dependencies on the FDQ and used to determine when an FDQ is ready for execution. Algorithm 4 shows how dependencies for known FDQs are tracked and used for predictive execution. After the execution of a given query template Qt_i , each dependent FDQ marks that dependency as satisfied. If all of an FDQ’s dependencies are now satisfied, we add it to a list of “ready FDQs”, resetting its dependencies so that they must be satisfied again before we determine the FDQ as being ready for future execution.

Algorithm 4 is used as part of a breadth-first approach to determine all runnable FDQs given the current query state. Apollo determines which FDQs are executable given the current system state and a newly executed query, adding them to the list of ready FDQs. Apollo then determines which other FDQs are executable given this FDQ list, repeating the process as necessary. This final list of FDQs is then executed in order, feeding result sets as parameters to dependent FDQs.

Algorithm 4 mark_ready_dependency

Input: an executed query Qt_i whose result set is now available

Output: a set ready_fdqs of FDQs ready for execution

```
ready_fdqs = {}
dependency_lists = get_dep_query_dlists( $Qt_i$ )
for all d_list  $\in$  dependency_lists do
  mark_dependency_satisfied(d_list,  $Qt_i$ )
  if all_deps_satisfied(d_list) then
    ready_fdqs = ready_fdqs  $\cup$  get_fdq(d_list)
    reset_dependencies(d_list)
  end if
end for
return ready_fdqs
```

3.2 Client Sessions

Apollo uses a client session consistency scheme [15], enabling its predictive cache to share cached results among clients and scale in the presence of write queries. In brief, each client has an independent session that guarantees that it accesses data at least as fresh as data it last read or wrote and that it efficiently shares cached entries with other clients.

Each client maintains a version vector (v_1, v_2, \dots, v_n) indicating its most recently accessed version v_i for each table R_i . Query results are stored in the cache and timestamped with a version vector (c_1, c_2, \dots, c_n) matching the version vector of the client that wrote it. When a client wants to execute a read query on a set of tables (R_1, R_2, \dots, R_n) , it checks if there exists an entry in the cache for that query with a version vector with $(c_1 \geq v_1, c_2 \geq v_2, \dots, c_n \geq v_n)$. If so, the client will retrieve and return the cached result, updating its client state for each of the tables to match that of the cached entry. If there is no such entry, the client will execute the query against the database, updating its version vector for each of the affected tables to match their versions in the database and storing the result in the cache. Write queries are never predictively executed (to prevent unnecessary rollbacks) and always execute against the database. After a client executes a write query, its version vector is updated to match the state of the database.

Since cache misses and write queries update a client's version vector, old cache entries may be stale under the client's new version vector. Therefore, if it is important to update a client's version vector only when strictly necessary, and by the minimum amount. As such, when a client could read two different versions of a cached key, Apollo will return the value for the cached key with a version vector that minimizes the distance from the client's version vector. Apollo uses a variety of optimizations to reduce the impact of write queries on predictive caching and system performance, discussed in Section 3.4.

Since a client's session is independent of the sessions of other clients, Apollo can easily scale horizontally. An individual client must route all of its requests to the same Apollo instance to maintain its session, but other clients and processes do not affect its session guarantees. Thus, extract, transform, load (ETL) processes, database triggers, and client write requests do not result in mass invalidations of cached data. Furthermore, Apollo instances do not need to communicate with each other to maintain sessions because a client's session is tracked by a single Apollo instance.

3.3 Publish–Subscribe Model

Since Apollo handles many concurrent clients, multiple clients may simultaneously try to execute the same read query. In these cases, it is beneficial to execute the query only once and return its result set to the waiting clients. Optimizing these queries is particularly important for predictive execution since a predicted query may not have finished execution before a client requests its result set.

Before executing a read query, Apollo consults a hash map to determine if a copy of the query is already executing. If so, Apollo blocks the query until the other query returns, passing along its result set. Otherwise, it will record an entry in the hash map with a semaphore for other clients and predictive pipelines to wait on. In this way, only one copy of a read query is executing at any time, including shared predictive query pipelines for multiple clients.

When Apollo determines that a client's query has multiple usable versions of its results cached, Apollo will use the earliest version regardless of whether another usable version is already being retrieved for a different client. Experimentally, we determined that it is better to retrieve results for earlier versions since reading later versions will result in large version vector updates for the client and may therefore cause misses for other cached results. Similarly, if Apollo must retrieve the result set from the database, Apollo will subscribe to any ongoing database retrievals of the same query.

3.4 Session-Aware Caching

Since write queries increment client version vectors, they preclude the client from reading any previously cached values. Therefore, if a client executes a write query after a predictive query is issued on that client's behalf, the predicted query results may be stale and unusable. If so, the system will have performed unnecessary work to execute and cache the query. To minimize the effects of writes on system performance, we avoid predictively executing queries whose results are likely to become stale before client queries can use their results (Section 3.4.1). Since ADQs can be executed at any time, we strive to keep valuable ADQs in the cache by reloading them if their results become outdated (Section 3.4.2).

3.4.1 Preventing Unusable Predictions. Apollo determines the likelihood of a write query or cache miss occurring using the query transition graph. Recall from Section 2.2 that each client has a single transition graph. However, by maintaining multiple independent transition graphs with different Δt intervals, we are able to determine the likelihood of a given query being executed by the client in each of these windows. Using this technique, we predict if a client will retrieve the results for a predictively executable query before its results become stale. Apollo will predictively execute and cache only query results that it deems are likely to be used.

To determine if predictively executing and caching a query's results will be helpful, Apollo first estimates the time it will take for the query to be executed and cached. Since all predictable queries are by definition FDQs, we use a simple estimate: the time to predictively execute an FDQ is given by the time it will take to execute its dependencies and the time to execute the FDQ itself. We calculate this estimate recursively: for a target FDQ, we return the maximum time to execute its dependency queries and add the time needed to execute the FDQ. In essence, this process returns the longest expected path from the child weighted by mean query runtimes. To provide an approximation of individual query runtimes, we use the mean execution time for each query

template. Although more sophisticated methods can be used [4, 45] to estimate query runtimes, we found that this method yields enough accuracy to determine the runtime of predicted query while still being performant.

Once the runtime for a given FDQ f has been determined (say t), Apollo looks up the client’s transition graph with smallest interval Δt where $\Delta t > t$. It then uses this graph to determine the likelihood of the client executing a query that would cause f ’s results — or the results of its dependencies — to become stale while f is executing. If this likelihood is sufficiently high (given the τ threshold), we avoid executing f to save on database execution costs. Therefore, only queries that are likely to be executed and useful to clients are predictively cached.

Although increasing the number of transition graphs per client necessitates additional processing of the query stream, we find that the simplicity of the query transition graph construction algorithm (Algorithm 1) combined with a configurable (but small) number of models per client results in low computational overhead for the system. Furthermore, since workloads [1, 42] tend to have a small number of unique query templates, the storage overhead is minimal.

3.4.2 Informed ADQ Reload. Write queries update a client’s version vector, and therefore provide an opportunity for optimization through informed query result reload. As ADQ dependencies are always satisfied and can be executed at any time, we immediately reload valuable ADQ hierarchies after a client executes a write query. Since there can be many ADQs and reloading a hierarchy may be expensive for the database to execute, we limit ADQ reload to only those predictions for query templates considered valuable according to the cost function $cost(Q_t) = P(Q_t) \cdot mean_rt(Q_t)$.² Specifically, the estimated $cost$ of an ADQ on the system is given by the probability of the ADQ executing and the estimated ADQ runtime. If the cost of the ADQ exceeds a predefined threshold α , we reload it into the cache. We discuss α and its effects further in Section 4.7.

4 PERFORMANCE EVALUATION

In this section, we present the system setup used to conduct experiments followed by performance results. Apollo is compared against Memcached [19], a popular mid-tier cache used in database and storage systems, as well as the Fido predictive cache [34]. We compare these systems using average query response time and tail latencies, which have been observed to contribute significantly to user experience and indicate concurrent interaction responsiveness [28].

The Fido engine serves as a drop-in replacement for Apollo’s prediction engine, and uses Palmer et al.’s associative-memory technique [34] for query prediction, scanning client query streams to predict upcoming queries. Fido-like approaches have been employed to prefetch objects in databases [8]. Fido’s implementation-independent middleware prediction engine makes it particularly well-suited as a comparison point against Apollo.

The remainder of this section is organized as follows. Section 4.1 describes our experiments’ setup and Section 4.2 provides performance experiments for TPC-W. In Section 4.3, we use TPC-C to assess Apollo’s scalability under increasing client load. Section 4.4 showcases Apollo’s ability to adapt to changing workloads using online learning. Geographic latency experiments and multi-Apollo instance experiments are shown in Sections 4.5

²Note that the techniques in Section 3.3 apply; shared query dependencies and overlapping client query submissions will not result in multiple executions of ADQs.

and 4.6 respectively, and Section 4.7 presents a sensitivity analysis of Apollo’s configurable parameters.

4.1 Experimental Setup

Our experiments use a geo-distributed setup in which Amazon EC2 nodes are located in the US-East (N. Virginia) region for: (i) Apollo with 16 virtual CPUs, 64 GB of RAM and a 50 GB SSD (ii) Memcached on a machine with 2 virtual CPUs, 4 GB of RAM, and a 50 GB SSD (iii) a node with concurrent clients running our benchmarks with 16 virtual CPUs, 64 GB of RAM, and a 50 GB SSD. We deploy a database machine in the US-West (Oregon) region for our experiments, which has 16 virtual CPUs, 64 GB of RAM, a 250 GB SSD, and uses MySQL v5.6 as the database. For each experiment, Memcached uses a cache size 5% of the size of the remote database to demonstrate that Apollo is effective with limited cache space. All results presented are the average over at least five independent runs, with bars around the means representing 95% confidence intervals.

Our experiments have three primary configurations: the Memcached configuration (in which the cache has been warmed for 20 minutes prior to benchmarking), the Apollo caching configuration, and the Fido prediction engine configuration [34]. In the Memcached configuration, we check for query results in the cache and forward queries on cache misses to the remote database, caching the retrieved query results. The Apollo and Fido configurations also load query results into the cache after they execute a read-only query on the remote database, but Apollo uses the predictive framework from Section 2 and Fido uses its own predictive engine, which is detailed below.

Unlike Apollo, Fido functions on an individual query level rather than on query templates. More concretely, if queries Q_1, Q_2, \dots, Q_n are present in a client’s query stream, Fido looks for a stored pattern that is prefixed by them, say $Q_1, Q_2, \dots, Q_n, P_1, P_2, \dots, P_m$, proceeding to predictively execute P_1, P_2, \dots, P_m and cache their results. In contrast to Apollo’s online learning capabilities, Fido requires *offline* training to make predictions. We provide Fido with client workload traces twice the length of the experiment interval to serve as its training set for comparison against a *cold start* Apollo. Additionally, we let Fido make up to 10 predictions for each matched prefix.

In all configurations, clients use session guarantees (Section 3.2) and queries executed at the remote database have their result sets immediately cached in Memcached. Thus, the difference in caching performance between the configurations is due to caching benefits provided by the query prediction engines.

Our experiments aim to answer three key questions. First, can Apollo analyze incoming queries and learn patterns within a workload? Second, are Apollo’s predictive caching capabilities effective in reducing query round-trip time by avoiding costly database query executions? Third, can Apollo’s predictive framework scale with an increasing number of clients? We present performance results in the next sections that include answers to these questions.

4.2 TPC-W Benchmark

The TPC-W Benchmark [42] generates a web commerce workload by having emulated browsers interact with servlets that serve webpages. The webpages require persistent data from storage so servlets execute database queries against the remote database to generate webpage content. The TPC-W benchmark includes 14 different web interactions for clients (e.g., Best Sellers, Order Inquiry) each with their own distinct set of queries. For a given

Figure 5: Experiment results for 20 minute TPC-W runs using Apollo, Fido, and Memcached (no prediction engine).

client, the next web interaction is chosen probabilistically based on the previous interaction. We use a popular implementation [35] of the TPC-W Benchmark specification.

The TPC-W benchmark represents an important use case for Apollo since even small changes in latency can significantly impact web traffic [20] and sales [30]. Further, it serves as a challenging workload for Apollo due to its inherent randomness and large number of different queries. This randomness serves to test the viability of Apollo’s predictive framework under a variable workload.

We generated a 33 GB TPC-W database with 1,000,000 items. We measured Apollo’s performance using the TPC-W benchmark browsing mix executed for 20 minute measurement intervals while scaling-up the number of clients using our default TPC-W parameters discussed in Section 4.7.

4.2.1 Performance Results. Figure 5(a) shows Apollo’s performance for an increasing number of clients compared to Memcached and Fido. Apollo significantly outperforms both Fido and Memcached, enjoying a large response time reduction of up to 33% over Memcached and 25% over Fido. Fido has slightly lower response time than Memcached due to query-instance level predictive caching but is unable to recognize query template patterns and generalize to unseen queries, precluding it from being competitive with Apollo. In the case of Memcached, we see its warmed cache offers little advantage over Apollo’s and Fido’s cold starts — invalidation and randomness limit the effects of cache warming.

Each configuration shows a reduction in response time as the number of clients increase, a consequence of the shared cache between clients. However, shared caching is unable to compete with our predictive caching scheme as in a shared cache, a client must incur a cache miss, execute, and then store query results before others can use it. Consequently, Apollo’s techniques of query prediction and informed ADQ reload prove superior, even as the client load is scaled up.

Figure 5(b) shows the distribution of tail response times for each of the experimental configurations for 50 client TPC-W runs. Apollo’s response times are significantly lower than any of the other methods, particularly for the higher percentiles, due to an improvement in cache hits. At the 97th percentile, Apollo reduces tail latencies by 1.8x over Memcached and Fido. Again, Fido tends to perform about as well as Memcached, despite its large training set size, as it cannot generalize its patterns to query templates for FDQ prediction and query reload.

Figure 5(c) shows average query response times in 4 minute intervals. We see that Apollo exhibits a downward trend in response time from the start of the measurement interval as it effectively

learns query correlations and parameter mappings, resulting in an improvement of 30% over its average response time during the first four minutes. Although the other systems’ performance oscillates according to workload patterns, they do not learn query patterns — their final average query response times are comparable to that incurred in their first few minutes.

To ensure that Apollo can provide these response time reductions without undue resource overhead, we added instrumentation to determine the time and memory needed to find and construct new FDQs. On average, it takes less than 1% of response time to discover new FDQs given a newly executed query, and less than 2% of response time to construct an FDQ. We have observed that Apollo uses scant system resources, requiring only 1.5% the amount of memory used by the database for tracking the transition graph and query parameter mappings. Apollo’s predictive techniques submit an additional 25% more queries to the remote database compared to the Memcached configuration. Apollo’s intelligent query caching techniques place little additional load on the remote database and use meager resources, while still providing substantially lower average query response times than both Fido and Memcached.

To answer the performance questions we had posed earlier in Section 4.1, Apollo is indeed able to make accurate and useful predictions for what to cache, predicting and retaining important result sets in the cache for longer without significant computation or memory overhead.

4.3 TPC-C Benchmark

The TPC-C Benchmark emulates an order-entry environment in which multiple clients execute a mix of transactions against a database system [1]. Each of these clients functions as a store-front terminal, which submits orders for customers, confirms payments, and updates stock levels. In contrast to TPC-W’s workload, TPC-C’s OLTP workload features many short-running queries which avoid contention by reduced locking of significant parts of the database. As such, the TPC-C benchmark serves to directly test the scalability of Apollo.

The TPC-C specification has two read-only transactions, Stock Level and Order Status, both of which present opportunities for predictive execution. Since the goal of our experimentation with TPC-C is to show the scalability of predictive execution under high numbers of clients, we scale up the mix of read-only transactions to 95% with updates making up the remaining 5%. In doing so, Apollo must track, construct, and execute far more opportunities for predictive queries than in the TPC-W experiments. Thus, this experiment’s purpose is to show how well Apollo can handle hundreds of clients executing predictive queries simultaneously.

Figure 6: Experiment results for 20 minute TPC-C runs using Apollo, Fido, and Memcached (no prediction engine).

Figure 7: Experiment results for changing the workload from TPC-C to TPC-W using Apollo, Fido, and Memcached (no prediction engine).

In our experiments, we use the OLTPBench TPC-C implementation from Difallah et al [18]. To properly assess scalability, we modified the read/write mix, with a final percentage of 5% Payments, 47.5% Order Status, and 47.5% Stock Level Transactions. This mix forces the prediction engines to construct and execute significantly more predictive queries.

A TPC-C database of size 100 GB with 1000 warehouses was generated and loaded into a US-West MySQL instance using the data generation mechanism of OLTPBench. For the following experiments, we used our default TPC-C parameters (discussed in Section 4.7) with a 5% write mix. We choose the warehouse parameter in our queries according to a uniform distribution, which results in more predictive executions than a skewed Zipf distribution — recall that Apollo will not predictively execute queries that are already cached (Section 3.3).

4.3.1 Performance Results. Figure 6 shows the scalability of Apollo, Fido, and Memcached for increasing numbers of clients. Apollo exhibits a significantly lower average response time than Memcached and Fido, even as the number of clients, and therefore the number of predictive query executions, increases. Apollo’s efficient data structures and algorithms for tracking and prediction allow scaling even with a large number of clients. Fido and Memcached perform about the same, even as we increase the number of clients. With a large database, query parameters are highly variable and rarely repeated, causing Fido’s non-template approach to see few queries from its training set and in turn reducing prediction accuracy. As the number of clients increase, the positive effects of shared caching dwarf that of Fido’s predictions, resulting in similar performance characteristics between Fido and Memcached.

These results show that Apollo can deliver significant performance gains while scaling effectively to hundreds of concurrent clients continuously executing predictive queries.

4.4 Adapting to Changing Workloads

To assess Apollo’s ability to adapt to changing workloads, we conducted an experiment in which the workload was changed from our TPC-C workload described in Section 4.3 to TPC-W partway through the experiment (Figure 7). We see that Apollo quickly learns predictions for the TPC-C workload, resulting in the performance gains shown in Figure 6. By contrast, Fido and Memcached have relatively constant performance during the TPC-C run since they are unable to generalize and make effective predictions for upcoming queries (Section 4.3).

Once the workload switches, shown by a dashed vertical line in Figure 7, each configuration experiences a brief penalty in performance because the predictive engines cannot make any predictions for queries in the new workload, and no TPC-W queries are cached. However, Apollo quickly returns to its typical performance on TPC-W (Figure 5(a)) since it uses online learning to discover query patterns. Fido and Memcached perform similarly after the switch since Fido is unable to make predictions for an untrained workload. Although Fido was trained for TPC-C in this experiment, we note that its performance is comparable to an appropriately trained Fido on the TPC-W portion. This observation further highlights the ineffectiveness of Fido’s prediction scheme for the correlated query patterns, which Apollo excels at predicting.

4.5 Geographic Latency Testing

To assess the effects of different geographic latencies between Apollo and the database, we deployed TPC-W databases in the US-East and Canada regions. Because Apollo, the cache and the benchmark machine are all located in the US-East region, the first configuration tests a “local” deployment, in which latency among the machines is minimal (a few milliseconds). The second configuration tests moderate latencies of 20 ms.

In both configurations (Figures 8(a) and 8(b)), we see that Apollo preserves its lead over the other systems despite limited geographic latency. Apollo reduces query response time by up to 50% in the US East region and by up to 40% in the Canada region. This improvement in the performance gap compared to the higher latency experiments is because cache misses in low latency environments have a larger effect on average performance than when latency is high. The reason for this effect is that Apollo’s advantage when caching expensive queries becomes even more significant with reduced latency; prioritizing expensive and frequently executed queries results in a substantial improvement and failure to predictively cache them (as in Memcached’s and Fido’s case) results in a relatively larger performance degradation.

These results are not to be interpreted as Apollo is “best” in a local setting with near zero latency — the *total* response time savings for the remote settings are larger than that of the local setting. Apollo provides substantial reductions in average and total response time in both settings, resulting in an enhanced user experience.

4.6 Multiple Apollo Instances

Apollo can scale to high loads by partitioning clients among multiple Apollo engine instances and cache stores. Each Apollo engine maintains a consistent session for each client connected to it, without interacting with the other instances or a centralized session manager.

To determine Apollo’s scaling characteristics, we deployed Apollo on less powerful m4.xlarge EC2 instances with 4 vCPUs

Figure 8: Experiment results for 20 minute TPC-W runs in different geographic regions and when using multiple Apollo instances.

and 16 GB of RAM. We use these less powerful machines as they are individually unable to handle large numbers of clients, necessitating a horizontal scale-out for Apollo instances. We test three different Apollo configurations: one with a single Apollo instance, another with two Apollo instances, and a third with three Apollo instances. Each Apollo instance is given its own dedicated cache, thereby avoiding the need to synchronize version vectors across instances to maintain client sessions. Clients are evenly distributed and pinned to Apollo instances.

The results of the experiment are shown in Figure 8(c). As the client load increases, we see that it quickly overwhelms the 1-instance Apollo configuration, resulting in a large increase in query response time. The 2-instance and 3-instance Apollo configurations show significantly improved scalability, though eventually the 2-instance configuration begins to show a similar upward trend in response time.

We observed that the 2-instance query response time at 20 clients is slightly lower than that of the 3-instance configuration. This effect is primarily due to splitting the clients across three machines rather than two, resulting in the 3-instance configuration receiving fewer queries to learn from. ADQs are shared among clients, which results in longer learning times to reach a steady state with fewer clients. With a larger number of clients, the increase in the amount of data to learn from and the computing power available result in improved performance over the 2-instance configuration.

Although having multiple Apollo instances share models and training data would reduce the effects of training data splitting, the trade-off is increased synchronization between otherwise independent nodes. We eschew this approach for two reasons. First, clients should be split across Apollo instances only when a single instance cannot handle the load. As seen in Figure 8(c), Apollo receives enough training data from clients well before it reaches its load capabilities, even on a less powerful machine. Second, slightly increased training times are a small price to pay for horizontal scalability. Addressing scalability issues in production systems is challenging — learning for a few more minutes is a simple and inexpensive solution to the insufficient data problem.

These multi-instance experiments demonstrate Apollo’s ability to scale to large numbers of clients through horizontal scaling and client-session consistency semantics. Since separate Apollo instances do not need to communicate, Apollo demonstrates excellent scaling characteristics.

4.7 Sensitivity Analysis

A key feature of Apollo is its ability to be configured to operate under different workloads and system deployments. This configurability is enabled by the provision of parameters that can be set according to a particular workload and deployment. In this section, we discuss the effects of these parameters on the overall performance of the system as well as our choice of their default settings.

For TPC-W, our default parameter choices were: $\Delta t = 15s$, $\tau = 0.01$, and a reload cost threshold of $\alpha = 0$. Per the specification [42], TPC-W uses randomized think times with a mean of 7s. Each client has its own application state, which is determined through a probabilistic transition matrix. Therefore, a client’s web interactions do not generate a pre-determined chain of queries.

The maximal time separation Δt and minimum probability threshold τ are correlated. As Δt decreases, the probability of correlated query templates executing within this interval also decreases, thereby requiring a lower τ value to capture the relationship between query templates. Similarly, as Δt increases, the probability of two correlated query templates executing within this interval also increases, so higher τ values are sufficient. If Δt is large and τ is small then it is likely that spurious relationships between query templates will be discovered, but such spurious relationships are filtered out by Apollo’s parameter mapping verification period, and are therefore seldom predictively executed. Since TPC-W’s workload bottlenecks on the database, Apollo filters out the spurious correlations in exchange for discovering as many relationships as possible. To do so, we set a high value of $\Delta t = 15s$ and a low threshold of $\tau = 0.01$. These values were empirically confirmed to yield the best results.

In Section 3.4.2, we defined α to be the minimum cost that an ADQ must have to be reloaded. Note that the cost of an ADQ is the mean response time multiplied by the probability of the query executing. Hence as α is increased, only ADQs that are both popular and expensive are reloaded. We experimented with different values of α and found that for small values of α (less than 5% of the mean query response time), there was little change in query response time. However, as α continued to be increased past this threshold, the mean query response time grew by over 10%, as valuable ADQs were not reloaded. To ensure that all ADQs were reloaded, α was set to 0 in our experiments.

We observed similar trends with Δt and τ in TPC-C as in TPC-W; therefore, our default parameter choices for TPC-C were the same. We left Δt large and τ small to place additional pressure on Apollo’s parameter mapping filtering functionality. These values were empirically confirmed to yield the best results.

In our experiments, we used a cache 5% the size of the database. We observed that increasing the cache beyond this size did not affect the relative performance differences between Apollo, Memcached, and Fido.

5 RELATED WORK

Fido [34], detailed in Section 4.1, uses an associative memory model for predictive prefetching in a traditional client/server database system. Query patterns in Apollo are tracked at the query template level so a single relationship in Apollo can map to many in Fido. Tracking individual data object accesses, or parameterized queries, means that if Fido has not previously seen a particular parameterized query it will not be able to make a prediction. In contrast, if Apollo has seen the query template (regardless of parameters), it can infer correlation between queries and predictively execute. As Fido requires offline training, it cannot adapt to changes in object access patterns. As we have shown, the online nature of Apollo's Markov model allows it to dynamically change over time and thus adapt to new query patterns.

Keller et al. [24] describe a distributed caching system for databases, which uses approximate cache descriptions to distribute update notifications to relevant sites and execute queries locally on caches. Each site's cached data is tracked using query predicates. Apollo differs from this work in that we focus on the predictive execution of consequent queries derived from query patterns, which Keller et al. do not consider.

Scalpel [10] tracks queries at a database cursor level, intercepting open, fetch and close cursor operations within the JDBC protocol. Since the JDBC API is translated to database specific protocols, Scalpel functions as a client-side cache rather than a mid-tier shared cache like Apollo. Unlike Apollo's online learning model, Scalpel requires offline training to find the patterns that it uses for query rewriting and prefetching. Scalpel employs aggressive cache invalidation on writes and at the start of new transactions, which differs from Apollo's client-centric consistency model. Given that Apollo supports mid-tier shared caching across multiple clients, this makes Scalpel unsuitable for comparison against Apollo.

Pavlo et al. [7] implement Markov models in H-Store and use them to optimize transaction execution for distributed database physical design. The system constructs a series of Markov models for stored procedures and monitors the execution paths under a set of input parameters. Their model can be leveraged to determine a base partition for stored procedures and to lock only partitions that are predicted to be accessed during procedure execution. Apollo operates beyond this stored procedure context, and provides benefits through caching future queries rather than by analyzing query execution paths.

DBProxy [5] is a caching system developed by IBM to cache query results on edge nodes. DBProxy uses multi-layered indexes and query containment to match queries to results, evicting stale and unused results. Its single session guarantees differ from Apollo's per-client sessions and limit scalability, in addition to not using online learning or predictive caching to improve performance.

Ramachandra et al. [36] propose a method for semantic prefetching by analyzing the control flow and call graph of program binary files. Given the source code for a database application, the system analyzes and modifies it, adding prefetch requests into the code as soon as the parameters are known and query execution guaranteed. Since this work is limited to requiring access to the source code of

application binaries, it only works for fixed workloads. Because Apollo analyzes query streams, it is able to adapt to changing query patterns over time.

Although proprietary middleware caching solutions have been developed [9, 16, 26], they do not use predictive analytics to identify future queries and preload them in the cache.

Scheuermann et al. [40] propose the Watchman cache management system, which uses query characteristics to improve cache admission and replacement algorithms. Unlike Apollo, Watchman does not discover query patterns for use in predictive execution and instead focuses solely on cache management.

Holze et al. [23] have broached the idea of modeling workloads using Markov models, but such work focuses only on determining when an application's workload has been altered rather than relying on statistical models for caching purposes, like Apollo. They suggest a Markov model as a means to achieve an automatic database, enabling features such as self-configuration, self-optimization, self-healing, and self-protection. In contrast, Apollo uses Markov models of user workloads to predict future queries and enables predictive query caching.

Promise [37] is a theoretical framework for predicting query behaviour within an OLAP database. Promise uses Markov models to predict user query behaviour by developing state machines for parameter value changes and transitions between OLAP queries, but does not consider direct parameter mappings, FDQ hierarchies, or pipelining predictions. Unlike Apollo, Promise does not validate its techniques through a system implementation.

Recent research in approximate query processing [6, 44] has proposed using previous query results as a means for approximating the answer to future queries. These works develop statistical methods to provide accurate, approximate answers and error bounds for upcoming queries, which differs from Apollo's focus on learning parameter mappings for predictive caching.

In the view selection problem [12], one must decide on a set of views to materialize so that execution of the workload minimizes some cost function and uses fixed amount of space. Most work in this area requires knowledge of the workload ahead of time [2, 22], with the remainder not considering machine learning techniques for uncovering patterns for use in view selection [17, 25].

XML XPath templates have some similarities to query templates [31], but are not used for online learning in predictive execution and caching. Instead, XPath views are selected using offline training in a warm-up period [29, 43], similar to that of Fido [34]. Similar ideas have been explored to cache dynamic HTML fragments [14].

6 CONCLUSION

In this paper, we propose a novel method to determine and leverage hidden relationships within a database workload via a predictive learning model. We present the Apollo system, which exploits query patterns to predictively execute and cache query results. Apollo's online learning method makes it suitable for different workloads and deployments. Experimental evaluation demonstrates that Apollo is a scalable solution that efficiently uses a cache and outperforms both Memcached, an industrial caching solution for different workloads and the popular Fido predictive cache.

ABSTRACT

Credit card frauds are unauthorized transactions that are made or attempted by a person or an organization that is not authorized by the card holders. Fraud with general-purpose cards (credit, debit cards etc.) is a billion dollar industry and companies are therefore investing significant efforts in identifying and preventing them.

It is typical to deploy mining and machine learning-based techniques to derive rules. However, such rules may not always capture the semantic reasons underlying the frauds that occur. For this reason, credit card companies often employ domain experts to manually specify rules that exploit general or domain knowledge for improving the detection process. Over time, however, as new (fraudulent and legitimate) transactions arrive, these rules need to be updated and refined to capture the evolving (fraud and legitimate) activity patterns. The goal of the RUDOLF system described in this paper is to guide and assist domain experts in this challenging task. RUDOLF automatically determines the “best” adaptation to existing rules to capture all fraudulent transactions and, respectively, omit all legitimate transactions. The proposed modifications can then be further refined by users and the process can be repeated until they are satisfied with the resulting rules. We show that the problem of identifying the best candidate adaptation is NP-hard in general and present PTIME heuristic algorithms for determining the set of rules to adapt. We have implemented our algorithms in RUDOLF and show, through experiments on real-life datasets, the effectiveness and efficiency of our solution.

1 INTRODUCTION

A *credit card fraud* is an unauthorized transaction made or attempted by an individual or organization who is not authorized by the card holder to use a credit card to perform the electronic payment. Fraud with general-purpose cards (credit, debit cards etc.) is a billion dollar industry. In fact, several independent news articles and studies that were carried out (e.g., [1, 2]) corroborate that there is a consistent, fast-growing, and upward trend on the total global payment-card frauds. Detecting and deterring credit card frauds are therefore of extreme importance to credit card companies. A core part of operations behind every credit card company is to (automatically) detect fraudulent transactions among the new transactions (e.g., [3]) that are received everyday.

To this end, models based on data mining and machine-learning techniques (e.g. [4–6]) have been used. A typical approach is to score each transaction where transactions whose scores are above a threshold are classified as fraudulent. However, the models and scoring system do not always have high precision and recall. Fraudulent transactions may be missed by the models and, likewise, legitimate transactions may be wrongly identified as fraudulent. The derived threshold also do not provide a semantic explanation of the underlying causes of the frauds. It is for this reason that credit card companies typically rely on *rules* that are

carefully specified by domain experts in addition to models for automatically determining fraudulent transactions.

Intuitively, a rule describes a set of transactions in the database and the goal is to arrive at a set of rules that, together with the automatically derived scores, captures precisely the fraudulent transactions. The use of rules written by users has the advantage that it allows employing general or domain knowledge to handle rare special cases.

Writing rules to capture precisely fraudulent transactions is a challenging task that is exacerbated over time as the types of fraudulent transactions evolve or as new knowledge is learnt. Typically, a set of rules that were curated by users already exists and the rules work well for capturing fraudulent transactions up to a certain day. However, these rules need to be adapted over time to capture new types of frauds that may occur. For example, there may be new reported fraudulent transactions coming from a certain type of store at a certain time that did not occur before and hence, not caught by existing rules. Analogously, there may be some transactions that were identified by the existing rules as fraudulent but later verified by the card holders to be legitimate. Hence, the rules have to be adapted or augmented over time to capture all (but only) fraudulent transactions. In this paper, we present RUDOLF, a system whose goal is to assist users to define and refine rules for fraud detection.

Note that our goal resembles in part that of previous works on query/rule refinement, which attempt to automatically identify minimal changes to the query/rule in order to insert or remove certain items from the query result (e.g., [7]). However, a key difference here is that such minimal modifications often do not capture the actual “ground truth”, namely the nature of ongoing attack, which may not yet be fully reflected in the data. By interacting with users to fine-tune rules, important domain knowledge can be effectively imported into the rules to detect the pattern of frauds often even before they are manifested in the transactions themselves.

Our goal also resembles previous work on discovering or learning decision rules from streams with concept drifts (e.g. [8, 9]). Like them, RUDOLF strives to discover or adapt rules as new transactions arrive. However, all previous work considered only domains over numerical values and hence do not immediately apply to our setting, which involves both categorical and numerical values. Furthermore, RUDOLF makes crucial use of a hierarchy of higher-level concepts over the domains (numerical or categorical) in the specification of rules. In addition, RUDOLF collaborates with the domain expert to improve upon the quality of the rules used for capturing only fraudulent transactions. The interplay between the domain experts and the use of higher-level concepts, whenever possible, enables the derivation of rules which can be used to explain the true nature ongoing frauds. Our experiments indicate that such interactions can be effective in deriving rules with good prediction quality.

An overview example The top of Figure 1 shows a simplified set of rules that is currently used to capture fraudulent transactions up to yesterday. Intuitively, the first two rules capture a suspicion of two attacks on an online store taking place at the first and

last few minutes of 6pm, charging amounts over \$110. The last rule captures a fraud pattern at Gas station A where false charges of amounts over \$40 are made soon after the closing time at 9pm. In practice each rule also includes some threshold condition (not shown) on the score (i.e., the degree of confidence that the transaction is fraudulent) for each transaction, as well as additional conditions on the user/settings/etc. The scores and the additional conditions are omitted so that we can focus our discussions on the semantic aspect of the rules shown in Figure 1.

Figure 2 shows an example of a relation which contains a number of transactions made today. The transaction tuples are ordered by the time of the transaction. In the figure, some transactions that were reported as fraudulent are labeled as “FRAUD”. Similarly, transactions that are reported to be legitimate may be correspondingly labeled “LEGITIMATE” (not shown in the figure). Transactions may also be unlabeled. The current set of rules captures only the shaded tuples shown in the transaction relation. Clearly, none of the new fraudulent transactions are captured by the existing rules whereas some unlabeled transactions are captured.

RUDOLF first attempts to capture the fraudulent transactions by generalizing the rules, semantically according to a given ontology whenever possible, before it specializes the rules to avoid unnecessarily capturing legitimate transactions. However, the changes proposed by RUDOLF may not correspond to the best or correct changes. The domain experts can view/accept/reject/modify the suggestions provided by RUDOLF, arriving for instance at the

- 1) $\text{Time} \in [18:05, 18:05] \wedge \text{Amt} \geq 100 \wedge \text{Type} = \text{Onl.}, \text{ no CCV.}$
- 2) $\text{Time} \in [18:55, 19:15] \wedge \text{Amt} \geq 100 \wedge \text{Type} = \text{Onl.}, \text{ no CCV.}$
- 3) $\text{Time} \in [20:45, 21:15] \wedge \text{Amt} \geq 40 \wedge \text{Location} \leq \text{Gas Station} \wedge \text{Type} \leq \text{Offline.}$

Intuitively, the first two rules above flag online transactions without CCV, charging amounts over \$100 in the respective time intervals as fraudulent transactions. The third rule flags offline transactions at the gas stations around closing time of amounts over \$40 as fraudulent transactions. Observe that the condition “ $\text{Location} \leq \text{Gas Station}$ ” is a semantic generalization of Gas Stations A and B, which are defined in an ontology to be contained within the category “Gas Station”. Similarly, “ $\text{Type} \leq \text{Offline}$ ” reflects the semantic category (shown at the bottom of Figure 1) which contains offline transactions with and without PIN.

Contributions This paper makes the following contributions.

- (1) We formulate and present a novel interactive framework for determining the “best” way to adapt and augment rules so that fraudulent transactions are captured and, at the same time, legitimate transactions are avoided.
- (2) We establish that the rule refinement problem is NP-hard even under special circumstances: (1) determine the best way to generalize rules to capture new fraudulent transactions when there are no new legitimate transactions, and (2) determine the best way to specialize existing rules to avoid capturing new legitimate transactions when there are no new fraudulent transactions.
- (3) In light of these hardness results, we develop a heuristic algorithm which is able to interactively adapt rules with domain experts until a desired set of rules is obtained. At each step, the algorithm makes a proposal of the best changes to a rule, and the domain expert can further refine the proposed changes or seek suggestions for other possible changes. Our algorithm represents a departure from prior algorithms on discovering or learning decision rules from streams with concept drifts in that it handles categorical

values in addition to numerical values, adapt rules with semantic concepts from available ontologies, and interacts with domain experts.

- (4) We have implemented our solution in the RUDOLF prototype system and applied it on real data, demonstrating the effectiveness and efficiency of our approach. We performed experimental evaluations on a real-life dataset of credit card transactions. We show that by interacting with users (even ones with only little knowledge specific to the domain of the datasets), our algorithms consistently outperform alternative baseline algorithms, yielding more effective rules in shorter time.

While most of our exposition on the features of RUDOLF is based on credit card frauds, we emphasize that RUDOLF is a general-purpose system that can be used to interact with users to refine rules. For example, for preventing network attacks, for refining rules for spam detection or for intrusion detection [10].

A first prototype of the system was demonstrated at VLDB’16 [11]. The short paper accompanying the demonstration gives only a brief overview of the system architecture whereas the present work provides a comprehensive description of the underlying model and algorithms.

The paper is organized as follows. The next two sections define the model and problem statement behind RUDOLF (Section 2 and, respectively, Section 3). The algorithm behind RUDOLF is described in Section 4. We then present our experimental results (Section 5) and related work (Section 6), before we present our conclusions (Section 7).

2 PRELIMINARIES

Transaction relation A *transaction relation* is a set of tuples (or *transactions*). The transaction relation is appended with more transactions over time. We assume that the domain of every attribute A has a partial order, which is reflexive, antisymmetric, and transitive, with a greatest element \top_A and least element \perp_A . W.l.o.g. we also assume that \perp_A does not appear in any of the tuples¹. For brevity, when an attribute name is clear from the context we will omit it and simply use the notations \top and \perp . Attributes that are associated with a partial order but not a total order are called *categorical attributes*. The elements in such partial order are sometimes referred to as *concepts*.

A transaction may be flagged as *fraudulent* which means that the transaction was carried out illegally or conversely, a transaction may be flagged as *legitimate*. Unmarked transactions are called *unlabeled* transactions. The labeling is assumed to correspond to the (known part of the) *ground truth*. In addition, each transaction has a *score* between 0 and 1, that is computed automatically using machine learning techniques, and depicts the estimated probability of each transaction to be fraud. The score may or may not agree with the ground truth and this discrepancy is precisely the reason why rules are employed to refine the fraud detection.

Example 2.1. Part of a transaction relation I with schema $T(\text{time}, \text{amount}, \text{type}, \text{location}, \dots)$ is shown in Figure 2. Each tuple records, among others, the time, amount, type of transaction, and location where the purchase was made through some credit card. The scores of the transactions, as computed by a machine learning module, are omitted from the figure. The last column annotates the type of transactions. The part of instance I that is shown contains only fraudulent and unlabeled transactions.

¹If this is not the case, add a new special element to the domain and set it smaller, in the partial order, than all other elements.

Existing fraud rules Φ from the previous day:

- 1) $\text{Time} \in [18:00, 18:05] \wedge \text{Amt} \geq 110$
- 2) $\text{Time} \in [18:55, 19:00] \wedge \text{Amt} \geq 110$
- 3) $\text{Time} \in [21:00, 21:15] \wedge \text{Amt} \geq 40 \wedge \text{Location} \leq \text{'Gas Station A'}$

Figure 1: Top: An existing set of rules. Bottom: Partial Order for type values.

The type `time` is discretized to minutes and is associated with a date (not shown). It thus has a partial order (in fact, a total order), given by the \leq relation. The type `amount` also has a total order with least element 0 and greatest element ∞ . The attribute `type` is a categorical attribute and its partial order is given by the hierarchy shown at the bottom of Figure 1. Some examples of concepts in the hierarchy are “Online” or “Offline, without PIN”. The type `location` is also a categorical attribute and its partial order (not shown) is given by, say, the geographical containment relationship. In particular, “Gas Station A” and “Gas Station B” are both concepts that are children of the concept “Gas Station”.

Rules For simplicity and efficiency of execution, we assume rules are typically written over a single relation, which is a universal transaction relation that includes all the necessary attributes (possibly aggregated or derived from many other database relations) for fraud detection. Hence, it is not necessary to consider explicit joins over different relations in the rule language.

To highlight the key principles of our approach we consider here a fairly simple rule language that captures a disjunction of conjunctions. For simplicity, our rule language allows only one condition over each attribute. Multiple disjunctive conditions over the same attribute can be expressed in multiple rules. Other extensions to the rule language are possible but will not be considered here. Note that the rule language that we consider, albeit simple, forms the core of common rule languages used by actual systems.

A *rule* is a conjunction of one or more conditions over the attributes of the transaction relation. More precisely, a rule is of the form $\alpha_1 \wedge \dots \wedge \alpha_n$ where n is the arity of the transaction relation, α_i is a condition is of the form ‘ $A_i \text{ op } s$ ’ or ‘ $A_i \in [s, e]$ ’, A_i is the i th attribute of the transaction relation, $\text{op} \in \{=, <, >, \leq, \geq\}$, and s and e are constants.

More formally, if φ is a rule that is specified over a transaction relation I , then $\varphi(I)$ denotes the set of all tuples in I that satisfy φ . We say that $\varphi(I)$ are the transactions in I that are *captured* by φ . If Φ denotes a set of rules over I , then $\Phi(I) = \bigcup_{\varphi \in \Phi} \varphi(I)$. In other words, $\Phi(I)$ denotes the union of results of evaluating every rules in Φ over I . Observe that $\Phi(I) \subseteq I$ since every rule selects a subset of transactions from I . For readability, in our examples we show only the non trivial conditions on attributes, namely omit conditions of the form $A_i \leq \top$.

Note that, for simplicity, each rule includes only one condition over each attribute, but multiple disjunctive conditions over the same attribute can be expressed using multiple rules.

Time	Amount	Transaction Type	Location	
18:02	107	Online, no CCV	Online Store	FRAUD
18:03	106	Online, no CCV	Online Store	FRAUD
18:04	112	Online, with CCV	Online Store	
19:08	114	Online, no CCV	Online Store	FRAUD
19:10	117	Online, with CCV	Online Store	
20:53	46	Offline, without PIN	GAS Station B	FRAUD
20:54	48	Offline, without PIN	GAS Station B	FRAUD
20:55	44	Offline, without PIN	GAS Station B	FRAUD
20:58	47	Offline, with PIN	Supermarket	
21:01	49	Offline, with PIN	GAS Station A	
:	:	:	:	:

Figure 2: A transaction relation containing new transactions.

Example 2.2. The top of Figure 1 illustrates a set Φ of three simplified rules currently used by the example credit card company to detect fraudulent transactions. The first rule captures all transactions made between 6pm to 6:05pm where the amount involved is at least \$110. As previously mentioned, in practice each rule also includes some threshold conditions (not shown here) on the score for each transaction, as well as additional conditions on the user/settings/etc. For simplicity we omit the score thresholds and the additional conditions and focus in the sequel on the simplified rules in this example.

For the new transaction relation shown in Figure 2, this rule captures the 3rd tuple (which is an unlabeled transaction). The 2nd rule captures no tuples, and the 3rd rule captures the 10th unlabeled tuple. Hence, the existing rules Φ do not capture any of the fraudulent transactions on the current day.

As we shall demonstrate, the rule language that we consider here, even though simple, is able to succinctly capture the fraudulent transactions (and avoid legitimate tuples) in our experiments with a real dataset. Other domains rules, e.g. access control for network traffic or spam detection rules can also be expressed in our language.

Cost and Benefit of modifications A *modification* to a rule is a change in a condition of an attribute in the rule. One may also *copy* an existing rule before modifying the copy, add rule or remove an existing rule. As we will elaborate in subsequent sections, our cost model assumes there is a cost associated with every operation/modification made to a condition in the rule.

To compare between possible modifications to rules and determine which modifications are better, we need to know not only the cost of each modification but also the “benefit” it entails. Intuitively, the gain from the modifications can be measured in three ways: (1) the increase in the number of fraudulent transactions that are captured by the modified rule, (2) the decrease in the numbers of legitimate transactions that are captured by the modified rule, and (3) the decrease in the numbers of captured unlabeled transactions. The assumption underlying (3) is that unlabeled transactions are typically assumed to be correct until explicitly reported/tagged otherwise and the more specific the rules are to fraudulent (and only) fraudulent transactions, the more precise they are in embodying possible domain-specific knowledge about the fraudulent transactions.

Observe that if our modifications are ideal, then after the modifications, there are more fraudulent transactions captured, and less

legitimate and unlabeled transactions caught. Subsequently, the overall update cost is defined as the cost of modifications minus their benefit. We give the formal definition in the next section.

3 PROBLEM STATEMENT

As described, the goal of RUDOLF is to identify minimal modifications to existing rules that would ideally capture all fraudulent transactions, omit all legitimate transactions, and at the same time, minimize the inclusion of unlabeled transactions. The modifications suggested by RUDOLF serve as a starting point for the domain expert who can either accept the proposed modifications or interactively refine them with the help of RUDOLF. Formally, the problem is stated below.

Definition 3.1 (General Rule Modification Problem). Let Φ be a set of rules on an existing transaction relation I . Let I' denote a new set of transactions over the same schema. Let $F, L \subseteq I$ (resp. $F', L' \subseteq I'$) be two disjoint sets of *fraudulent* and *legitimate* transactions in I (resp. I'). Let $R = I - (F \cup L)$ (resp. $R' = I' - (F' \cup L')$) be the remaining *unlabeled* transactions in I (resp. I').

The GENERAL RULE MODIFICATION PROBLEM is to compute a set M of modifications to Φ to obtain Φ' so that $\text{cost}(M) - (\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R)$ is minimized, where $\alpha, \beta, \gamma \geq 0$, and

- $\Delta F = |(F \cup F') \cap \Phi'(I \cup I')| - |(F \cup F') \cap \Phi(I \cup I')|$,
- $\Delta L = |(L \cup L') \cap \Phi(I \cup I')| - |(L \cup L') \cap \Phi'(I \cup I')|$, and
- $\Delta R = |(R \cup R') \cap \Phi(I \cup I')| - |(R \cup R') \cap \Phi'(I \cup I')|$.

The term $(\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R)$ represents the benefit of applying the given modifications to the rules. In our rule language, if a fraudulent transaction is not captured by a set of rules, then at least some condition of a rule needs to be generalized to select that fraudulent transaction. At the same time, making a condition more general may capture also legitimate or unlabeled transactions. Conversely, if a legitimate transaction is captured by a set of rules, then at least some condition of a rule needs to be made more restrictive so that the legitimate transaction is excluded. Such modifications carry the risk of omitting some fraudulent transactions that should be captured. The coefficients α, β and γ are non-negative and are typically provided by the user to tune the relative importance of each category (resp. correctly capturing the fraudulent transactions, avoiding misclassifying legitimate transactions, and excluding unlabeled transactions) in the calculation of benefit. The overall goal is to identify the modifications having the best cost-benefit balance.

Observe that if α, β and γ are set to large numbers (e.g. greater than the maximal update cost) then the most beneficial modifications are those leading to a “perfect” set of rules, namely one that will (1) capture all fraudulent transactions, (2) exclude all legitimate transactions, and at the same time, (3) does not capture any unlabeled transactions.

4 THE GENERAL RULE MODIFICATION ALGORITHM

The rule modification algorithm (outlined below) first interactively refines the rules to capture fraudulent transactions. The expert can stop the refinement whenever she is satisfied with the rules and believes that the omission of the remaining fraudulent transactions is tolerable. The resulting set of rules may capture some (existing) legitimate tuples. Hence, in the second step, the algorithm continues to interactively refine the rules to avoid the legitimate transactions. Here again the user may stop the algorithm when she believes that the inclusion of the remaining legitimate transactions

is acceptable. However, the rules that result after this step may no longer capture some fraudulent transactions that were previously captured. The domain expert can either repeat the process described above to remedy this, or choose to end the rule refinement process at this point. In the latter case, the domain expert has a choice to leave the result as-is or allow the algorithm to create transaction-specific rules to capture each of the remaining transactions.

- (1) Generalize rules to capture fraudulent transactions. See Algo. 1, section 4.1.
- (2) Specialize rules to avoid legitimate transactions. See Algo. 2, section 4.2.
- (3) Exit if the domain expert is satisfied. Otherwise, repeat the steps above.

Observe that it is essential for the generalization algorithm (Algo. 1) to be applied before the specialization algorithm (Algo. 2) as one can always add rules to capture specific fraudulent transactions without accidentally capturing legitimate transactions. On the other hand, one cannot always add/modify rules to avoid specific legitimate transactions without accidentally excluding fraudulent transactions with our current rule language.

As we shall show in the next sections, finding an optimal set of changes to the rules is computationally expensive in either case. For this reason, instead of computing an optimal set of modifications to the rules to generalize or special rules to capture fraudulent and, respectively, avoid legitimate tuples, we develop heuristic algorithms to identify the best update candidates in each of the cases.

4.1 Rule Generalization Algorithm

We first consider how rules can be generalized to capture fraudulent transactions when the set I' of new transactions contains only fraudulent transactions. The goal here is to adapt the existing set of rules Φ to capture all fraudulent transactions. We call this problem the RULE GENERALIZATION PROBLEM

THEOREM 4.1. *The RULE GENERALIZATION PROBLEM is NP-hard even if Φ is perfect for I , (namely, $F \subseteq \Phi(I)$ and $L \cap \Phi(I) = R \cap \Phi(I) = \emptyset$). The problem is NP-hard even when I contains only unlabeled transactions and I' consist of only one fraudulent transaction.*

PROOF. We prove the two claim simultaneously by reduction from the minimum hitting set problem which is known to be NP-hard. We recall of the Minimum Hitting Set Problem below.

Definition 4.2 (Minimum Hitting Set). Consider the pair (U, S) where U is a universe of elements and S is a set of subsets of U . A set $H \subseteq U$ is a hitting set of S if H hits every set in S . In other words, $H \cap S' \neq \emptyset$ for every $S' \in S$. A minimum hitting set H is a minimum cardinality hitting set s.t. $\forall e \in H$, we have $H \setminus \{e\}$ is not a hitting set of S .

We assume that each rule modification is associated with a unit cost. Given an instance of the hitting set problem, we construct an instance of the RULE GENERALIZATION PROBLEM were there no fraudulent or legitimate transactions in I and I' consist of only one fraudulent transaction, as follows.

The transaction relation has $|U|$ columns, one for each element in U . The transaction relation I has a characteristic (unlabeled) tuple for every set $s \in S$. That is, for every set s in S , we construct a characteristic tuple of s in I by placing a 0 in position i if $x_i \in s$ and 1 otherwise. Hence there are $|S|$ tuples in the transaction

relation I and these are unlabeled tuples that we would like to minimize capturing with the rules. There are no existing fraudulent or legitimate tuples in I . The set Φ is initially empty. Hence, $\Phi(I)$ does not capture any transaction (and thus, by definition, is “perfect” for D). The instance I' consists of a single transaction $(1,1,1,\dots,1)$, which is the new fraudulent transaction that we wish to capture.

As an example, consider the following hitting set where $U = \{A_1, A_2, A_3, A_4, A_5\}$ and $S = \{s_1, s_2, s_3\}$, where $s_1 = \{A_1, A_2, A_3\}$, $s_2 = \{A_2, A_3, A_4, A_5\}$, and $s_3 = \{A_4, A_5\}$. The transaction relation $I \cup I'$ (where I' is highlighted in gray) is shown below. The last column annotates the type of tuple (e.g., the last tuple is a fraudulent transaction).

A ₁	A ₂	A ₃	A ₄	A ₅	
0	0	0	1	1	
1	0	0	0	0	
1	1	1	0	0	
1	1	1	1	1	F'

It is straightforward to verify that the construction of the instance of the Rule Modification Problem can be achieved in polynomial time in the size of the input of the Hitting Set Problem. We now show that a solution for the Minimum Hitting Set Problem implies a solution for the Rule Modification Problem and vice versa.

Let H be the minimum hitting set. For every element x_i in H , we add a condition $a_i = 1$ to the same rule. (The condition can also be $a_i \geq 1$ or $a_i > 0$ but wlog we assume $a_i = 1$ is used.) The cost of changing $a_i = 1$ is 1. Clearly, we have that $\Phi'(I \cup I')$ contains the fraudulent transaction and since H hits every set $s \in S$, for every $s \in S$, there must be at least an attribute a_i in the corresponding tuple of s whose value 0 when the condition $a_i = 1$ according to the new rule Φ' . Hence, it follows that $\Phi'(I \cup I')$ does not contain any tuples in $I \cup I'$ other than the fraudulent tuple.

We show next that the expression $\text{cost}(M) - (\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R)$ is the minimum possible, assuming that $\alpha = \beta = \gamma > 1$ (β is actually irrelevant here) and the cost of each modification is 1. Suppose there is another set of modifications whose cost is lower than the above. It must be that none of the unlabeled tuples are selected by the modified rules since one can always avoid capturing an unlabeled tuple and lower the cost even further by adding an appropriate condition $a_i = 1$. Furthermore, by the same reason, the fraudulent tuple must be selected by the modified rules. Thus, the expression $\text{cost}(M) - (\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R)$ is the minimum possible when the number of $a_i = 1$ conditions correspond to the size of a the minimum hitting set. Any smaller value will mean we have a smaller cardinality hitting set which is a contradiction to our assumption that H is a minimum hitting set.

For the converse, let M be the set of modifications made to Φ such that $\text{cost}(M) - (\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R)$ is minimum. Again, wlog, we may assume that the modifications must be of the form $a_i = 1$.

Let $H = \{x_i \mid a_i = 1 \text{ in the modified rule}\}$. We show next that H is a minimum hitting set. First, we show that H is a hitting set. Suppose not, then there is a set $s \in S$ such that $H \cap s = \emptyset$. Let t be the tuple that corresponds to s in the transaction table. This means that $\Phi'(I \cup I')$ contains t , since t contains the value 1 in every attribute a_i where $a_i = 1$ in the modified rule. Pick an element, say $x_j \in s$ such that $x_j \notin H$. Now if we add the modification $a_j = 1$, the change in cost is $+1 - \gamma$. Since $\gamma > 1$, we have that the new total cost is lower than the original cost which contradicts the assumption that M is a set of modifications that would give the minimum total cost.

Next, we show that H is a minimum hitting set. Suppose not, then there is another hitting set H' where $|H'| < |H|$. With H' , it is straightforward to construct a set of modifications whose cost is lower than $\text{cost}(M) - (\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R)$.

In our running example, a modified rule is

$$A_1 \leq \top \wedge A_2 = 1 \wedge A_3 \leq \top \wedge A_4 = 1 \wedge A_5 \leq \top$$

since a minimum hitting set is $\{A_2, A_4\}$. \square

The reduction of the above proof shows that the NP-hardness result may arise because we allow the size of the schema of the transaction relation to vary. We show next that, even if we fix the size of the schema, the NP-hardness result continues to hold.

THEOREM 4.3. *The RULE GENERALIZATION PROBLEM is NP-hard even if Φ is perfect for I and the size of the schema of the transaction relation is fixed.*

SKETCH. The proof makes use of a reduction from the set cover problem and in the reduction, a single unary transaction relation is used. We build a taxonomy of the elements of a set cover instance according to which element belongs to which set. The relation is initially empty and assume Φ is initially empty as well. The cost of adding rule with a condition is 1 and we assume that the cost of adding the condition $A \leq \top$ is very high (i.e., it is prohibited). The new transaction relation I' consists of n new fraudulent transactions, one for each element of the universe in the set cover instance. One can then establish that a set of rules of minimum cost can be derived from a minimum set cover and vice versa. Intuitively, each rule has the form $A \leq S_i$ where each S_i is part of the solution to the instance of the minimum set cover problem. \square

The Algorithm In view of the hardness result, we develop a heuristic algorithm (Algo. 1) for determining a best set of generalizations to capture a given set of fraudulent transactions.

In the algorithm, we use I to denote both old and new transactions. Observe that one reason for the hardness of the rule generalization problem comes from the desire to identify a set of modifications that captures all fraudulent transactions and is *globally optimal*. Instead, our heuristic works in a greedy manner, gradually covering more and more uncaptured transactions. Rather than treating each transaction individually, we split the fraudulent transactions into smaller groups (clusters) of transactions that are similar to each other, based on a distance function, and treat each cluster individually. We denote the set of clusters by C . Each cluster in C is represented by a *representative tuple*. Intuitively, a representative tuple of a cluster is a tuple that “contains” every tuple in that cluster. Hence, if a rule is generalized to capture the representative tuple, then it must also capture every tuple in the associated cluster. The algorithm then identifies for each representative tuple the (top-k) best rule modifications to capture it. The proposed modifications are verified with the domain expert, who may interactively further adapt them or ask for additional suggestions. Note that the modifications made to the rules by the algorithm may result in capturing some legitimate tuples. We will see how this too may be avoided later.

We next describe our algorithm more formally. We first define each of the components, then provide a comprehensive example that illustrates all.

Representative tuple of a cluster The *representative tuple* f of a cluster C is a tuple with the same schema as tuples in C such that for every attribute A , $f.A$ contains $t.A$ for every $t \in C$. If A is an attribute with a total order, then $f.A$ is an interval that contains $t.A$.

Algorithm 1: Generalize rules to capture new fraudulent tuples

Input: A set Φ of rules for a transaction relation I (contains old and new transactions), with $F \subseteq I$ and $F' \subseteq I$.

Output: A new set Φ' of rules that captures $F \cup F'$.

```
1 Let  $C$  denote the result of clustering tuples in  $F \cup F'$ .
2 foreach  $C \in C$  do
3   Let  $f(C)$  be the representative tuple of  $C$ .
4   Let  $\text{Top-}k(f(C))$  denote the top- $k$  rules for  $f(C)$  based on
   Equation 2.
5 foreach  $C \in C$  do
6   while there does not exist a rule  $r$  such that  $f(C) \in r(I)$  do
7     if  $\text{Top-}k(f(C))$  is non-empty then
8       Remove the next top rule  $r$  from  $\text{Top-}k(f(C))$ .
9       Construct the smallest generalization of  $r$  to  $r'$  so
       that  $f(C) \in r'(I)$ .
10      Ask whether the rule  $r'$  is correct.
11      if the domain expert agrees with the modified  $r'$  then
12        Replace  $r$  with  $r'$  in  $\Phi$ .
13      else
14        Ask the domain expert which modifications in  $r'$ 
        are undesired.
15        Revert the modifications to the original
        conditions of  $r$  as indicated by the domain
        expert.
16        Allow the domain expert to make further
        generalizations to the proposed rule.
17      else
18        Create a rule that will select exactly  $f(C)$  and add it
        to  $\Phi$ .
19 return  $\Phi$  as  $\Phi'$ .
```

If A is a categorical attribute, then $f.A$ is a concept that contains $t.A$ for every $t \in C$. Furthermore, $f.A$ is the smallest interval (resp. concept) that has the above property.² In other words, f is the “smallest” such tuple that contains every tuple in C . Intuitively, the clustering step, which generates representative tuples, provides a higher-level semantic abstraction to the fraudulent tuples that are to be captured.

Distance of a rule from a representative tuple The notation $|f - r|$ denotes the *distance* of a rule r from a representative tuple f . Intuitively it reflects how much the conditions in the rule need to be generalized for the rule to capture the representative tuple. It is formally defined as:

$$\sum_i^n (f.A_i - r.A_i), \quad (1)$$

where $r.A_i$ denotes the interval or concept associated with the condition of attribute A_i in the rule r , and n is the arity of the transaction relation.

The distance between two attribute intervals is defined as follows. If $f.A$ is the interval $[s_1, e_1]$ and $r.A$ is the interval $[s_2, e_2]$, then $|[s_1, e_1] - [s_2, e_2]|$ is the sum of sizes of the smallest interval(s) needed to extend $[s_2, e_2]$ so that it contains $[s_1, e_1]$. For example, the distance of $|[1, 5] - [5, 100]|$ is 4, while the distance of $|[1, 100] - [1, 5]|$ is 95. The distance of $|[5, 10] - [1, 100]|$ is 0, since $[1, 100]$ already covers $[5, 10]$. If an attribute A is categorical, then $|f.A - r.A|$ is the length of the smallest “ontological distance” that need to be added to $r.A$ so that it contains $f.A$. For example, $|\text{Offline with PIN - Online with CCV}|$ is 1, and $|\text{Offline without}$

$\text{PIN - Online with CCV}|$ is 2. By leveraging concepts in the ontology when available, the resulting rules have a more meaningful interpretation.

The overall cost function The overall cost of modifying a rule r to capture a representative tuple f then reflects the amount of modifications that need to be carried (Equation 1) minus the benefit derived from those modifications:

$$\sum_i^n (f.A_i - r.A_i) - (\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R) \quad (2)$$

Putting things together We now have all the ingredients for describing our algorithms. The algorithm proceeds by clustering the transactions into groups and then computes a representative tuple for each cluster.³ For every cluster C , we compute its representative tuple $f(C)$ as well the cost (according to Equation 2) of modifying each of the rules to capture it, and select the k rules with minimal cost. We refer to them as the top- k rules (see Line 4 of Algo. 1). In Line 8, we pick the top rule in $\text{top-}k(f(C))$. If the rule $r(I)$ does not already contain $f(C)$, we will attempt to make the smallest generalization on r to r' so that $r'(I)$ contains $f(C)$. Whenever the interval or concept of an attribute $r.A$ does not contain $f.A$, we will attempt to modify $r.A$ by computing the smallest extension needed on $r.A$ based on its distance from $f.A$. We perform this extension on every attribute A of r where $r.A$ does not contain $f.A$. This is what we mean by “generalize r minimally to r' so that $f(C) \in r'(I)$ ” in line 9.

Next, we proceed to verify the new rule r' with our potential modifications with the domain expert. If the domain expert agrees with the proposed modifications (lines 11,12), we will replace r with the new rule r' in Φ . Otherwise, we will refine our question to probe the domain expert further on whether or not there are parts of the modifications that are desired even though the entire rule r' is not what the domain expert desires (lines 14,15). We then modify only the desired modifications, if any. The next step allows the domain expert to make further generalizations to the rules. After this, the algorithm proceeds to pick another closest rule to $f(C)$ to attempt to capture $f(C)$. Line 18 captures the case when we ran out of rules to modify. If this happens, we will construct a new rule to cover f by stating the exact conditions that are required.

We conclude with a remark regarding the computational complexity of the algorithm. All components of the algorithm (i.e., clustering, computation of representative tuples for each cluster and the top- k rules) execute in PTIME in the size of its input. Hence each iteration executes in PTIME in the size of the input. The number of iterations per cluster is dependent on the amount of refinements that the expert makes to the suggested rule modifications (shown in our experiments to be fairly small).

Example 4.4. The relation below depicts the representative tuples of the clusters formed from the six fraudulent transactions from Figure 2. The first tuple is the representative tuple of the cluster that consists of the first two tuples in Figure 2. The second (resp. third) tuple below is the representative of the cluster that consists of only the 4th tuple in Figure 2 (resp., 6th, 7th, and 8th tuples).

²If there are multiple such concepts, e.g. in non tree-shaped concept hierarchies, we pick one.

³In our implementation, we use the clustering algorithms of [12], but other clustering algorithms can be similarly be used.

Representatives of fraudulent transactions in Figure 2:

Time	Amount	Transaction Type	Location
[18:02,18:03]	[106,107]	Online, no CCV	Online Store
[19:08,19:08]	[114,114]	Online, no CCV	Online Store
[20:53,20:58]	[44,48]	Offline, without PIN	GAS Station B
⋮	⋮	⋮	⋮

Consider a domain expert, Elena, that is working with the system. The first rule in Figure 1 is the closest to the first representative tuple above. This is because Equation 2 evaluates to $(0+4+0+0)-(2+0+0)=2$ for the first rule and the first representative tuple, whereas the second and third rule of Figure 1 and the first representative tuple have scores $(53+4+0+0)-(2+0-1)=56$ and $(178+0+0+1)-(6+0-3)=168$, respectively, and are thus ranked lower than the first rule. The number '1' in the last calculation denotes the ontological distance between "Gas Station A" and "Gas Station B". Since they are both contained under "Gas Station", the distance is 1.

Algo. 1 will thus propose to modify the condition of the first rule from "Amt ≥ 110 " to "Amt ≥ 106 " to capture the representative tuple. It then proceeds to verify the modification with Elena. Suppose Elena accepts the proposed modification but further generalizes the condition rounding it down to "Amt ≥ 100 " instead. So the new rule 1 is

- 1) $Time \in [18:00,18:05] \wedge Amt \geq 100$.

Besides the fact that rounded values may be preferred by domain experts over more specific values, such rounding may embody domain-specific knowledge that may possibly lead to the discovery of more fraudulent transactions, particularly from transactions that are unlabeled, or the discovery of legitimate transactions that should not have been labeled as legitimate.

For the second and third cluster, similar interactions occur between RUDOLF and Elena. The new rules that result are:

- 2) $Time \in [18:55,19:15] \wedge Amt \geq 110$.
- 3) $Time \in [20:45, 21:15] \wedge Amt \geq 40 \wedge Location \leq Gas\ station'$.

To conclude, observe that Algo. 1 allows Elena to make further generalizations to the rules. Elena rounded the value down from 106 to 100 because her experience tells her that if frauds occur with amount greater than \$106, then it is likely to occur a few dollars below \$106 as well. Hence, she generalized (i.e., rounded down) the value to \$100. In making such generalizations, the fraudulent transactions will continue to be captured. However, the modified rules may now capture (more) non-fraudulent transactions. Nonetheless, we still allow such generalizations since these are deliberate changes made by Elena, the domain expert. More typically, however, such "rounding generalizations" tend to be meaningful generalizations that may lead to the discovery of more fraudulent transactions (i.e., unlabeled transactions that should be classified as fraudulent or legitimate transactions that are mistakenly labeled as legitimate)⁴. As we shall show in Example 4.7, Elena can also leverage her experience or domain knowledge to pinpoint the right conditions for avoiding legitimate transactions. We describe next how over-generalization may be treated.

4.2 Rule Specialization Algorithm

In the previous subsection, we have seen how one generalizes rules to capture fraudulent transactions. We now discuss the opposite case, where we wish to specialize rules instead, in order to exclude legitimate transactions when there no new fraudulent transactions or unlabeled transactions but there are new legitimate transactions.

⁴This is from our conversations with domain experts on credit card fraud detection.

We call this special case the RULE SPECIALIZATION PROBLEM. Here again we can show hardness results analogous to Theorem 4.1 and 4.3.

THEOREM 4.5. *The RULE SPECIALIZATION PROBLEM is NP-hard even if Φ is perfect for I . The problem is NP-hard even when I contains only unlabeled transactions and I' consists of only one legitimate transaction.*

PROOF. Given an instance of the hitting set problem, we construct an instance of the RULE SPECIALIZATION PROBLEM as follows.

The transaction relation has $|U|$ columns, one for each element in U . For every set s in S , we construct a characteristic tuple of s by placing a 0 in position i if $x_i \in s$ and 1 otherwise. Hence there are $|S|$ tuples in the transaction relation I so far and the fraudulent transactions $F = I$. The set Φ consists of a single rule

$$A_1 \leq \top \wedge \dots \wedge A_{|U|} \leq \top,$$

where \top denotes the top element, and hence, $\Phi(I)$ currently captures all fraudulent transactions F . The new transaction relation I' consists of a single tuple $(1,1,\dots,1)$. This set L' of legitimate transactions is a singleton set consisting of only $(1,1,\dots,1)$. That is, $L' = I'$. This is the legitimate transaction that we wish to exclude.

With $F' = L = \emptyset$, our goal is to specialize the rule in Φ to capture exactly the fraudulent tuples F only. Like in the proof of Theorem 4.1, we assume that each modification is associated with a unit cost and $\alpha = \beta = \gamma > 1$.

As an example, consider the same hitting set as in the proof of Theorem 4.1, where $U = \{A_1, A_2, A_3, A_4, A_5\}$ and $S = \{s_1, s_2, s_3\}$, where $s_1 = \{A_1, A_2, A_3\}$, $s_2 = \{A_2, A_3, A_4, A_5\}$, and $s_3 = \{A_4, A_5\}$. The transaction relation $I \cup I'$ is shown below (where I' is shown in gray). The last column annotates the type of tuple (i.e., F for tuples in F and L' for tuples in L').

A ₁	A ₂	A ₃	A ₄	A ₅	
0	0	0	1	1	F
1	0	0	0	0	F
1	1	1	0	0	F
1	1	1	1	1	L'

It is straightforward to verify that the reduction to an instance of the RULE SPECIALIZATION PROBLEM can be achieved in polynomial time in the size of the input of the Hitting Set Problem. We now show that a solution for the Minimum Hitting Set Problem implies a solution for the RULE SPECIALIZATION PROBLEM and vice versa.

Let H be a minimum hitting set. For every element x_i in H , we duplicate the original rule (except if this is the last element in H) and modify the corresponding condition to $a_i = 0$ in the copy of the rule. (The condition can also be $a_i \leq 0$ or $a_i < 1$ but wlog we assume $a_i = 0$ is used.) Recall that the cost of changing $a_i = 0$ is 1, and the cost of duplicating a rule is 1. Clearly, we have that $\Phi'(I \cup I')$ contains F . Indeed, since H hits every set $s \in S$, there must be an element in s whose corresponding value under an attribute a_i is 0 when the condition $a_i = 0$ according to a new rule in Φ' . Hence, it follows that $\Phi'(I \cup I')$ contains F and since each rule in Φ' contains a condition of the form $a_i = 0$, the legitimate transaction $(1,1,\dots,1)$ will not be among $\Phi'(I \cup I')$.

We show next that the expression $\text{cost}(M) - (\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R)$ is the minimum possible. Suppose there is another set M' of modifications to Φ'' such that $\text{cost}(M') - (\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R)$ is less than the previous expression. Observe that every rule in Φ'' must contain at least a condition that is specific to selecting

a fraudulent transaction. That is, for every rule, $a_i = 0$ for some i since otherwise, the rule is either redundant or the legitimate transaction will be selected. Also, we can assume that every other condition in the rule in Φ'' cannot contain a condition that selects 1s (e.g., of the form $a_i = 1$). If a rule r contains a condition $a_i = 1$, then we can omit this condition and assume it is $a_i \leq \top$ instead. The rule with $a_i \leq \top$ captures all tuples that are captured by r (and possibly more) and hence, we will continue to capture all fraudulent tuples and continue to exclude the legitimate tuple under this assumption. Similarly, if a rule r contains multiple conditions $a_i = 0$ s, then we can omit all but one of the $a_i = 0$ s and assume the rest are $a_i \leq \top$. We can now construct a hitting set from M' that is smaller than H , which is a contradiction.

For the converse, let M be the set of modifications made to Φ such that $F \subseteq \Phi'(I \cup I')$, the legitimate transaction l is such that $l \notin \Phi'(I \cup I')$, and $\text{cost}(M) - (\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R)$ is minimum. As before, observe that each rule must contain at least one modification of the form $a_i = 0$ for some i so that l is not selected. Furthermore, it is easy to see that each rule must contain exactly one such condition $a_i = 0$ only as additional conditions such as $a_j = 1$ or $a_j = 0$ are redundant and can only increase the cost.

Let $H = \{x_i \mid a_i = 0 \text{ in any of the modified rules}\}$. We show next that H is a minimum hitting set. First, we show that H is a hitting set. Suppose not, then there is a set $s \in S$ such that $H \cap s = \emptyset$. In other words, for every element $x_i \in s$, there does not exist a rule in Φ' where $a_i = 0$. Let f be the tuple that corresponds to s in the transaction table. This means that $f \notin \Phi'(I \cup I')$, which contradicts our assumption that $F \subseteq \Phi'(I \cup I')$.

Next, we show that H is a minimum hitting set. Suppose not, then there is another hitting set H' where $|H'| < |H|$. With H' , it is straightforward to construct a set of modifications whose cost is lower than M 's cost.

In our running example, Φ' contains two rules:

$$\begin{aligned} A_1 \leq \top \wedge A_2 = 0 \wedge A_3 \leq \top \wedge A_4 \leq \top \wedge A_5 \leq \top \\ A_1 \leq \top \wedge A_2 \leq \top \wedge A_3 \leq \top \wedge A_4 = 0 \wedge A_5 \leq \top \end{aligned}$$

since a minimum hitting set is $\{A_2, A_4\}$. \square

Similarly, we can show that the NP-hardness continues to hold even if we fix the size of the schema.

THEOREM 4.6. *The RULE SPECIALIZATION PROBLEM is also NP-hard even if Φ is perfect for I and the size of the schema of the transaction relation is fixed.*

SKETCH. The proof of the above result is similar to that of Theorem 4.3. It makes use of a reduction from the set cover problem and in the reduction, a single unary transaction relation is used. We build a taxonomy of the elements of a set cover instance according to which element belongs to which set. The relation initially contains all elements of the universe of the set cover instance and these transactions are all fraudulent. The set Φ consists of a single rule $A \leq \top$ which captures all fraudulent transactions. The cost of adding a rule and modifying a condition cost 1 each. The new transaction relation I' consists of a single legitimate tuple whose value does not occur among the existing values. One can then establish that a set of rules of minimum cost can be derived from a minimum set cover and vice versa. Intuitively, each rule has the form $A \leq S_i$ where each S_i is part of the solution to the instance of the minimum set cover problem. \square

Algorithm 2: Adapt rules to exclude legitimate tuples

Input: A set Φ of rules for a transaction relation I (contains old and new transactions) with $L \subseteq I$ and $L' \subseteq I$.

Output: A new set Φ' of rules that excludes $L \cup L'$.

```

1  foreach  $l \in (L \cup L')$  do
2      Let  $\Omega_l = \{r \in \Phi \mid l \in r(I)\}$ .
3      foreach  $r \in \Omega_l$  do
4          repeat
5              Let  $A$  be an attribute that has not been considered
6              before and where splitting on  $A$  to exclude  $l.A$  will
7              minimize the cost associated with splitting on  $A$ .
8              Suppose the existing condition on  $A$  is  $A \in [b, e]$ .
9              Split  $r$  into  $r_1$  and  $r_2$  on  $A$  as follows:
10             Let  $r_1$  be a copy of  $r$  except that the condition on  $A$ 
11             is  $A \in [b, \text{prev}(r.A)]$ .
12             Let  $r_2$  be a copy of  $r$  except that the condition on  $A$ 
13             is  $A \in [\text{succ}(r.A), e]$ .
14             Ask the domain expert whether the split into  $r_1$  and
15              $r_2$  is correct.
16             if the domain expert agrees with the modification
17             then
18                 Add  $r_1$  and  $r_2$  to  $\Phi$ .
19                 Allow the domain expert to make further
20                 modifications to the proposed rules.
21                 Break out of repeat loop.
22             until all attributes have been considered;
23             Remove  $r$  from  $\Phi$ .
24  return  $\Phi$  as  $\Phi'$ .
```

The Algorithm In view of the hardness results, we develop a heuristic algorithm (Algo. 2) that greedily determines the best attribute to “split” to avoid capturing each legitimate tuple.

In Algo. 2, we use I to denote both old and new transactions. For each legitimate transaction l in $(L \cup L')$, we determine the set Ω_l of rules that will capture l and modify every rule in Ω_l to ensure that the modified rules will no longer capture l . For a rule r in Ω_l , the algorithm proceeds to pick an attribute A where we can split the condition of the attribute to exclude the value $l.A$. The attribute A that we pick is the one that maximizes the benefit according to the benefit $\alpha * \Delta F + \beta * \Delta L + \gamma * \Delta R$, assuming a fixed cost of modification where we copy the rule and split on the attribute. If there are multiple attributes with the same maximum benefit, we randomly pick one of them. Observe that the heuristic of greedily selecting an attribute that will maximize benefit may not be globally optimal in the end. In the proof of Theorem 4.5, this greedy heuristic is analogous to the strategy of repeatedly picking the attribute (and splitting on the attribute) that will “hit” the most sets until all sets are hit.

Splitting on attributes Once an attribute is selected, the rule is duplicated into r_1 and r_2 and the condition on A in both rules is modified to exclude $l.A$. Observe that since $r(I)$ captures l , we must have that $l.A$ satisfies the rule r 's condition on A . In the split, r_1 's condition on A accept values from b to the element that is the predecessor of $l.A$, where b denotes the smallest value accepted by the existing condition of r on A . The rule r_2 selects only elements from the successor element of $l.A$ to the largest value (i.e., e) accepted by the existing condition of r on A .

For domains that are discrete and has a total order, the above procedure, $\text{prev}(r.A)$ and $\text{succ}(r.A)$ are well-defined. However, when domains are categorical and has only a partial order, the rules will be split according to the partial order. Let O denote the

set of all concepts (excluding $l.A$) that are parents of \perp in the partial order (i.e., the leaf nodes of the partial order excluding \perp). To exclude $l.A$, the algorithm considers how to select a minimum set of concepts to “cover” all concepts in O that excludes $l.A$ at the same time. It can be shown that the problem of computing such a minimum set is analogous to computing a minimum set cover for O . Our procedure adopts the greedy heuristic where we greedily pick a concept in the partial hierarchy that covers the most number of uncovered concepts in O until all nodes in O are covered. For categorical attributes, it may be necessary to duplicate r more than twice, where there is a rule to select each concept in the cover. For example, referring to Figure 1, to exclude “Online, with CCV”, we may pick “Offline” and “Online, without CCV” to cover the remaining concepts that are parents of “None”. Observe that similar to our algorithm on rule generalization, our rule specialization algorithm also makes use of the ontology whenever available to split the attributes meaningfully. In this case, attributes are split into meaningful concepts in the “lower-level” according to the ontology.

After this, we ask whether the domain expert agrees with the split. If the domain expert agrees, we add both rules r_1 and r_2 to Φ . The domain expert can also add further modifications to the rules (line 13), such as excluding more values than what is suggested by the algorithm, and we break out of the repeat loop. Otherwise, we repeat the loop to attempt to split r on another attribute to avoid capturing l . Note that since l has to be excluded, one of the splits must be deemed correct by the domain expert. After this, we remove r from Φ and repeat the same procedure to modify Φ to exclude the selection of another legitimate transactions.

Example 4.7. We will now illustrate Algo. 2. The legitimate transactions from Figure 2 that are captured by the modified rules of Example 4.4 are shown below for convenience.

	Time	Amount	Transaction Type	Location
l_1	18:04	112	Online, with CCV	Online Store
l_2	19:10	117	Online, with CCV	Online Store
l_3	21:01	49	Offline, with PIN	GAS Station A
	:	:	:	:

Modified rules Φ from Example 4.4:

- 1) $Time \in [18:00,18:05] \wedge Amt \geq 100$.
- 2) $Time \in [18:55,19:15] \wedge Amt \geq 110$.
- 3) $Time \in [20:45, 21:30] \wedge Amt \geq 40 \wedge Location \leq Gas\ station'$.

We would like to adapt the rules to exclude these legitimate transactions (and still continue capture fraudulent transactions). For this example, assume that $\alpha = \beta = \gamma = 1$.

The algorithm considers every legitimate transaction. Since l_1 is caught by rule (1) above, Algo. 2 proceeds to determine which attribute of the rule to split in order to exclude l_1 . Splitting on `time` or `amount` or `type` will result in the same maximum benefit: $(1*0$ (zero unlabeled transactions on either day) $+ 1*0$ (the number of fraudulent transactions that are caught remains unchanged) $+ 1*1$ (one less legitimate transaction that is caught)). Splitting on the attribute `location`, however, will cause additional fraudulent transactions (i.e., the first two transactions in Figure 2) to be missed and hence has a lower benefit than the rest of the attributes.

Suppose the algorithm proposes to split on `time` (an arbitrary choice among `time`, `amount` or `type`). This will result in two rules that will capture all fraudulent transactions that were previously caught by the rule and exclude l_1 at the same time.

- $$r_{11}: Time \in [18:00,18:03] \wedge Amt \geq 100.$$
- $$r_{12}: Time \in [18:05,18:05] \wedge Amt \geq 100.$$

At this point, Elena can accept this proposal or ask for alternatives. For the purpose of illustrating our algorithm, suppose Elena asked for an alternative proposed modification. Our algorithm may now propose to split on `type` instead. Since there is currently no condition on `type` in the first rule, the condition is implicitly “`type \leq T`”. And because the concepts “Offline” and “Online, without CCV” cover all possible type values (i.e., values immediately above the “None” node in Figure 1) except “Online,with CCV” which we wish to exclude, we have the following two rules:

- $$r_{11}: Time \in [18:00,18:05] \wedge Amt \geq 100 \wedge Type \leq Offline.$$
- $$r_{12}: Time \in [18:00,18:05] \wedge Amt \geq 100 \wedge Type \leq Onl, no CCV.$$

Using domain knowledge that only online purchases, especially those without CCVs are of concern, Elena eliminates the rule r_{11} .

After this, our algorithm proceeds in a manner that is similar to what was described before to split the second rule of Φ to omit l_2 (and similarly, the third rule of Φ for l_3). We omit the details here but show the final rules that are obtained.

- $$r_{22}: Time \in [18:55,19:15] \wedge Amt \geq 100 \wedge Type \leq Onl, no CCV.$$
- $$r_{31}: Time \in [20:45,21:15] \wedge Amt \geq 40 \wedge Location \leq Gas Station \wedge Type \leq Online.$$
- $$r_{32}: Time \in [20:45,21:15] \wedge Amt \geq 40 \wedge Location \leq Gas Station \wedge Type \leq No code.$$

Observe that whenever a condition is generalized (in Algo. 1), more legitimate or unlabeled tuples may be inadvertently captured by the rule. Hence, further refinements may be needed to tune the rules to a desired state. Conversely, if a condition is specialized, some fraudulent tuples may be inadvertently omitted. Hence, further refinements may be needed to tune the rules to a desired state. As we shall describe next, the rules are interactively refined based on the input of a domain expert such as Elena. In particular, there may be several rounds of refinements through generalizations and specializations before a desired set of rules is obtained.

5 IMPLEMENTATION AND EXPERIMENTS

RUDOLF is implemented in PHP/JavaScript and uses MySQL as the DB engine. Detailed system architecture described in [11].

Datasets We have access to a real-world datasets of credit card transactions by a financial company XYZ⁵. Due to the sensitivity of credit card-related information, we used anonymized version of the dataset. The dataset consists of transaction sets of various sizes from 15 financial institutes (FIs) for the first quarter of 2016. Each transaction set varies from 100K to 10M transactions and most of them consists of about 500K transactions. The percentage of fraudulent transactions varies between 0.5% to 2.5% between different FIs. The number of misclassified transactions (i.e., fraudulent transactions that are marked as legitimate and vice-versa) varies between 35% and 50%. The transactions contain both numerical (time, amount, number of previous actions, etc.) and also categorical (location, client type, etc) data. Along with the transactions, we obtained 15 rules-sets, one for each of the 15 FIs for the same time period from company XYZ. We also obtained the change history and versions of those rules. A small FI typically has about 10 rules while a big FI typically has about 130 rules. Most FIs have about 55 rules on average. Each time the rules are modified, the rules undergo about 10 rounds of modifications on average. The transactions in the data sets are annotated as fraudulent/legitimate, and we take these annotations as the ground truth. Each transaction also has a risk score, which is a value between 0 and 1000, that is generated by the company’s machine learning algorithm to determine the chance that the transaction is fraudulent. The

⁵Name omitted per company request

fraudulent transactions can be captured by the set of rules given by the company and allowing the users to refine the rules over time. Another option is to apply a rule that classify all transactions with risk score above a certain threshold as fraudulent.

Ontology In the experiments for the location attributes we used a geographical ontology (containing different relations, e.g., capital city, located in, region, continent, etc) that was built semi-automatically (using DBPedia [13]) and manually verified by the domain experts.

Experiment scenarios The different sizes of transaction sets allowed us to vary our experiments with different dataset sizes (from 100K to 10M, with the average value being 500K).

We run each experiment with 8 users (fraud detection experts from company XYZ) and as the variance was less than 2% we present here the average. We also ran our experiments with 10 student volunteers to determine whether the level of expertise affects the results. To simulate the work of a domain expert, we split each dataset into two parts of approximately the same size, before and after a certain point in time. We advanced in time from this point and examined, at different points in time, how the expert adapts the rules in response to transactions arriving up to that point.

We compared the performance of RUDOLF to three alternative solutions, to be detailed below. For each of the algorithms and each of the datasets, we varied the number of new transactions arriving between consecutive rounds of rule refinement. The number of new transactions varies from 10% to 20% of the dataset, with the default being 10%, and this corresponds closely to what happens in real-life between rounds of rule refinement.

Baseline algorithms We consider the two extreme baselines: A *fully-manual* setting, where rules are manually refined by experts without the help of the system (the current setting that is used by company XYZ experts in their daily work), and a *fully-automatic* setting that uses the risk score produced by the ML algorithm and a single rule that selects fraudulent transactions based on their risk scores. Observe that this algorithm essentially generates a single new rule of the form *score greater than threshold* (rather than refining an existing set of rules). We also compared to the baseline algorithm *No Change*, which denotes the given rules without any changes.

Observe that the fully manual setting is arguably our “toughest” competitor since the rules are modified by experts and the experts are not limited by any time constraint to refine the rules.

In addition to the above, we also consider a variant of RUDOLF, denoted RUDOLF⁻, that automatically refines the existing set of rules by accepting the modifications proposed by the system without consulting an expert. We also considered RUDOLF^{-s}, which is the system RUDOLF that does not refine categorical attributes (and hence does not use ontologies) of rules. To the best of our knowledge, all existing systems refine only numerical attributes of rules. Hence the performance of RUDOLF^{-s} will allow us to understand how RUDOLF compares with systems that are only restricted to refine numerical attributes. In fact, we discovered that RUDOLF^{-s} gives almost same results as the fully-manual system and also RUDOLF⁻. Hence, we omit the results of RUDOLF^{-s} completely.

Measurements In our experiments, we measured the efficiency of the algorithms in terms of the effectiveness of the derived rules and the amount of time that the domain experts saved as a consequence of using our system. We also measured the running time required by RUDOLF to select the proposed modifications.

For our datasets this was always at most one second, and we thus omit the exact measures.

To measure the effectiveness of a set of rules derived by any of the methods, we consider its *prediction quality*, namely how correctly it identifies future frauds. For that, we examine the set of transactions from the given point in time where the rules were derived and until the end of the dataset. For these future transactions we count, for each set of rules, the percentage out of all fraudulent (resp. legitimate) transactions that it identifies (resp. wrongly classifies as fraudulent).

To understand of how many modifications each method entailed, we also computed the cumulative number of rule updates that each method required. We measure this only for RUDOLF, RUDOLF⁻, and the fully-manual methods, which directly change existing rules.

Finally, we measured the time the experts took to refine the rules.

Results We first report on our experiments with the domain experts. Our first experiment examines the performance of the algorithms as time advances, with all parameters set to their default value. As explained above, at each point in time, (i.e. after a certain percentage of the transactions has been observed), the algorithms are invoked to derive a corresponding updated set of rules. Figure 3(a) shows the (cumulative) number of modifications that RUDOLF, fully-manual and RUDOLF⁻ method performed to the rules. We see that RUDOLF performs less modifications than its competitors.

We can see this more clearly in Figure 3(b), which illustrates the prediction quality of the derived sets of rules, in terms of the percentage of misclassified future transactions (lower percentage of error implies better prediction quality). RUDOLF performs the best, providing the best prediction. The fully manual rule derivation provides less accurate predictions, though still better than the two automatic competitors. Among the two, RUDOLF⁻, that incrementally refines the rules, still performs better than the threshold-based ML approach.

We note that the difference in performance between RUDOLF⁻ and RUDOLF demonstrates the importance of incorporating experts and their domain knowledge in the loop.

For the experiments above, the rules were periodically refined in hops of 10% of the transactions. For different hops sizes, the results are also similar, except that convergence naturally arrives after fewer (proportionally) iterations for larger hops.

Our next experiment examines the performance of the algorithms for varying dataset, with almost the same percentage of fraud, but different sizes. The size had no significant effect on the number of rule modifications performed by the algorithms, but the prediction quality slightly improved as more data was available. Figure 3(c) illustrate, for varying dataset sizes, the prediction quality of the rules after the first refinement round, in terms of the percentage of misclassified transaction. Here again, lower percentage means better quality. As before, RUDOLF yields best results. We can see that the error of all algorithms slightly decreases as the size of the data set grows. The improvement is only small as fraudulent transactions of the existing fraud patterns are distributed throughout the datasets, so the additional data reveals some, but not huge, amount of new information. Similar results were obtained for the following refinements rounds and we thus omit the graphs.

Next, we examine the performance of the algorithms for varying percentages of fraudulent transactions. We took 4 different

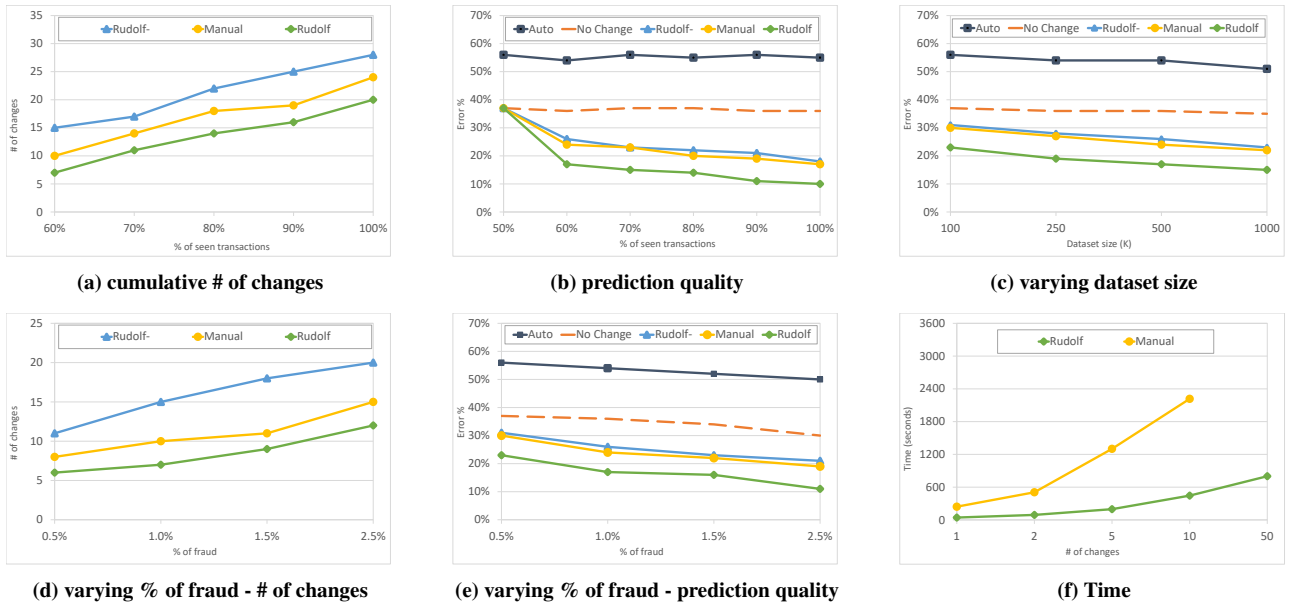

Figure 3: Experimental results

customers databases of roughly the same size, but different fraud percentages (0.5% to 2.5%). All other parameters are set to their default values. Figures 3(d) 3(e) show, respectively, the number of rule updates and percentage of error after the first refinement round. We can see that an increased number of fraudulent transaction entails more rule modifications to capture them. The classification error slightly increases with more fraudulent transactions, but here again RUDOLF achieves the lowest error.

Finally we note that rule refinement with RUDOLF not only consistently yielded superior fraud prediction, but also reduced the time required from the experts by a factor between 4 to 5. (Around 50 seconds per round for RUDOLF compared to 4-5 minutes without). We measured time of our experts performance, depicted in figure 3(f). We asked them to fix up to 50 problematic transactions in both manual and automatic way. Interestingly, no expert finished all 50 fixes in the manual mode (a well-trained expert from company XYZ usually can fix 30-40 transactions per work-day). The fact that RUDOLF leads in performance across all parameters is interesting as the rules derived manually by experts are typically considered as ground truth and yet, RUDOLF is able to do better (i.e., with less changes, and with lower percentage of error) with less data. This was consistent in all the experiments. Furthermore, all users reported that working with RUDOLF was convenient and effective in the sense that the rules/modifications proposed by the system helped them identify and focus on the problematic rules and the needed treatment. To conclude we observed that around 75% of the modifications were condition refinements, 20% rule splits, and 5% rule addition.

Interestingly, our experiments with novice users (student volunteers) show similar trends. In particular, also for novice users, the rules generated with the assistance of RUDOLF were of best quality and produced much faster than in all alternatives. We omit the graphs for space constraints and only note that as expected, compared to the domain experts, the overall prediction quality, even with RUDOLF, was lower (by about 5%) than for the experts, but still significantly better (by 25%) than what the novice users would have achieved alone.

6 RELATED WORK

The identification of fraudulent transactions is essentially a classification problem. Classification has been a fundamental problem in machine learning and data management [14, 15], and crowdsourcing has recently emerged as a major problem solving paradigm [16]. Many classification works have used crowdsourcing to obtain training data for learning [17–20]. This is complimentary to our work: In RUDOLF the crowd (of experts) is employed to maintain classifications rules, which might have been initially learnt through such training. Besides learning-based models, rules are also used for classification. Most of the previous research in rule-based classifiers focus on how to learn rules from the training data. In contrast, [21] employs both learning and analyst experts that manually create classification rules using regular expressions. In [22] that describes LinkedIn’s job title classification system, experts and crowdsourcing are also heavily used. In both cases however the ongoing refinement of rules in a changing environment, which is the focus of RUDOLF, is not considered.

In addition to machine learning-based methods, there are multiple fraud-detection techniques that have been considered. For example [4] uses a decision tree, defined recursively for nodes and edges of the tree and using the ratio between number of transactions that satisfy some condition to label them accordingly. Other methods, e.g. [5], are based on genetic programming, used to classify transactions into suspicious and non-suspicious ones. Another class of the algorithms for fraud detection is based on clustering techniques. An example is [6] that clusters users based on common behavior and then considers as suspicious the transactions that take the user outside its cluster. Bayesian networks are used both to detect fraud in telecommunications (e.g. [23]) and in the credit card industry (e.g. [24]). Neural networks are also used for fraud detection. For instance [25] presents an online fraud detection system, based on a neural classifier. All these techniques are complimentary to ours and can be used to deriving the initial base-set of rules.

Another class of work similar RUDOLF is that of Concept Drifts, which are changes that occur on the distribution of the input that affects the learning system and thus the output. [8] deals with concept drifts by using sliding window that adaptively remembers more or less items from the training set (the closest

past) according to whether it recognized a concept drift or not. Other system ([9]) is classification system based on decision rules. Even though these systems can compute the nearest neighbors for the closest rules and generalization for numerical values, they do not support generalization and specification on categorical attributes, do not involve a human expert in the loop, and do not allow configuration of weight for different kind of errors (false positives and false negatives).

Finally, if we view our transaction relation as the source database and the set of fraudulent transactions as our target database, then the work on deriving queries or schema mappings based on source-target databases (e.g., [26–28]) is also relevant. Similarly, techniques for rule mining and, in particular, inductive logic programming (e.g., [29]) can also be used for fraud detection, where the fraudulent transactions can be seen as positive examples and the legitimate transactions can be seen as negative examples. However, the language of schema mappings and inductive logic programming are different from our rule language and more importantly, the rules derived cannot be interactively adapted.

7 CONCLUSION AND FUTURE WORK

We present RUDOLF, a novel system that assists domain experts in defining and adapting rules in dynamic environments. We show that the problem of identifying the best candidate adaptation for a core language is NP-hard and present PTIME heuristic algorithms for determining the set of rules to adapt and working interactively with the domain experts until they are satisfied with the resulting rules. Our experiments with real-world data sets demonstrate the promise that RUDOLF is an effective and efficient tool for rule refinement.

One direction for future work is the use of more sophisticated cost model. Instead of associating a cost with every modification made to a condition in the rule, one can vary the cost depending on the attribute or even rule that is modified and these costs/weights can be learned or adjusted based on user feedback, satisfaction of the suggested modification etc. Similarly, the parameters α , β and γ used in our cost formula to weight the importance of misclassifying of fraudulent/legitimate/unlabeled transactions may also be dynamically adapted based on such user feedback.

ABSTRACT

Group k -nearest neighbor (k GNN) search allows a group of n mobile users to jointly retrieve k points from a location-based service provider (LSP) that minimizes the aggregate distance to them. We identify four protection objectives in the privacy preserving k GNN search: (i) every user's location should be protected from LSP; (ii) the group's query and the query answer should be protected from LSP; (iii) LSP's private database information should be protected from users, i.e., the users cannot learn more information beyond the answer they requested; (iv) every user's location should be protected from the other users in the group.

We propose the first approach to meet the four privacy goals in the k GNN query. Our approach provides an accurate query answer and does not rely on heavy pre-computation on LSP like previous works. Our approach considers the most hostile environment that any $n - 1$ users in the query group may collude to infer the location of the remaining user. Though we consider k GNN, the proposed privacy preserving approach can be easily adopted to any group query because it treats the query answering (i.e., k GNN) as a black box. Theoretical and experimental analysis suggest that our approach is highly efficient in both user computation and communication while incurring some reasonable overhead on LSP.

1 INTRODUCTION

The embedding of positioning capabilities (e.g., GPS) in mobile devices facilitates the emergence of location-based services (LBS), which allows the users to publish their location data for retrieving desired information from a database maintained by a location-based service provider (LSP). One typical application is the *group k -nearest neighbor* query (k GNN) proposed in [24], also known as aggregate nearest neighbor query [25] or aggregate similarity search [18, 19, 28]. The k GNN query allows a group of n users to retrieve top- k locations from the LSP's database to minimize some aggregate cost function F over all n users. Figure 1 shows that users u_1, u_2, u_3 ($n = 3$) jointly retrieve the top-2 meeting places $\{p_1, p_2\}$ ($k = 2$), where p_1 has the shortest total distance to the users, and p_2 has the second shortest total distance to the users. By generalizing the classic k -nearest neighbor (k NN) query from a single user in a query to multiple users in a query, the

Figure 1: A k GNN query ($k = 2$): $\{u_1, u_2, u_3\}$ retrieves p_1, p_2 as top-2 locations

k GNN query offers richer semantics with broader applications in spatial databases [18, 19, 24, 25, 28].

We consider four privacy concerns that arise in the k GNN query scenario. **Privacy I:** every user's location privacy against LSP since location can reveal the private information of users. **Privacy II:** query privacy and answer privacy against LSP because the query discloses the combination of users' locations and the relationship between users, and the query answer such as a meeting place may disclose the nature of the meeting or event. **Privacy III:** LSP's data privacy against users. LSP's database is the valuable and protected business asset [8, 12, 33] and the principle of least privilege [29] applies where no more information than the requested query answer should be returned to the users. Another reason for this privacy is the pay-per-result model [8, 33] where the users who pay for k results should not receive more than k results. **Privacy IV:** every user's location privacy against other users because users might not trust other users. For example, two business competitors like to query some meeting places but want to hide their own locations from each other. The most hostile environment is the *full user collusion* where $n - 1$ users in the query collude to infer the location of the remaining user. In Figure 1, for example, colluding u_2, u_3 can infer that u_1 is located in the shaded area based on their own locations and the query answer $\{p_1, p_2\}$ received. If the shaded area is too small, u_1 's location privacy may be compromised. **Privacy IV** is required only in the case of $n > 1$.

Although many solutions, such as [1, 3, 12, 13, 17, 21, 26, 27, 30, 34, 36, 37], are proposed for the single user query (i.e., $n = 1$), only a few works addressed the group query (i.e., $n > 1$) [2, 14] but none of them achieves all four privacy concerns. Most existing work achieved **Privacy I** through returning candidate answers (e.g., [3, 13, 14, 17, 21, 26, 30]) or approximate answers (e.g., [1, 2, 34, 37]). However, returning candidate answers not only increases the communication cost but also violates **Privacy III**, while returning approximate answers degrades the answer utility as well as violates **Privacy II** since LSP knows the query answer that users obtained. [12, 27, 36] achieve **Privacy I-III** in

*This work was done when this author visited Simon Fraser University.

[†]Corresponding author.

the single user query case by heavily relying on pre-computing the query answers for all queries. These approaches are not applicable to the group query where the number of possible queries is large. A more detailed discussion of related work is presented in Section 9.

In this paper, we design a privacy preserving approach to the k GNN query for the general case of $n \geq 1$ while protecting **Privacy I-IV**. Our approach has the following novelties. *First*, it eliminates the need for pre-computing all query answers in order to address the privacy issues, while producing the exact answer. Hence, our approach can easily handle a dynamic database on LSP. *Second*, for **Privacy IV** we consider the most hostile environment, called *full user collusion*, where $n - 1$ users may collude to infer the location of the remaining user. *Third*, we aim to reduce user computational cost and communication cost at a reasonable overhead on LSP, which particularly makes sense in the mobile user scenario. *Fourth*, though we consider k GNN, the proposed privacy preserving approach can be easily adopted to any group query because it treats the query answering (i.e., k GNN) as a black box. For example, our approach works with any choice of aggregate cost function F and other location based group queries; to solve the privacy preserving meeting location determination (PPMLD) [5, 16, 31], we can replace the black box for k GNN in our approach with any existing (non-privacy preserving) meeting location determination algorithm.

The rest of the paper is structured as follows.

- Section 2 formulates the privacy preserving k GNN query problem, called PPGNN, where n users jointly retrieve k -nearest neighbors from LSP while meeting the requirements of **Privacy I-IV**.
- Section 3 proposes a solution to PPGNN with $n = 1$. To our knowledge, this is the first work that eliminates the need for pre-computing all the query answers to achieve **Privacy I-III**.
- Section 4 proposes a solution to PPGNN with $n \geq 1$ while achieving **Privacy I-III**.
- Section 5 extends the solution to PPGNN with $n \geq 1$ to achieve **Privacy I-IV** under the full user collusion assumption. As far as we know, this is the first solution that achieves **Privacy I-IV**.
- Section 6 presents an optimization of the PPGNN solution, denoted PPGNN-OPT, to further reduce the communication cost and user computational cost.
- Section 7 theoretically analyzes the performance of the PPGNN solution and PPGNN-OPT solution.
- Section 8 presents empirical results on a real-world dataset, showing that the proposed approaches are highly communication efficient for the privacy guarantees achieved.
- Section 9 reviews the related work.

2 PROBLEM STATEMENT

We formally define the problem studied in this paper. Table 1 summarizes the frequently used notations. We assume that LSP owns a database of Points of Interest (POIs) where each POI has a location (e.g., latitude and longitude) and other associated information, and each user has a location. Both users and LSP are semi-honest: they follow the protocol exactly as specified, but may try to infer others' private information. Users can acquire their locations from satellites anonymously. A base station is responsible for the communication within users and between users and LSP (e.g., mobile communication provider). The base station

Table 1: Summary of notations

Notation	Description
n	the number of users in the group
d	anonymity parameter for Privacy I
δ	anonymity parameter for Privacy II
θ_0	privacy parameter for Privacy IV
$l_{i,*}$	real location of u_i
\mathbb{C}_*	real query $\{l_{1,*}, \dots, l_{n,*}\}$ of the group
\mathbb{L}_i	u_i 's location set
$l_{i,j}$	j -th location in \mathbb{L}_i
\vec{n}, \vec{d}	partition parameters
$[\mathbf{v}]$	encrypted indicator vector for \mathbb{C}_*
\mathbf{A}	answer matrix for all candidate queries
N	the product of two large primes determined by pk

will not collude with LSP, and there is a secure communication channel (e.g., Tor¹) so that LSP cannot infer users' locations by IP addresses. We also assume that LSP does not collude with users. This assumption is reasonable because the penalty of collusion involving LSP is very high, including losing the trust of users and being prosecuted.

2.1 k GNN Query

Let $\mathbb{D} = \{p_1, \dots, p_D\}$ be a database (owned by LSP) of D POIs, and $\mathbb{C}_* = \{l_{1,*}, \dots, l_{n,*}\}$ be the locations of n users. Both \mathbb{D} and \mathbb{C}_* are in a metric space where a spatial distance function dis is defined for any two locations, e.g., Euclidean distance [24, 25], road-network distance [38]. Let F be a monotonically increasing aggregate function,

$$F(p, \mathbb{C}_*) = F(dis(p, l_{1,*}), \dots, dis(p, l_{n,*})) \quad (1)$$

where p can be any POI in \mathbb{D} . Commonly used F includes *sum*, *max* and *min*. For example, with *sum* the query retrieves a meeting place with the minimum total distance to the users, and with *max* the query retrieves a collection place for the troops that leads to the earliest meet time (by minimizing the maximum distance for every troop to reach that place [25]), and with *min* the query retrieves a place that leads to the earliest time for any user to reach that place. In general, the query finds the k best POIs p from \mathbb{D} in an ascending order of $F(p, \mathbb{C}_*)$, as defined below.

Definition 2.1 (kGNN query [28]). Given a spatial database \mathbb{D} , n query locations \mathbb{C}_* , distance function dis , and aggregate function F , a k GNN query ($k \leq D$) retrieves a subset $\mathbb{P} = \{p_1, \dots, p_k\}$ from \mathbb{D} , such that $\forall p_i \in \mathbb{P}$ and $\forall p \in \mathbb{D} - \mathbb{P}$, $F(p_i, \mathbb{C}_*) \leq F(p, \mathbb{C}_*)$, and for $1 \leq i < j \leq k$, $F(p_i, \mathbb{C}_*) \leq F(p_j, \mathbb{C}_*)$. \square

2.2 Privacy Preserving k GNN Query

Definition 2.2 (Privacy preserving kGNN query, or PPGNN). Let \mathbb{D} and \mathbb{C}_* be those in Definition 2.1. A k GNN query is privacy preserving if the following conditions are satisfied:

- (1) **Privacy I:** $\forall i \in [1, n]$, each user u_i 's location $l_{i,*}$ is indistinguishable from d equally likely locations by LSP, $d > 1$;
- (2) **Privacy II:** the query location \mathbb{C}_* and its answer are indistinguishable from δ equally likely candidates by LSP, $\delta \geq d$;
- (3) **Privacy III:** the users can learn nothing more than the requested answer to the query \mathbb{C}_* .
- (4) **Privacy IV:** $\forall i \in [1, n]$, u_i 's location $l_{i,*}$ is hidden in a region from other users, where the size of the region is no less

¹<https://www.torproject.org/>

than θ_0 fraction of the size of the whole location space, $\theta_0 \in (0, 1]$. Under the *full user collusion assumption*, this property should hold even if any $n - 1$ users collude, by sharing their locations, to infer the remaining user's location with the help of the query answer received. \square

Condition (1) guarantees that the probability for LSP to infer a user's location is $\frac{1}{d}$. Condition (2) guarantees that the probability for LSP to infer the group's query, i.e., all users' locations, as well as the query answer, is $\frac{1}{\delta}$, where $\delta \geq d$. Condition (3) guarantees that the users learn only the query answer as defined by the query, in order to protect the LSP's private database. Condition (4) guarantees that any user's location can not be inferred by other users. The strength of these privacy guarantees depends on the setting of the privacy parameters (d, δ, θ_0) , which are specified by the users.

3 SINGLE USER QUERY

In this section, we consider PPGNN with single user, i.e., $n = 1$. In this case, there is no **Privacy IV**, and $\delta = d$. Section 3.1 gives some background knowledge about the generalized Paillier cryptosystem [10]. Section 3.2 presents our solution.

3.1 Generalized Paillier Cryptosystem

Generalized Paillier cryptosystem ε_s ($s \geq 1$) [10] is a probabilistic asymmetric encryption scheme that provides semantic security. Let \mathbb{Z}_{N^s} and $\mathbb{Z}_{N^s}^*$ be the residue class ring module N^s and the prime residue class group module N^s , respectively.

Generalized Paillier cryptosystem is composed of three algorithms (**Gen**, **Enc**, **Dec**): (1) given a security parameter *keysize*, the *key generation* algorithm $(sk, pk) = \mathbf{Gen}(\text{keysize})$ returns secret key sk and public key pk . N is the product of two large primes determined by pk . (2) The *encryption* algorithm $c = \mathbf{Enc}(x, pk)$ maps a plaintext $x \in \mathbb{Z}_{N^s}$ to a ciphertext $c \in \mathbb{Z}_{N^{s+1}}^*$ using pk . (3) The *decryption* algorithm $x = \mathbf{Dec}(c, sk)$ executes reverse operation of encryption by sk , obtaining plaintext x . The exact construction of **Enc** and **Dec**, which can be found in [10], is not important for this work, but the following homomorphism properties of the generalized Paillier cryptosystem are used by our solutions. For simplicity, we omit the public key pk in the **Enc** algorithm. Let x_1, x_2 denote the plaintexts in \mathbb{Z}_{N^s} .

Homomorphic addition \oplus : given two ciphertexts $\mathbf{Enc}(x_1)$, $\mathbf{Enc}(x_2)$, the ciphertext of the sum $x_1 + x_2$ can be obtained by multiplying the ciphertexts, i.e.,

$$\mathbf{Enc}(x_1) \oplus \mathbf{Enc}(x_2) : \mathbf{Enc}(x_1) \cdot \mathbf{Enc}(x_2) = \mathbf{Enc}(x_1 + x_2) \quad (2)$$

Homomorphic multiplication \otimes : given a plaintext x_1 and a ciphertext $\mathbf{Enc}(x_2)$, the ciphertext of the product $x_1 x_2$ can be obtained by raising $\mathbf{Enc}(x_2)$ to the power x_1 :

$$x_1 \otimes \mathbf{Enc}(x_2) : \mathbf{Enc}(x_2)^{x_1} = \mathbf{Enc}(x_1 x_2) \quad (3)$$

Homomorphic dot product \odot : given a ciphertext vector $\mathbf{Enc}(\mathbf{v}) = (\mathbf{Enc}(v_1), \dots, \mathbf{Enc}(v_m))^T$ and a plaintext vector $\mathbf{x} = (x_1, \dots, x_m)$, the ciphertext of the dot product $\mathbf{v} \cdot \mathbf{x}$ can be obtained by:

$$\begin{aligned} \mathbf{x} \odot \mathbf{Enc}(\mathbf{v}) &: (x_1 \otimes \mathbf{Enc}(v_1)) \oplus \dots \oplus (x_m \otimes \mathbf{Enc}(v_m)) \\ &= \mathbf{Enc}(x_1 v_1 + \dots + x_m v_m) \\ &= \mathbf{Enc}(\mathbf{x} \cdot \mathbf{v}) \end{aligned} \quad (4)$$

For simplicity, we write $\mathbf{Enc}(x)$ with ε_1 as $[x]$. One application of Eqn (4) is privately selecting the i -th element in a vector \mathbf{x} without disclosing the value of i . Specifically, let $[\mathbf{v}] =$

Figure 2: Single user query example (l_3 is real)

$([v_1], \dots, [v_m])^T$ where $v_i = 1$ and $v_j = 0$ for all $j \neq i$. Eqn (4) becomes $\mathbf{x} \odot [\mathbf{v}] = [\mathbf{x} \cdot \mathbf{v}] = [x_i]$, which returns x_i in ciphertext. We will use this private selection to design our solution.

3.2 Proposed Solution

Figure 2 shows the idea of our solution through a running example. The user sends a location set $\{l_1, l_2, l_3, l_4\}$ to LSP, where $d = 4$, as well as an encrypted indicator vector $([0], [0], [1], [0])$ that implicitly specifies that l_3 is the real user location. LSP calculates the query for every location in the location set, producing the answers $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3, \mathbf{a}_4$, and privately selects \mathbf{a}_3 through the result $[\mathbf{a}_3]$ according to the homomorphism properties. This solution has three stages: query generation, query processing, and answer decryption. We discuss each stage in details. We denote the user's real location by l_* .

Query Generation. At first, the user randomly selects $d - 1$ dummy locations from the location space and constructs a location set $\mathbb{L} = \{l_1, \dots, l_d\}$ containing the real location l_* . Then the user creates an indicator vector $\mathbf{v} = (v_1, \dots, v_d)^T$:

$$v_i = \begin{cases} 1, & l_i = l_* \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

After that, the user generates (sk, pk) by calling the key generation algorithm with the security parameter *keysize* (e.g., the most commonly used is 1024 bits [23]), and executes element-wise encryption algorithm on \mathbf{v} , obtaining an encrypted $[\mathbf{v}] = ([v_1], \dots, [v_d])$. Finally, the user sends $\{k, \mathbb{L}, pk, [\mathbf{v}]\}$ to LSP, where k is the number of POIs to retrieve.

Query Processing. After receiving the user's query, LSP computes the k NN query for each location in the location set, resulting in d query answers, $\mathbf{a}_1, \dots, \mathbf{a}_d$, where each query answer is a list of k POIs. The k NN query is computed on *plaintext*, so any plaintext solution for k NN query, such as [24], can be applied. We assume that each query answer \mathbf{a}_i is represented by a vector of integers, $\mathbf{a}_i = (a_{i,1}, \dots, a_{i,m})^T$, such that every element is less than N , where m is the maximum number of integers required for any of the d answers. If the number of integers encoded for a query answer is less than m , 0's are padded as placeholders.

Let $\mathbf{A}^{m \times d} = (\mathbf{a}_1, \dots, \mathbf{a}_d)$ be the query answer matrix. The next theorem suggests that LSP can obtain the encrypted query answer for the real location l_* by a private selection using \mathbf{A} and $[\mathbf{v}]$. The encrypted query answer is returned to the user.

THEOREM 3.1 (PRIVATE SELECTION). *Given an encrypted indicator vector $[\mathbf{v}] = ([v_1], \dots, [v_d])^T$ such that $[v_i] = [1]$ and $[v_j] = [0]$ for all $j \neq i$, and the answer matrix $\mathbf{A}^{m \times d} = (\mathbf{a}_1, \dots, \mathbf{a}_d)$, then*

$[a_i]$ is computed by $A \otimes [v]$ defined as follows:

$$\begin{aligned} A \otimes [v] &= \begin{pmatrix} a_{1,1} & \cdots & a_{d,1} \\ \vdots & \ddots & \vdots \\ a_{1,m} & \cdots & a_{d,m} \end{pmatrix} \otimes \begin{pmatrix} [v_1] \\ \vdots \\ [v_d] \end{pmatrix} \\ &= \begin{pmatrix} [a_{1,1}v_1 + \cdots + a_{d,1}v_d] \\ \vdots \\ [a_{1,m}v_1 + \cdots + a_{d,m}v_d] \end{pmatrix} \\ &= \begin{pmatrix} [0 + \cdots + a_{i,1} + \cdots + 0] \\ \vdots \\ [0 + \cdots + a_{i,m} + \cdots + 0] \end{pmatrix} = \begin{pmatrix} [a_{i,1}] \\ \vdots \\ [a_{i,m}] \end{pmatrix} = [a_i]. \square \end{aligned}$$

The notation \otimes represents the homomorphic matrix multiplication, which executes homomorphic dot product operations in Eqn (4) between each row in A and $[v]$.

Answer Decryption. After receiving $[a_i]$, the user can execute the decryption algorithm on the ciphertext to get the exact query answer a_i for l_* .

In this solution, **Privacy I** is satisfied by anonymizing the user's real location among d locations. **Privacy II** is satisfied because the real query answer is anonymized in d query answers (note $\delta = d$ when $n = 1$) and the selection process is private. Also, LSP returns only the query answer for l_* , so **Privacy III** is satisfied.

4 GROUP QUERY

We now present the PPGNN solution for the group query where $n \geq 1$, which subsumes the solution in Section 3 as a special case. Section 4.1 presents a candidate query generation method that helps satisfy **Privacy II**. Section 4.2 describes the PPGNN solution. Section 4.3 proves the protection of **Privacy I-III**. The protection of **Privacy IV** is addressed in Section 5.

Recall that the real location of each user u_i is denoted as $l_{i,*}$, $1 \leq i \leq n$, and $l_{i,*}$ is hidden in the location set $\mathbb{L}_i = \{l_{i,1}, \dots, l_{i,d}\}$. From \mathbb{L}_i , $1 \leq i \leq n$, LSP can obtain a set of *candidate queries*, where each candidate query is a set of n locations that contains exactly one location from every \mathbb{L}_i . One candidate query is the *real query*, denoted by $\mathbb{C}_* = \{l_{1,*}, \dots, l_{n,*}\}$.

Naive Solution. With $\delta \geq d$, one straightforward method to satisfy both **Privacy I** and **Privacy II** is that every user u_i generates a length δ , instead of length d , location set \mathbb{L}_i , and all users arrange their real locations on the same position in \mathbb{L}_i , $1 \leq i \leq n$. Then LSP can extract one candidate query from the same position in the n location sets, resulting in δ candidate queries. One of these candidate queries is the real query. However, this solution incurs the additional computational cost to generate $\delta - d$ extra dummy locations (e.g., using the dummy generation algorithm [20, 22]) for every user, and the additional communication cost to send the extra dummy locations to LSP. With users' computational power being limited (e.g., mobile devices) and the communication bandwidth being precious, this approach is not practical. To address this special requirement in the mobile user scenario, we propose a solution that aims to reduce the user computational cost and the communication cost at some overhead of the LSP computational cost.

4.1 Candidate Query Generation

Our solution keeps the location set \mathbb{L}_i at the size d but defines a novel protocol for LSP to generate at least δ candidate queries

from the location sets \mathbb{L}_i , $1 \leq i \leq n$. With each \mathbb{L}_i having d elements, d^n candidate queries can be generated by the cartesian product $\times_{i=1}^n \mathbb{L}_i$. We assume $\delta \leq d^n$, otherwise, a larger d should be specified by the users.

Clearly, generating the maximum number of candidate queries, d^n , will satisfy **Privacy II**, but if $\delta \ll d^n$, this means that LSP will compute many unnecessary queries. Our method will generate a minimum number δ' of candidate queries such that $\delta' \geq \delta$, thus, satisfying **Privacy II**. To this end, we partition the user group into α subgroups of the size $\bar{n} = (\bar{n}_1, \dots, \bar{n}_\alpha)$, and partition every location set \mathbb{L}_i into β segments of the size $\bar{d} = (\bar{d}_1, \dots, \bar{d}_\beta)$. $\{\bar{n}, \bar{d}\}$ is called *partition parameters* and is known to both users and LSP. We will determine these parameters shortly. To ensure that the real query will be generated as one of the candidate queries, the following constraint must be satisfied by subgroups and segments: all users arrange their real locations in the *same segment*, and all users from the same subgroup arrange their real locations on the *same position* of that segment. Our query generation in Section 4.2 will enforce this constraint.

Example 4.1. In Figure 4a, the user group is partitioned into 2 subgroups by $\bar{n} = (2, 2)$, and the location sets are partitioned into 2 segments by $\bar{d} = (2, 2)$. All users arrange their real locations in *segment₂*, highlight in red. Also, the users in *subgroup₁* arrange the real locations on the 2-nd position of *segment₂*, and the users in *subgroup₂* arrange the real locations on the 1-st position of *segment₂*. \square

Given the location sets and the partition parameters, LSP generates the candidate queries as follows. Let $G_{i,j,t}$ be the subset of locations from the t -th position of the i -th segment and the j -th subgroup, and let $G_{i,j,:}$ be the subset of locations from the i -th segment and the j -th subgroup. Note that $G_{i,j,:}$ contains \bar{d}_i locations. See Figure 4b for some examples. For $1 \leq i \leq \beta$, LSP computes the candidate queries for the i -th segment by the cartesian product

$$\times_{j=1}^{\alpha} G_{i,j,:} \quad (6)$$

This gives a total number of $\sum_{i=1}^{\beta} (\bar{d}_i)^\alpha$ candidate queries since there are $(\bar{d}_i)^\alpha$ combinations for the i -th segment. Each candidate query is uniquely identified by a sequence of the indexes (i, j, t) for $G_{i,j,t}$, and all candidate queries are listed in the lexicographic order of such indexes. We call this list the *candidate query list*.

Figure 3c illustrates the cartesian product for each segment, generating a total of 8 candidate queries. Figure 3d shows the candidate query list, in which the real query \mathbb{C}_* is at the position 7. This position of the real query can be calculated by the users based on the segment and the positions where the real locations are placed in all location sets. However, LSP does not know this position of the real query because the segment and positions for the real locations are confidentially chosen by the users.

Determining the partition parameters $\{\bar{n}, \bar{d}\}$. The partition parameters are determined by solving the problem

$$\text{minimize}_{\alpha, \beta, \bar{d}} \quad \delta' = \sum_{i=1}^{\beta} (\bar{d}_i)^\alpha \quad (7)$$

$$\text{subject to} \quad \delta' \geq \delta \quad (8)$$

$$\sum_{i=1}^{\beta} \bar{d}_i = d \quad (9)$$

$$\alpha \in \mathbb{N}_{\leq n}, \beta \in \mathbb{N}_{\leq d}, \{\bar{d}_i\}_{i=1}^{\beta} \in \mathbb{N}_{\leq d} \quad (10)$$

Figure 3: Candidate query generation, where $n = 4$, $d = 4$, and $\delta = 8$: (a) the partition parameters are $\bar{n} = (2, 2)$ and $\bar{d} = (2, 2)$; (b) $G_{2,1,1}$ represents the set $\{l_{1,3}, l_{2,3}\}$ for $segment_2$, $subgroup_1$, and the first position in $segment_2$, while $G_{2,1,*} = \{G_{2,1,1}, G_{2,1,2}\}$; (c) candidate queries $C_1 - C_4$ are generated for $segment_1$, and candidate queries $C_5 - C_8$ are generated for $segment_2$; (d) the candidate query list contains the real query (in red).

δ' in Eqn (7) is the total number of candidate queries generated above. Eqn (9) requires that the sum of all segment sizes should be d , and Eqn (10) requires that the parameters should be integers. The sizes of subgroups are not included in Eqn (7) because they are irrelevant. d, δ, n are constants and the rest are unknown variables. For the single user query, $n = 1$ and $\delta = d$, we can choose $\beta = d$ with each segment size equal to 1. The above is a nonlinear integer programming problem, which is NP-hard [4]. However, the results for frequently used (n, d, δ) can be pre-computed off line (e.g., using open-source solvers [6], Bonmin²). This only needs to be done once.

4.2 PPGNN Solution

The PPGNN solution has three stages: query generation, query processing, and answer decryption. Following [14], we assume that a coordinator user u_c is selected randomly from the query group to assist query generation and answer decryption. Like any other user, no additional trust is assumed of u_c .

Query Generation. Algorithm 1 presents the query generation stage. u_c first determines the partition parameters $\{\bar{n}, \bar{d}\}$ based on $\{n, d, \delta\}$ and calculates the number of candidate queries δ' . As discussed above, the partition parameters could be pre-computed for frequently used $\{n, d, \delta\}$. u_c randomly selects a segment seg from $[1, \beta]$ according to the probability distribution based on the segment sizes, i.e.,

$$\mathcal{P} = \left(\frac{\bar{d}_1}{\bar{d}}, \dots, \frac{\bar{d}_\beta}{\bar{d}} \right) \quad (11)$$

and u_c randomly and uniformly selects a relative position x_j of that segment for the j -th subgroup, and broadcasts pos_j to all users in the j -th subgroup, $1 \leq j \leq \alpha$, where pos_j is the absolute position (over all segments) corresponding to x_j . Then u_c computes the position of the real query C_* in the candidate query list, called *query index*, denoted by QI_{C_*} as follows. Note that the candidate query list is arranged by the lexicographic order of the triples (segment index, subgroup index, position in the segment).

$$QI_{C_*} = \sum_{i=1}^{seg-1} (\bar{d}_i)^\alpha + \sum_{j=1}^\alpha (x_j - 1)(\bar{d}_{seg})^{\alpha-j} + 1 \quad (12)$$

where the first term is the number of candidate queries before reaching the seg -th segment, and the second term is the number of candidate queries before reaching C_* in the seg -th segment.

Example 4.2. In Figure 4a, with $seg = 2$, $\alpha = 2$, and $\bar{d}_1 = 2$, the first term in Eqn (12) is 4, and with $x_1 = 2$ and $x_2 = 1$, the second term is $(2 - 1) * 2^1 + (1 - 1) * 2^0 = 2$, thus $QI_{C_*} = 7$. \square

²<https://neos-server.org/neos/solvers/>

Algorithm 1: Query Generation

Input: $n, d, \delta, k, \text{keysize}, \{l_{i,*}\}_{i=1}^n, \theta_0$;
Output: Query $\{k, pk, \bar{n}, \bar{d}, [\mathbf{v}], \theta_0, \{(i, \mathbb{L}_i)\}_{i=1}^n\}$;

- 1 **Coordinator u_c :**
- 2 $\{\bar{n}, \bar{d}\} \leftarrow$ find the partition parameters; // Eqn (7)-(10);
- 3 $seg \leftarrow$ randomly select a segment by Eqn (11);
- 4 **for** $j \in [1, |\bar{n}|]$ **do**
- 5 $x_j \leftarrow$ randomly and uniformly select from $[1, \bar{d}_{seg}]$;
- 6 $pos_j \leftarrow \sum_{i=1}^{seg-1} \bar{d}_i + x_j$;
- 7 **Send** pos_j to all users in $subgroup_j$;
- 8 $\{sk, pk\} \leftarrow \text{Gen}(\text{keysize})$; // key generation
- 9 $\mathbf{v} \leftarrow$ construct indicator vector by the query index; // Eqn (12)
- 10 $[\mathbf{v}] \leftarrow$ element-wise encryption $\text{Enc}(\mathbf{v}, pk)$;
- 11 **Send** $\{k, pk, \bar{n}, \bar{d}, [\mathbf{v}], \theta_0\}$ to LSP;
- 12 **Every user u_i in $subgroup_j$:**
- 13 receive pos_j from u_c ;
- 14 $\mathbb{L}_i \leftarrow$ generate location set, arranging $l_{i,*}$ on the pos_j -th position;
- 15 **Send** (i, \mathbb{L}_i) to LSP;

Algorithm 2: Query Processing

Input: Query $\{k, pk, \bar{n}, \bar{d}, [\mathbf{v}], \theta_0, \{(i, \mathbb{L}_i)\}_{i=1}^n, \mathbb{D}\}$;
Output: $[a_*]$;

- 1 $\{C_t\}_{t=1}^{\delta'} \leftarrow$ generate the candidate query list by $\{\bar{n}, \bar{d}, \{(i, \mathbb{L}_i)\}_{i=1}^n\}$; // Section 4.1
- 2 **for** $t \in [1, \delta']$ **do**
- 3 $\mathbb{P}_t \leftarrow$ compute k GNN query by (k, C_t, \mathbb{D}) ;
- 4 $\mathbb{P}'_t \leftarrow \text{answerSanitation}(\theta_0, \mathbb{P}_t, C_t)$; // Section 5.2
- 5 $\mathbf{a}_t \leftarrow$ encode \mathbb{P}'_t into integer vector by N stated in pk ;
- 6 $\mathbf{A} = (\mathbf{a}_1, \dots, \mathbf{a}_{\delta'})$;
- 7 $[a_*] = \mathbf{A} \otimes [\mathbf{v}]$; // Theorem 3.1
- 8 **Send** $[a_*]$ to u_c

Then, u_c constructs the encrypted indicator vector $[\mathbf{v}]$ of length δ' , where \mathbf{v} has 1 at the position QI_{C_*} and 0 everywhere else. Finally, u_c sends the query $\{k, pk, \bar{n}, \bar{d}, [\mathbf{v}], \theta_0\}$ to LSP.

Meanwhile, every user $u_i (i \in [1, n])$ in the j -th subgroup arranges its real location $l_{i,*}$ at the received position pos_j in \mathbb{L}_i and dummy locations at the remaining positions, and sends (i, \mathbb{L}_i) to LSP independently. With the user ID i , LSP can reconstruct $subgroup_1$ as the first \bar{n}_1 users, $subgroup_2$ as the next \bar{n}_2 users, and so on. Note that no user, including u_c , knows other users' real locations, because each user sends the location set to LSP directly.

Query Processing. Algorithm 2 presents the query processing stage. After receiving the query from users, LSP generates the candidate query list containing δ' candidate queries as described in Section 4.1, and executes the k GNN query for each candidate query. Line 4 calls the answerSanitation method to ensure that the query answer satisfies **Privacy IV**, which will be presented in Section 5.2. Let $A^{m \times \delta'}$ be the answer matrix for the query answers $(a_1, \dots, a_{\delta'})$. LSP privately selects the query answer $[a_*]$ for \mathbb{C}_* following Theorem 3.1, and sends $[a_*]$ to u_c .

The answer decryption stage is the same as that in Section 3, except that u_c will broadcast the answer a_* to all other users.

4.3 Privacy Guarantees

THEOREM 4.3. *The PPGNN solution satisfies **Privacy I-III**.*

PROOF. Privacy I: The segment seg containing the real locations is selected following the probability distribution corresponding to the segment sizes, Eqn (11), thus, the probability that LSP infers this segment is \bar{d}_{seg}/d . The position for the real locations in the seg -th segment for each subgroup is selected randomly and uniformly, so given the segment seg , the probability that LSP can infer this position is $1/\bar{d}_{seg}$. Overall, the probability for LSP to identify each user's real location is $(\bar{d}_i/d) \cdot (1/\bar{d}_i) = 1/d$.

Privacy II: LSP generates $\delta' (\geq \delta)$ candidate queries and obtain δ' query answers before the private selection. So the probability for LSP to identify group's query \mathbb{C}_* and the query answer is $1/\delta'$, which is no larger than $1/\delta$.

Privacy III: The private selection ensures that only the answer for \mathbb{C}_* is returned, so the users learn no extra POI information beyond the query answer requested. \square

5 FULL USER COLLUSION

So far, the PPGNN solution satisfies only **Privacy I-III**. We now consider answerSanitation on line 4 in Algorithm 2 to enforce **Privacy IV** under the full user collusion assumption. Our first observation is that the only communication within the user group is $\{pos_j\}_{j=1}^n$ that are broadcast from u_c to let all users arrange their real locations in their location sets. This information alone does not allow any $n-1$ colluding users to learn the real location of the remaining user. However, after receiving the query answer, $n-1$ colluding users can infer some possible region that contains the remaining user's real location, with the help of the ranking and location information of the POIs in the query answer. We first present this attack in Section 5.1, and devise a method to prevent this attack and satisfy **Privacy IV** in the rest of the section.

5.1 Inequality Attack

Suppose the users $\{u_1, \dots, u_n\}$ located at the locations $\mathbb{C}_* = \{l_{1,*}, \dots, l_{n,*}\}$ respectively obtain the query answer in the form of k ranked POIs $\mathbb{P} = \{p_1, \dots, p_k\}$ such that

$$F(p_i, \mathbb{C}_*) \leq F(p_j, \mathbb{C}_*), \forall 1 \leq i < j \leq k \quad (13)$$

Without loss of generality, let us assume that u_1 is the attack target and $\{u_i\}_{i=2}^n$ collude together to infer u_1 's location. Therefore, there is only one unknown variable $l_{1,*}$ in Eqn (13) because $l_{2,*}, \dots, l_{n,*}$ as well as the query answer \mathbb{P} are known to the colluding users. Consequently, the colluding users can construct $k-1$ independent inequalities to infer the possible region of $l_{1,*}$:

$$F(p_i, \mathbb{C}_*) \leq F(p_{i+1}, \mathbb{C}_*), \forall 1 \leq i \leq k-1 \quad (14)$$

We refer this inference as the *inequality attack*. Suppose that the area of the solution region for Eqn (14) is θ (in percentage) of

the area of the whole data space, **Privacy IV** is satisfied if and only if $\theta > \theta_0$ for every target user u_1 ; otherwise, i.e., $\theta \leq \theta_0$ for some target user u_1 , **Privacy IV** is not satisfied, and we say the inequality attack succeeds. For instance, **Privacy IV** is not satisfied in Figure 1 if $\theta_0 = 0.5$, because the possible region for u_1 's location (in shaded) is less than half of the whole location space.

5.2 Answer Sanitation

One solution to prevent the inequality attack is that LSP randomly perturbs the order of POIs in \mathbb{P} such that the inequalities in Eqn (14) cannot be correctly constructed. This solution will degrade the utility of the query answer because the users need to know the rank of returned locations. In addition, it is unclear how to ensure that the colluding users cannot reconstruct the original order or a partial order.

Instead, we design a sanitation method for LSP to return the longest prefix $\mathbb{P}' = \{p_1, \dots, p_t\}$ of \mathbb{P} while satisfying **Privacy IV**. In fact, LSP can simulate the inequality attack for every user using a prefix \mathbb{P}' of \mathbb{P} in Eqn (14). If $\theta > \theta_0$ holds on \mathbb{P}' for every target user, where θ is the relative size of the solution region of Eqn (14), \mathbb{P}' is safe of satisfying **Privacy IV**. We will consider how to test $\theta > \theta_0$ shortly. LSP can start with the shortest prefix $\mathbb{P}' = \{p_1\}$, which is always safe, and examine the length t prefix only if the length $t-1$ prefix is safe. The query answer for a candidate query then is the prefix $\mathbb{P}' = \{p_1, \dots, p_t\}$ that is safe, and if $t < k$, the next prefix $\{p_1, \dots, p_{t+1}\}$ is not safe. Note that if the query answer for every candidate query is safe of satisfying **Privacy IV**, the returned answer for \mathbb{C}_* after private selection satisfies **Privacy IV**.

5.3 Testing $\theta > \theta_0$

We now present how to test whether $\theta > \theta_0$ for a target user, where θ is the relative size of the solution region of Eqn (14). One approach is finding the exact solution region of Eqn (14). Unfortunately, finding this solution region is not straightforward, especially for any choice of the aggregation function F and an arbitrary shape of the data space. On the other hand, it is easy to test whether a point $l_{1,*}$ satisfies all inequalities in Eqn (14), that is, falls into the solution region, without explicitly finding the solution region. This observation motivates the following statistic test.

Consider two hypothesis H_0 and H_1 :

$$H_0 : \theta \leq \theta_0, \quad H_1 : \theta > \theta_0 \quad (15)$$

There are two types of errors:

- **Type I Error:** $\Pr(\text{reject } H_0 | H_0 \text{ is true})$ is the probability that a successful attack is not identified for a target user.
- **Type II Error:** $\Pr(\text{not reject } H_0 | H_1 \text{ is true})$ is the probability that a non-attack is identified as a successful attack for a target user.

A small probability for Type I Error provides more confidence on privacy protection and a small probability for Type II Error provides more confidence on better utility of the returned answer. We want to bound these probabilities.

To test whether H_0 should be rejected, LSP can uniformly and independently sample N_H points X_1, \dots, X_{N_H} from the data space. The outcome of each sample is a Bernoulli random variable

$$B = \begin{cases} 1, & \text{if } X_i \text{ satisfies the inequalities in Eqn (14)} \\ 0, & \text{otherwise} \end{cases}$$

The probability of $B = 1$ is equal to the relative size θ of the solution region of Eqn (14). $X = X_1 + \dots + X_{N_H}$ follows a Binomial distribution. For a large N_H , this Binomial distribution can be approximated by the normal distribution. In this case, LSP can reject H_0 through the Z -test statistic [7]: reject H_0 if

$$X > N_H \theta_0 + z_\gamma \sqrt{N_H \theta_0 (1 - \theta_0)} \quad (16)$$

where z_γ is the critical value of the normal distribution and γ is a desired upper bound for the Type I Error probability, i.e., $\Pr(\text{reject } H_0 | H_0 \text{ is true}) \leq \gamma$.

To test if $\theta > \theta_0$ in the answer sanitation, LSP tests the inequality in Eqn (16) instead. From the above discussion, the probability of capturing a successful attack, i.e., $\Pr(\text{not reject } H_0 | H_0 \text{ is true})$, is at least $1 - \gamma$. Since this approach only requires testing if a point satisfies the inequalities in Eqn (14) (for computing X), it is applicable to any choice of the aggregation function F and any shape of the data space.

To determine the sample size N_H , we need to take the probability of Type II Error, i.e., $\Pr(\text{not reject } H_0 | H_1 \text{ is true})$, into consideration. Let θ_1 denote the minimum θ value in H_1 that we want to significantly differentiate from θ_0 . [15] suggests $\frac{\theta_1}{\theta_0} = (1 + \phi)$, where ϕ is the ratio difference between θ_1 and θ_0 . The two types of errors can be bounded given enough samples, as stated below.

THEOREM 5.1 (SAMPLE SIZE [11]). *In the one-tailed hypothesis testing, the sample size N_H required for $\Pr(\text{Type I Error}) \leq \gamma$ and $\Pr(\text{Type II Error}) \leq \eta$ is given by*

$$N_H \geq \left[\frac{z_\gamma \sqrt{\theta_0(1 - \theta_0)} + z_\eta \sqrt{\theta_1(1 - \theta_1)}}{\theta_1 - \theta_0} \right]^2. \quad \square \quad (17)$$

The commonly used γ, η, ϕ are $\gamma = 0.05, \eta = 0.2$, and $\phi = 0.1$. Once the users specify θ_0 , LSP can determine the sample size N_H using Eqn (17).

5.4 Privacy Guarantees

THEOREM 5.2. *The PPGNN solution with the answer sanitation satisfies **Privacy I-IV** under the full user collusion assumption.*

PROOF. Privacy I-III follows from Theorem 4.3. Suppose the returned query answer for \mathbb{C}_* is \mathbb{P}_* , which passes the answer sanitation. Therefore, for every target user u_i in the group query, the Type I Error probability, $\Pr(\text{reject } H_0 | H_0 \text{ is true})$, is bounded by γ . In other words, u_i 's real location is guaranteed to hide in a region that is at least θ_0 (in percentage) of the whole space with the confidence $1 - \gamma$, i.e., **Privacy IV** is satisfied.

A noteworthy point is that the answer sanitation does not affect the protection for **Privacy I-III** because it only reduces the number of POIs in the query answer returned to the users (by returning a prefix of the original top- k answer). The users learn from the reduced list of POIs that the remaining POIs in the answer are not returned because there is an inequality attack. However, without these remaining POIs, the users cannot perform such attacks. \square

6 OPTIMIZED PPGNN

The indicator vector \mathbf{v} with length δ' has only a single 1 (specifying \mathbb{C}_*) and $(\delta' - 1)$ 0's. If δ' is large, additional user computational cost and communication cost are spent on encrypting and transmitting many 0's. In this section, we present an optimization of PPGNN solution, called PPGNN-OPT, to reduce these costs. Let $\llbracket \cdot \rrbracket$ denote the ciphertext generated by the generalized Paillier cryptosystem ε_s with $s = 2$ (see Section 3.1), and as before, let $[\cdot]$

Figure 4: Optimization example: (a) changes on the user side; (b) two phases private selection on the LSP side

denote the ciphertext generated by ε_s with $s = 1$. The encryption and decryption with ε_2 can use the same public key and secret key as those with ε_1 [10].

To explain our optimization, Figure 4 illustrates the changes made on the user side and the LSP side for the example in Figure 3 where $\delta' = \delta = 8$. Instead of using the original indicator vector $\mathbf{v} = (0, 0, 0, 0, 0, 0, 1, 0)^T$ to indicate the position of the real query, u_c uses two small vectors $\mathbf{v}_1 = (0, 0, 1, 0)^T$ and $\mathbf{v}_2 = (0, 1)^T$. On the user side, u_c executes element-wise encryption on \mathbf{v}_1 with ε_1 and executes element-wise encryption on \mathbf{v}_2 with ε_2 , obtaining $\llbracket \mathbf{v}_1 \rrbracket = ([0], [0], [1], [0])^T$, $\llbracket \mathbf{v}_2 \rrbracket = (\llbracket 0 \rrbracket, \llbracket 1 \rrbracket)^T$. These vectors are sent to LSP. In this case, the user computational cost and the communication cost are that for computing and transmitting $\llbracket \mathbf{v}_1 \rrbracket$ and $\llbracket \mathbf{v}_2 \rrbracket$, instead of that for $\llbracket \mathbf{v} \rrbracket$.

On the LSP side, after obtaining the answer matrix A , LSP privately selects the desired answer in two phases. Firstly, LSP partitions A into two sub-matrices (A_1, A_2). For each sub-matrix, LSP executes a private selection using $\llbracket \mathbf{v}_1 \rrbracket$ (Theorem 3.1), resulting in the vector $([a_3], [a_7])$. Secondly, LSP selects the final answer $\llbracket [a_7] \rrbracket$ from $([a_3], [a_7])$ using $\llbracket \mathbf{v}_2 \rrbracket$, by treating the ciphertext of ε_1 as a plaintext of ε_2 in Theorem 3.1. u_c can decrypt $\llbracket [a_7] \rrbracket$ two times to obtain the plaintext query answer a_7 .

In general, if the length of \mathbf{v}_2 is ω , the length of \mathbf{v}_1 is δ'/ω . We assume that δ'/ω is an integer by padding 0's at the end of \mathbf{v} if necessary. We want to choose ω that minimizes the total communication cost between users and LSP. We focus on the ciphertexts transmitted between u_c and LSP because the plaintext location sets transmitted between users and LSP remain unchanged. The length of a ciphertext of ε_2 , which is in \mathbb{Z}_{N^3} , is about twice the length of a ciphertext of ε_1 , which is in \mathbb{Z}_{N^2} . Let L_e denote the length of a ciphertext with ε_1 . We want the integer ω such that

$$\underset{\omega \in \mathbb{N}_{\leq \delta'}}{\text{minimize}} \quad \text{cost}(\omega) = (2\omega + \delta'/\omega + 2m) \cdot L_e \quad (18)$$

where the first term accounts for the length of $\llbracket \mathbf{v}_2 \rrbracket$, the second term accounts for the length of $\llbracket \mathbf{v}_1 \rrbracket$, and the third term accounts for the length of the returned answer (m is the number of ciphertexts required for storing an answer). The optimal ω for Eqn (18) is the nearest integer to $\sqrt{\delta'/2}$, with the minimum communication cost $\text{cost} \approx 2(\sqrt{2\delta'} + m) \cdot L_e$.

In comparison, the communication cost of using the original encrypted indicator vector $\llbracket \mathbf{v} \rrbracket$ is $\text{cost}' = (\delta' + m) \cdot L_e$, where δ' accounts for the length of $\llbracket \mathbf{v} \rrbracket$ and m accounts for the length of the returned answer. The above optimization reduces the cost when $\text{cost} < \text{cost}'$, or $2\sqrt{2\delta'} < \delta' - m$. Since $2\sqrt{2\delta'}$ is positive, $2\sqrt{2\delta'} < \delta' - m$ holds only if $\delta' > m$, and in this case, we have $\delta'^2 + b\delta' + c > 0$, where $b = -(2m + 8)$ and $c = m^2$. The solutions for $\delta'^2 + b\delta' + c > 0$ are $\delta' > r_1$ or $\delta' < r_2$, where

Table 2: Performance analysis

	PPGNN	PPGNN-OPT
Total Communication Cost	$O(nd)L_l + O(\delta')L_e + O(k)L_e$	$O(nd)L_l + O(\sqrt{\delta'})L_e + O(k)L_e$
User Computational Cost	$O(nd)C_l + O(\delta')C_e + O(k)C_e$	$O(nd)C_l + O(\sqrt{\delta'})C_e + O(k)C_e$
LSP Computational Cost	$O(\delta')(C_q + C_s) + O(\delta'k)C_e$	$O(\delta')(C_q + C_s) + O(\delta'k)C_e + O(\sqrt{\delta'k})C_e$

$r_1 = m + 4 + 2\sqrt{2m + 4}$ and $r_2 = m + 4 - 2\sqrt{2m + 4}$. However, since $\delta' > m$ and $r_2 < m$, only $\delta' > r_1$ can be the solution.

In conclusion, on the communication cost, PPGNN-OPT outperforms PPGNN if and only if $\delta' > r_1$ holds. Usually k is not very large and several POIs' information can be encoded into one big integer, therefore m is small and PPGNN-OPT can reduce the cost.

7 PERFORMANCE ANALYSIS

Table 2 summarizes the performance analysis of the PPGNN and PPGNN-OPT solutions in terms of communication cost, user computational cost, and LSP computational cost.

Communication cost. Let L_l and L_e denote the length of a location and the length of a ciphertext of ϵ_1 , respectively. The communication cost of PPGNN includes: n location sets with size d each, i.e., $O(nd)L_l$, $[\mathbf{v}]$ with size δ' , i.e., $O(\delta')L_e$, the returned answer with m encrypted integers that is proportional to the number of POI to be retrieved k , i.e., $O(k)L_e$. The total cost is $O(nd)L_l + O(\delta')L_e + O(k)L_e$. With PPGNN-OPT, the cost for location sets does not change, but the cost for ciphertexts is $O(\sqrt{\delta'})L_e + O(k)L_e$ (see Section 6). Therefore, the total cost is $O(nd)L_l + O(\sqrt{\delta'})L_e + O(k)L_e$.

User computational cost. Let C_l denote the cost for generating a dummy location, and C_e denote the cost for execution on a ciphertext of ϵ_1 (e.g., encryption, decryption). The user computational cost of PPGNN includes: location sets with size d generated by all the users, i.e., $O(nd)C_l$, encryption of $[\mathbf{v}]$ with size δ' computed by u_c , i.e., $O(\delta')C_e$, and decryption of the returned answer, i.e., $O(k)C_e$. The total cost is $O(nd)C_l + O(\delta')C_e + O(k)C_e$. Similar to the analysis of communication cost, for PPGNN-OPT, the total cost is $O(nd)C_l + O(\sqrt{\delta'})C_e + O(k)C_e$.

LSP computational cost. Let C_q denote the cost for executing a k GNN query (e.g., MBM algorithm [24]), and C_s denote the cost for answer sanitation for one candidate query. The LSP computational cost of PPGNN includes: k GNN queries and answer sanitation for $O(\delta')$ candidate queries, i.e., $O(\delta')(C_q + C_s)$, and the private selection on δ' answers with size m , i.e., $O(\delta'k)C_e$. Hence, the total cost is $O(\delta')(C_q + C_s) + O(\delta'k)C_e$. For PPGNN-OPT, the costs for k GNN query and answer sanitation remain unchanged, but the cost for private selection is $O(\delta'k)C_e + O(\sqrt{\delta'k})C_e$ because of the two phases private selection, where the first phase operates on $O(\delta')$ answers and the second phase on $O(\sqrt{\delta'})$ answers. The total cost is $O(\delta')(C_q + C_s) + O(\delta'k)C_e + O(\sqrt{\delta'k})C_e$.

In summary, the communication cost of PPGNN-OPT is asymptotically better than that of PPGNN. However, since the above analysis ignores constant coefficients, in practice, whether PPGNN-OPT is better depends on δ' and m , as discussed at the end of Section 6 (note that $m = xk$, where x is the number of big integers needed to encode one POI). The comparison on user computational cost is similar. The LSP computational cost of PPGNN-OPT is always larger than PPGNN because the second private selection is an extra cost comparing to PPGNN. We will experimentally compare the two solutions in Section 8.

8 EXPERIMENTS

We evaluated the performance of PPGNN (Section 4.2), PPGNN-OPT (Section 6), and the Naive solution (the beginning of Section 4). Since the baseline methods for $n = 1$ and $n > 1$ are different, we consider the single user query scenario ($n = 1$) in Section 8.2, and the group query scenario ($n > 1$) in Section 8.3.

8.1 Experimental Setup

We conducted experiments on a machine with Intel (R) Core (TM) i7-3770 CPU @ 3.40 GHz×8 machine with 15.6G of RAM, running Ubuntu 16.04.1 LTS. All algorithms were implemented in C++. The classic Minimum Bounding Method (MBM) [24] is applied as our plaintext k GNN algorithm in PPGNN, PPGNN-OPT, and the Naive solution, and the aggregation function F is *sum*. We employed the *GMP*³ library for big integer computation and *libhcs*⁴ library for operations of the generalized Paillier scheme. The *keysize* for ϵ_1 is 1024 bits and the *keysize* for ϵ_2 is 2048. Table 3 summarizes all parameters and their ranges.

Dataset. We used a real-world dataset Sequoia⁵, which is widely used in previous studies [12–14, 27, 36]. The dataset contains 62556 POIs from California, including the coordinate and name. As in these previous works, the location space is normalized into a square space, and the real location for every user in a group query was randomly generated as a point in this space. The coordinates of POIs (8 bytes per POI) are returned as the query answer.

Baselines. For $n = 1$, we choose the approximate private k NN query approach, APNN, in [36] as the baseline. In APNN, LSP partitions the data space into grid cells and pre-computes k NN results with respect to the center of each cell and encrypts them. At the query time, the user chooses a square cloak-region containing her location which consists of b^2 cells, and initiates a two-stages cryptographic protocol to retrieve the desired answer. The protocol ensures that LSP does not know which cell the user is located in, nor which answer is retrieved, which ensures **Privacy I-II** with the privacy level b^2 , and the user can only decrypt the requested answer, which ensures **Privacy III**. In our experiments, APNN has a query cloak-region consisting of 5^2 grid cells, which is equivalent to our default setting $d = 25$ for **Privacy I**. Note that APNN produces only approximate answers and relies on pre-computation of k NN results with respect to the center of every cell. This method is not suitable if the exact answer is required or if the database is dynamic. Also, it cannot be extended to the group query scenario because the number of possible queries is significantly large. We did not consider other approaches such as [12, 27] because they are less efficient than APNN according to [36].

For $n > 1$, the first baseline is the incremental pruning private filter (IPPF) algorithm in [14], which is the first work considering users' location privacy in the k GNN query. With the cloak-region technique, IPPF ensures **Privacy I-II** but not **Privacy III-IV**. The

³<http://gmplib.org>

⁴<https://github.com/tiehuis/libhcs>

⁵<http://chorochronos.datastories.org/?q=node/58>

second baseline is the group location privacy (GLP) algorithm in [2], which applies a secure multiparty computation technique for the users to compute their centroid, and LSP returns the k NN query answer with respect to the centroid. GLP ensures **Privacy I** and **III**, but not **Privacy II** and **IV**. A more detailed discussion for IPPF and GLP solutions can be found in Section 9.

Metrics. We measured three dominating costs for the queries: the total *communication cost* (including communications between the user group and LSP, as well as the communications within the user group), the total *user cost* (the sum of all users' computational cost), and the *LSP cost* (all the computations execute on LSP during the query process). In the group query scenario, we also evaluated the number of POIs returned to the users, an indicator of the quality of the answer while resisting the full user collusion inequality attack. We executed 500 queries and reported the average cost.

For the discussion below, the reader is referred to Table 3 for the ranges and default settings of all parameters.

Table 3: Parameters evaluated

	Parameter	Range	Default
$n = 1$	Privacy I parameter (d)	[5, 50]	25
	POI to be retrieved (k)	[2, 32]	8
$n > 1$	Privacy II parameter (δ)	[25, 200]	100
	POI to be retrieved (k)	[2, 32]	8
	user number (n)	[2, 32]	8
	Privacy IV parameter (θ_0)	[0.01, 0.1]	0.05

8.2 Evaluation for Single User Query ($n = 1$)

For $n = 1$, we evaluated PPGNN and PPGNN-OPT by varying d and k . We did not evaluate Naive that is designed for $n > 1$.

Varying d : Figure 5a-5c compares the three costs of PPGNN and PPGNN-OPT for varying d . Note that APNN does not depend on d and is not included. All three costs increase as d increases because each user needs to generate more dummy locations and executes more encryption on the indicator vector, and LSP needs to compute more candidate queries and select the final answer from more query answers. Figure 5a shows that $d = 15$ is the threshold for PPGNN-OPT to outperform PPGNN regarding the communication cost. When $d \geq 15$ (note that $\delta' = d$ when $n = 1$), the communication cost reduction of PPGNN-OPT starts to take effect, which is consistent with the analysis in Section 7. Figure 5b shows a similar trend for the user cost, but with a different threshold $d = 25$ for PPGNN-OPT to beat PPGNN, since the coefficients in Eqn (18) are different with respect to user cost. Usually the cost of operation using ϵ_2 consumes more than 2 times (≈ 3 times in our experiments) than that using ϵ_1 , leading to a larger threshold required. For the LSP cost (Figure 5c), PPGNN always performs better because LSP needs to execute two-phases private selection in PPGNN-OPT. In the mobile user scenario, reducing the communication cost and the user cost has a priority over reducing the LSP cost.

Varying k : Figure 5d-5f reports the performance of PPGNN, PPGNN-OPT, and APNN for varying k . The communication costs (Figure 5d) of the three solutions have a staged growth when k goes up because 15 POIs information can be encoded by a big integer in our settings. Figure 5e shows a similar trend on the user cost for the three solutions. For PPGNN and PPGNN-OPT, the LSP cost (Figure 5f) increases when k becomes larger because the k NN query time and private selection time increase. APNN has

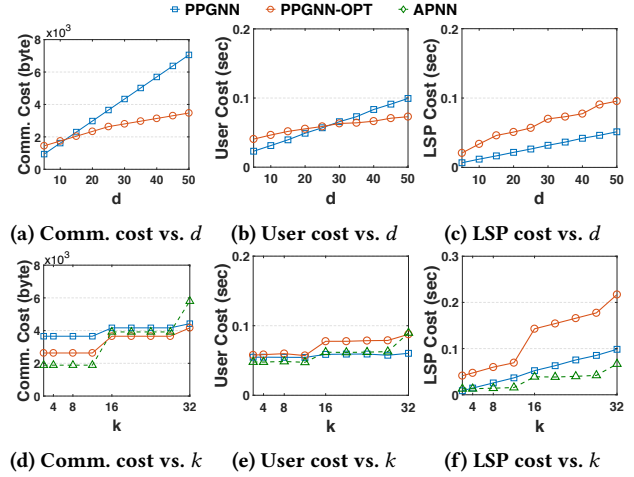

Figure 5: Effect of parameters when $n = 1$

the lowest LSP computational cost because of pre-computed k NN query answers for all grid cells. This computational gain is paid by returning only approximate k NN answers and the potentially expensive update cost for recomputing all k NN answers for a dynamic database.

8.3 Evaluation for Group Query ($n > 1$)

When $n > 1$, we evaluated PPGNN, PPGNN-OPT and Naive in Section 8.3.1 by varying δ , k , n , and θ_0 . We set $d = 25$ by default and did not show its effect because of the relatively stable performance. We experimentally tested for every (n, d, δ) where $n \in [2, 32]$, $d \in [5, 50]$, $\delta \in [50, 200]$ and the average difference between δ' and δ is approximately 1, i.e., $\delta' \approx \delta$. We used the commonly used confidence levels $\gamma = 0.05$, $\eta = 0.2$ and $\phi = 0.1$ in all experiments in the hypothesis testing. The comparison with the baselines IPPF and GLP, which have only two parameters same as ours, k and n , is reported in Section 8.3.2.

8.3.1 Evaluation of Our Approaches. Varying δ : Figure 6a-6c shows the comparison for varying δ . Unlike the comparison for $n = 1$ in Section 8.2, the communication cost and user cost of PPGNN-OPT are much smaller than those of PPGNN and this advantage increases as δ increases. In fact, the size of the encrypted indicator vectors ($[\mathbf{v}_1]$, $[\mathbf{v}_2]$) in PPGNN-OPT is proportional to $O(\sqrt{\delta'})$, whereas the size of the encrypted indicator vector ($[\mathbf{v}]$) in PPGNN is proportional to $O(\delta')$. Therefore, for a large enough δ , although the encryption using ϵ_2 in PPGNN-OPT consumes about three times the cost of the encryption using ϵ_1 , the user cost is still much lower.

The Naive solution incurs the most communication cost because every user in the group needs to send extra $\delta - d$ dummy locations. The LSP costs are almost the same for the three solutions, and are much larger than that for the single user query. Because when $n > 1$, the answer sanitation in Section 5.1 is activated to ensure **Privacy IV**, and this operation dominates the LSP cost. We will discuss more about the LSP cost for answer sanitation in Section 8.3.2.

Varying k : 6d-6f shows the comparison for varying k . The relative comparison of the three solutions is similar to Figure 6a-6c, except that the communication cost and user cost are relatively stable as k increases, with PPGNN-OPT being the best performer. Figure 6f shows that, when k increases, the LSP costs for the

Figure 6: Effect of parameters when $n > 1$

three solutions first go up because the number of inequalities in answer sanitation increases, and become stable when k reaches a number since the number of safe POIs becomes stable as k increases (see Figure 7a).

Varying n : Figure 6g-6i shows the comparison for varying n . The trend is similar to Figure 6a-6c, with PPGNN-OPT being the best performer for the communication cost and user cost. For PPGNN and PPGNN-OPT, n does not affect the size of encrypted indicator vector(s), but for the Naive solution, every user needs to generate and send extra $\delta - d$ dummy locations, which leads to the faster increase in the communication cost and user cost. The LSP cost of three solutions increases linearly because the total number of inequalities considered in the answer sanitation grows linearly with n .

Varying θ_0 : Figure 6j-6l shows the comparison for varying θ_0 . The communication cost and user cost are stable since θ_0 only affects the computation on LSP through the sample size N_H required as in Eqn (17). The LSP cost first decreases greatly and becomes stable as θ_0 increases because the sample size in Eqn (17) behaves this way. In other words, a stronger Privacy IV level means a faster answer sanitation because fewer samples are required in the hypothesis testing.

Number of POIs returned: Recall that the answer sanitation will remove some lower ranked POIs in the top- k answer to ensure Privacy IV under the full user collusion assumption. Thus, the number of POIs actually returned to the users could

Figure 7: The number of POIs returned per answer

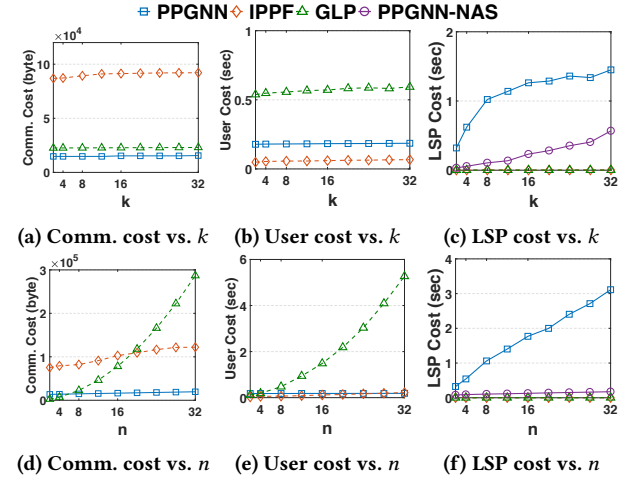

Figure 8: Comparison with other approaches.

be smaller than k . This experiment will study how the answer sanitation affects this number. We only consider PPGNN because PPGNN-OPT and Naive will return the same answer as PPGNN. Note that k , n , and θ_0 can affect this number, but δ cannot.

Figure 7a-7c shows the number of POIs returned per answer for varying k , n , and θ_0 . The default settings of k , n , and θ_0 are 8, 8, and 0.01, respectively. In Figure 7a, as k increases, the number of POIs returned first increases and then becomes stable around 4. This is because, with $n = 8$ and $\theta_0 = 0.01$, 4 inequalities usually lead to a successful inequality attack and a larger k has no additional impact. In Figure 7b, the number of returned POIs rises slightly as n increases. At first glance, this seems counter-intuitive because ensuring no attack on more users is more restrictive. At a closer look, with more users involved in a query, the target user's location $l_{1,*}$ weights less in determining if the inequalities in Eqn (14) hold or not, therefore, there are more choices for $l_{1,*}$, thus, a larger solution region for $l_{1,*}$ and it is easier to add the next POI in the answer. The trend in Figure 7c is expected because a larger θ_0 leads to a stronger Privacy IV, consequently, fewer POIs can be returned.

To conclude, the top 2 to 5 POIs are still returned for a query even after the answer sanitation. In practice, such numbers are usually sufficient because the users might only need to select one from them.

8.3.2 Comparison with Baseline Approaches. We compared PPGNN with the baselines IPPF and GLP for varying k and n . d , δ , and θ_0 specific to PPGNN are set to their default values. We only consider PPGNN because the experiments above have shown that PPGNN-OPT is better than PPGNN. While PPGNN satisfies Privacy IV assuming full user collusion, let PPGNN-NAS denote

Table 4: Comparison with existing work

Group Size	Approaches	Technique	Privacy I	Privacy II	Privacy III	Privacy IV
$n = 1$	[3, 9, 21]	Cloak-Region	✓	✓	×	-
	[17, 30]	Dummy	✓	✓	×	-
	[13, 26]	Private Information Retrieval	✓	✓	×	-
	[1, 34, 37]	Perturbation	✓	×	✓	-
	[12, 27, 36]	Hybrid Techniques	✓	✓	✓	-
	Our approach	Dummy+Paillier	✓	✓	✓	-
$n > 1$	[14]	Cloak-Region	✓	✓	×	×
	[2]	Secure Multiparty Computation	✓	×	✓	×
	Our approach	Dummy+Paillier	✓	✓	✓	✓

the relaxed PPGNN that satisfies **Privacy IV** assuming no user collusion. So PPGNN-NAS does not run the answer sanitation. For IPPF, we chose the query rectangle area (for each user) to be 0.0005% of the data space, which is comparable to choosing $d = 25$ locations (our default setting) as the location set from 5000,000 addresses in California⁶. For GLP, we chose the same *keysize* as PPGNN.

Varying k : Figure 8a-8c shows the comparison for varying k . The communication cost of IPPF is much larger than PPGNN and GLP. In fact, IPPF returns all the candidate POIs, which can be several thousands per query on average, to the users, and the users have to filter the candidate POIs. GLP consumes more user cost than PPGNN and IPPF because there are $O(n^2)$ cryptographic operations and every user has to transmit encrypted values to all other users. In Figure 8c, the gap between PPGNN and PPGNN-NAS is the LSP time spent on the answer sanitation, which dominates the LSP cost. IPPF and GLP consume less LSP cost, however, IPPF cannot satisfy **Privacy III** and **IV**, and GLP cannot satisfy **Privacy II** and **IV** and provide only an approximate answer.

Varying n : Figure 8d-8f shows the comparison for varying n . PPGNN is significantly communication efficient than IPPF and GLP. The communication cost for GLP increases quickly with n because the number of transmitted encrypted values is $O(n^2)$. There is a similar trend on the user cost. Again, Figure 8f shows that PPGNN spent significant LSP time on the answer sanitation to deal with the full user collusion, whereas PPGNN-NAS has almost the same LSP time as IPPF and GLP.

8.4 Summary

For $n = 1$, our solutions, PPGNN and PPGNN-OPT, are comparable with or better than the existing solution APNN that heavily relies on pre-computing the answers for all possible queries to reduce the run-time cost. However, APNN produces only approximate answers and the pre-computation means an expensive update cost. For $n > 1$, which is the main focus of this paper, PPGNN and PPGNN-OPT, have significantly smaller communication cost and user cost than existing solutions IPPF and GLP while providing stronger privacy guarantees, i.e., **Privacy I-IV**, and PPGNN-OPT performs better than PPGNN in most cases. We believe that reducing the communication cost and user communication cost is the priority in the mobile user scenario as considered here. The pay for achieving the stronger privacy guarantee is some increase in the LSP cost, especially when dealing with the full user collusion assumption for **Privacy IV**. To our knowledge, this is the first work considering this assumption.

9 RELATED WORK

Most existing work focus on the single user query case, i.e., $n = 1$. To protect **Privacy I**, some techniques obfuscate user’s exact location in a cloak-region (CR) [3, 9, 21] or use dummy query locations [17, 30]. Another technique [13, 26] is based on private information retrieval (PIR), allowing the user to retrieve a particular record from LSP without revealing which record is retrieving. In these techniques, LSP needs to return a super-set of the exact query answer, which not only increases the communication cost but also sacrifices **Privacy III**. Data transformation [37] and differential privacy approach [1, 34] perturb user’s exact location to a false location, so the query answer is approximate, and meanwhile, **Privacy II** is sacrificed because LSP knows the query answer. The approaches [12, 27, 36] that based on a hybrid of PIR and cryptography technique can protect **Privacy I-III**, but LSP needs to pre-compute the answers to all possible queries. This technique does not work for $n > 1$ because of too many group queries. Also, if a POI information is updated, LSP needs to re-compute all answers, which is too expensive.

For the group query scenario, i.e., $n > 1$, Hashem *et al.* [14] obfuscates each user’s exact location into a region, and LSP executes the k GNN query *w.r.t.* these regions, returning a super-set of the query answer. Beside the extra work of filtering the answer set by the users, this approach sacrifices **Privacy III** since extra POI information is returned to the users. **Privacy IV** is also violated because a user’s exact location is compromised if its predecessor and successor collude in the filtering phase [2]. In the work by Talouki *et al.* [2], users compute their centroid by secure multiparty computation (SMC) [35] and LSP returns the k NN answer for that centroid. This approach cannot protect **Privacy II** and **Privacy IV** because LSP knows the query answer and $n - 1$ users can recover the last user’s exact location by their own locations and the centroid.

Table 4 summarizes and compares the above works with our work.

In the privacy preserving meeting location determination (PPMLD) [5, 16, 31], a group of users each chooses a preferred meeting location and send the encrypted locations to the server, who then selects the one to minimize the aggregate distance to all preferred locations. In our work, the query answer is selected from the POI database of LSP and the users specify their current locations, instead of preferred meeting locations. The PPMLD method cannot be adopted to our privacy preserving k GNN problem because their cryptographic selection is specific to PPMLD. On the other hand, our approach can be adopted to PPMLD by replacing the k GNN building block with any existing non-privacy preserving meeting location determination solution.

The data ownership and privacy implication in our problem are different from most works on secure query processing in the outsourcing database (ODB) model [32]. In ODB, the users and the data owner are trusted and the server is not trusted. The data owner outsources the encrypted database to the server and the user retrieves the query answer from the server. The privacy objective is to prevent the server from learning anything about the database and the user query. In our problem, LSP owns the data and multiple users jointly specify a query, and no party trusts anyone except herself.

10 CONCLUSION

This work identifies four privacy objectives for the group k -nearest neighbor query, k GNN, and designs a privacy preserving k GNN solution, PPGNN. To our knowledge, this is the first work that address all of these privacy objectives. Though we consider k GNN, the proposed privacy preserving approach can be easily adopted to any group query because it treats the query answering (i.e., k GNN) as a black box.

ABSTRACT

Due to the wide availability of social media and the wide range of real-life and human-centered applications, social networks have become an attractive research area. However, the temporal aspect of relations between entities in a social network has been widely ignored. We argue that the temporal aspect of social networks is the key to understand interactions and other phenomena happening in these networks and should thus be considered more closely. In this work we address the problem of pattern search in temporal social networks, thus finding all occurrences of a temporal pattern in a large temporal social network. As a first step, we define a temporal pruning criterion, which allows to quickly reduce the search space of candidates. Then, we present an index structure which allows to quickly find the occurrences of simple temporal network structures, from which more complex query structures can be derived from. Our experimental evaluation on a real-world temporal social network shows the effectiveness of our pruning approach and our proposed index structures, reducing the search-time for small temporal patterns by many orders of magnitude.

Figure 1: Example evolution of a social network.

1 INTRODUCTION

Social networks and other interaction networks¹ are dynamic by nature. Bonds of friendship can last for an eternity, but often break and fade away over time. Active collaborations between researchers naturally change over time. Thus, any social network today will look significantly different tomorrow. Keeping in mind the dynamic nature of human beings, the history of a social network showing how interactions between individuals evolve over time should be considered when inferring knowledge from it, because the knowledge about the evolution of a social network yields further semantic information. For instance, in a collaboration network it might be interesting to see in which order a

group of researchers formed a network, which researchers only have short-term collaborations and which have rather long and sustainable research collaborations. However, existing solutions that consider only a snapshot in time, or building the union of all past collaborations, are not able to take such information into account. By considering this dynamic aspect of a social network, it becomes possible to identify more interesting and meaningful patterns. As a minimal example, consider Figure 1, showing an evolving social network. Initially, only one social link exists, between Anna and Brian. In the next month, an additional link is added between Brian and Chris. Finally, the triangle is closed with a link between Chris and Anna. In this example, Brian might act as a social hub, who brings Anna and Chris together. In practice, more detailed temporal social patterns could matter, as for instance the duration of a social link between Anna and Chris, which was induced by Brian, may be of interest. The temporal development of edges like in our example has been addressed for more than a hundred years through the concept of ‘triadic closure’, where the future creation of the third connection in a

¹Though this paper mainly refers to social network, the proposed concepts are also applicable for other interaction networks, e.g. economical networks, etc.

triangle is tried to be estimated, e.g. through link prediction in social networks. A more complex temporal structure in a social graph is the ‘microtaboo’, where it is frowned upon when persons *Alice* and *Dave* want to engage in a relationship, but there exist prior relationships between *Alice* and *Bob*, *Bob* and *Carol*, and *Carol* and *Dave* (“don’t date your ex-girlfriend’s boyfriend’s ex-girlfriend”) [2].

Another example are communication and transportation networks, where links between nodes and hubs are only established temporarily. Routing policies of computer networks may decide differently at various time points on how to create links between network nodes in order to transmit data. Transportation networks with feeder trucks, cargo aircraft and delivery vehicles link hubs differently according to current demand. To analyze the behaviour of those networks, a temporal pattern analysis of the interaction graph can help in mining information from the graph’s history to deduct findings and information for future optimization.

In this paper we address the problem of efficient evolution pattern search in large temporal social networks. Our approach bridges the gap between social network analysis and temporal logic. The contributions of this paper can be summarized as follows:

- We formally introduce the temporal subgraph matching query as a new problem.
- We introduce a language to express such pattern-based queries.
- We introduce and discuss several query filter strategies.
- We propose an index structure that allows us to search for temporal subgraph patterns in large temporal social network graphs.
- We provide a broad evaluation of the performance of our approaches based on real world datasets and show that our approach significantly outperforms state-of-the-art approaches. Though our problem is a generalization of the subgraph isomorphism problem, which is known to be NP-complete [6, 11], we can show that our index-based solution is able to find simple temporal social patterns in large real-world social networks efficiently.

We define the problem of temporal social subgraph search in Section 2. In Section 4, we propose filter strategies and introduce our new indexing method in Section 5. Our experimental evaluation is given in Section 7.

2 PROBLEM DEFINITION

We first introduce our representation of a temporal social network which we define as a graph where each node refers to an individual and each edge between two nodes is associated with a discrete function that maps time to the domain $\{0,1\}$ specifying the presence and absence of the edge over time.

Definition 2.1 (Temporal Social Graph). Let $\mathcal{T} = \{0, 1, \dots, m\}$ be a discrete time domain. A temporal social graph (TSG) $G = (V^G, E^G, F^G)$ is a graph, where $V^G = \{v_1^G, v_2^G, \dots, v_n^G\}$ is the set of nodes, $E^G \subseteq V^G \times V^G$ the set of links (with $(v_i^G, v_k^G) \in E^G$), and $F^G = \{f_{v_i^G, v_k^G}^G(t) | (v_i^G, v_k^G) \in E^G\}$ a set of discrete time-dependent functions, where $f_{v_i^G, v_k^G}^G(t) \in \{0, 1\}$ describes the existence of a

connection between v_i^G and v_k^G (0 indicating no connection and 1 indicating there is a connection) at time $t \in \mathcal{T}$. Furthermore, an edge (v_i^G, v_k^G) is only an element of E^G if $\exists t \in \mathcal{T} : f_{v_i^G, v_k^G}^G(t) \neq 0$.

Based on this definition we are now able to define temporal subgraph matching which finds a subgraph from a TSG that exactly matches a given temporal subgraph query.

Definition 2.2. [Temporal Subgraph Matching] Let $G = (V^G, E^G, F^G)$ be a TSG defined on the time domain $\mathcal{T} = \{0, 1, \dots, m\}$. And let $q = (V^q, E^q, F^q)$ be a query TSG defined on the time domain $\mathcal{T}^q = \{0, 1, \dots, t^q\}$ where $t^q \leq m$. A temporal subgraph matching query retrieves the set \mathcal{S} of all temporal subgraphs $S \ni S = (V^S \subseteq V^G, E^S \subseteq E^G, F^S \subseteq F^G)$, such that there exists a bijection $h : V^q \rightarrow V^S$ and $\Delta_t \in \{0, \dots, m - t^q\}$ that satisfies $\forall (v_i^q, v_k^q) \in E^q : (h(v_i^q), h(v_k^q)) \in E^S$ and $\forall t \in [0, t^q] : f_{v_i^q, v_k^q}^q(t) = f_{h(v_i^q), h(v_k^q)}^S(t + \Delta_t)$.

An example for a temporal social graph G is given in Figure 2(a). For convenience we labeled the edges (v_i, v_k) with the set of time steps $t \in \mathcal{T}$ for which the function $f_{v_i, v_k}(t) = 1$. Figure 2(b) illustrates a temporal subgraph query q . A pattern match of q can be found at \clubsuit in G for $\Delta_t = 2$, $h(v_1^q) = v_4^G$, $h(v_2^q) = v_2^G$ and $h(v_3^q) = v_1^G$. A more sophisticated query q' is depicted in Figure 6, which matches for $h(v_1^{q'}) = v_{11}^G$, $h(v_2^{q'}) = v_8^G$, $h(v_3^{q'}) = v_9^G$, $h(v_4^{q'}) = v_{10}^G$, and $h(v_5^{q'}) = v_6^G$ at $\Delta_t = 5$ (around the \heartsuit marker).

A summary of the notations used throughout this paper can be found in Table 1.

3 RELATED WORK

Various applications of temporal graphs and sources of temporal graph data can be found in surveys on temporals graphs [4, 10]. Existing research on temporal graphs primarily focuses to temporal paths and their applications [1, 4, 12, 13, 15, 19, 22, 23]. None of these works study the search of a given query pattern. Most related is existing work on temporal community detection over temporal networks [9, 14, 25, 26] and multi-layer networks [3]. These work first identify communities in a static network, then identify the evolution of the communities from the changes of the network. Specifically, the problem of finding dense patterns in temporal graphs has been studied in [25, 26]. This work allows to find diversified dense regions, thus minimizing the temporal and social redundancy of the returned patterns. Such diversification may also be applied to the arbitrary patterns mined in this work, but is not in this paper’s scope. A recent approach [16] considers relations between edges, namely the time-respecting subgraph isomorphism problem, where edges are put into temporal sequence of each other. This is useful to model propagation in a network, but cannot handle more complex temporal constraints in the query. The authors propose a time-first, topology-first and a hybrid solution to approach their problem. A consideration of the fact that edges can appear and disappear over time is made in [18], which focuses on finding structural subgraph patterns in the graph that persist over the longest period of time. This is supported by three index structures that store label information, neighbourhood constellations and path maps.

In summary, these works can be used to find dense regions such as cliques and quasi-cliques in a temporal network, but do not allow to find patterns arbitrarily shaped over time. Thus, to

Table 1: Notations used throughout this paper.

the best of our knowledge, our work is the first one for finding patterns in temporal graphs such that the query pattern exhibits temporal constraints.

A further line of related work is pattern search on static (non-temporal) graphs. The solution to this problem was proposed by Ullmann [21] and serves as our baseline. This problem, for which a survey of solutions is found in [5], still attracts vivid research attention (e.g., [17, 20]). This pattern search has further been extended to labelled vertex-graphs, as surveyed in [8]. While this research field has received extensive attention, these solutions are not applicable to our problem setting since they do not consider any time-dependent network structures, which increases the complexity of the problem.

Furthermore, solutions have been presented for the problem of finding subgraphs in a large collection of small graphs [24]. This approach first mines frequent structures and stores for each frequent structure the IDs of the graphs that contain it (similar to an inverted file). A query can then be answered by identifying the frequent structures contained in it and intersecting the corresponding lists of IDs. Although, this problem setting is also fundamentally different, it nonetheless inspired us for the index structure proposed in this work.

4 BASIC TEMPORAL SUBGRAPH MATCHING

The problem of temporal subgraph matching is related to the classic subgraph isomorphism counting problem, which is to find the set \mathcal{S} of *all* subgraphs of a non-temporal graph G that are isomorphic to a given non-temporal query graph q . This problem is a generalization of the NP-complete subgraph isomorphism problem [6, 11], where the challenge is to decide whether *any* such subgraph $S \in \mathcal{S}$ exists in G . Consequently, the subgraph isomorphism counting problem is NP-hard, since its result can be used in to decide the subgraph isomorphism problem in $O(1)$, by testing the number of subgraphs for positivity. The current best-known algorithm for obtaining the exact count of an arbitrary query graph q is in $O(n^{\frac{\omega k}{3}})$, where k is the size of query graph q and ω is the exponent of fast matrix multiplication [7]. Our problem is at least as hard as subgraph counting, as we want to enumerate all instances of q in G , while also considering temporal constraints on edges.

The problem of finding all subgraph isomorphisms on static (non-temporal) graphs can be extended to temporal subgraphs as follows: Given a temporal query subgraph $q = (V^q, E^q, F^q)$, initialize the non-temporal graph $q^\perp = (V^q, E^q)$, where $F^{q^\perp} \neq 0$. In informal words, two nodes in q^\perp are connected iff their corresponding vertices in q are connected at least at one point of time. This can be seen as a projection of the temporal query q to a single point of time. Now this projection is applied on the temporal graph $G = (V^G, E^G, F^G)$ as well, yielding the non-temporal graph $G^\perp = (V^G, E^G)$. Now solve the subgraph isomorphism problem on the “flattened” by finding the set of all subgraphs \mathcal{S}^\perp of G^\perp that are isomorphic to q^\perp . This yields, for each any edge e in any resulting graph $S^\perp \in \mathcal{S}^\perp$ a mapping $h(e)$ to an edge in G as described in Definition 2.2.

Since the temporal subgraph query is more selective than the non-temporal query by considering temporal constraints, an additional refinement step is necessary. For any $S^\perp \in \mathcal{S}^\perp$ to be verified as a result of the overall temporal subgraph query, there must exist a time offset Δ_t such that the time-dependent function F^q matches the time dependent function of S . More formally, $S^\perp = (V^S, E^S)$ satisfies the temporal subgraph query of q iff $\exists \Delta_t \in \{0, \dots, m - q^t\} : \forall e \in S^\perp : \forall t \in [0, t^q] : f_e^q(t) = f_{h(e)}^G(t + \Delta_t)$.

4.1 Subgraph Isomorphism in Non-Temporal Graphs

Ullmann [21] introduces a viable method for solving the (non-temporal) subgraph isomorphism problem, which we will extend and briefly describe in this chapter: Let G be a non-temporal graph, which is the special case of a temporal graph having a singular time domain $\mathcal{T} = \{0\}$ and having all edges in E^G exist at time 0. For every subgraph $S = (V^S, E^S) \in G$ that is isomorph to a query graph q , we can define a $|V^q| \times |V^G|$ matrix M^S , such that $M_{i,j}^S = 1$ iff $h(v_i^q) = v_j^G$ and 0 otherwise. M^S can therefore be interpreted as an assignment map that locates the vertices of the subgraph in the larger graph. Note that in every row of M^S , there is exactly one cell with the value of 1, while in every column there is at most one cell to contain a 1.

Let furthermore M^0 be a matrix having the same dimensions as M^S and $M_{i,j}^0 = 1 - \prod_{S \in \mathcal{G}} (1 - M_{i,j}^S)$, so that M^0 gives information

about whether there exists any unspecified subgraph S so that $h(v_i^S) = v_j^G$. It is now possible to retrieve the individual subgraph matrices M^S from M^0 , along with possible other matrices, which do not belong to a valid subgraph query solution: Alter the cells of M^0 by setting different cells from 1 to 0, until the constraints of a subgraph representation are fulfilled (exactly one 1 per row, max. one 1 per column).

The main idea is to mine candidate subgraphs S from M^0 , which are matching in the “flattened” graph G^\perp that is oblivious to the time constraints. Therefore, a cell $M_{i,j}^0 = 0$ implies that there exists no subgraph S where $h(v_j^S)$ would map vertex v_j^S to vertex v_i^G in the social network. Analogously, a value of 1 implies that such a graph may possibly exist. A trivial case is to set every $M_{i,j}^0$ to 1, which means that every vertex in G can be part in any subgraph that fulfills q . But in order to improve the runtime of the algorithm, it is desirable to reduce the number of subgraph combination. This can be achieved by setting as many cells in M^0 to 0 as possible. There are different methods to prune candidates with varying complexity and efficiency:

- **Pruning based on a node’s degree.** If $\deg(v_i^S) > \deg(v_j^G)$, then $M_{i,j}^0$ can be set to 0. Note however, that in social networks the degree of the vertices is usually much higher than the degree of vertices in the query pattern q , which is why this approach yields limited pruning power.
- **Pruning based on invalid neighbour mappings.** Vertices can be pruned if there is no valid assignment for its neighbours, although the node itself can be mapped between S and q . More formally, a cell $M_{i,j}^0 = 1$ can be set to 0 (and thus be pruned), if there is a neighbour vertex v_u^S of v_i^S (i.e. $(v_i^S, v_u^S) \in E^S$) and no neighbour v_w^G of v_j^G (i.e. $(v_j^G, v_w^G) \in E^G$) such that $M_{u,w}^0 = 1$:

$$M_{ij}^0 \leftarrow M_{ij}^0 \cdot \left(\prod_{(v_i^S, v_u^S) \in E^S} \left(1 - \prod_{(v_j^G, v_w^G) \in E^G} (1 - M_{uw}^0) \right) \right)$$

Pruning a cell may allow for further pruning of other cells, so a new pruning iteration should be invoked after a successfully setting a cell to 0. This method can be stacked with other methods to further remove further candidates after another method was successful in removing candidates.

4.2 Additional Pruning Filters for Temporal Graphs

Besides the generic filter steps enlisted in Section 4.1, we furthermore introduce two more viable filter steps that can be applied in the context of *temporal* subgraph isomorphisms:

- **Pruning based on time offset.** As described before, every derived subgraph S that is a candidate to be isomorph to the query (represented through M^S) needs to be refined in the sense that there needs to exist a Δ_t so that the time-dependant functions match. When testing various Δ_t , it is feasible to create a copy $M_{\Delta_t}^S$ of M^S . Since only the time frame from Δ_t until $\Delta_t + t^q$ is relevant for the matching of the functions, the graph G can be projected onto a more sparse graph N_{Δ_t} than N by only inserting an edge into

$E^{\Delta t}$, if the corresponding edge in G exists in this more narrow time frame.

- **Pruning based on network distance.** When iterating through M^0 , after setting a candidate value for the first processed row of M^0 , we can try to cut down the number of columns that can contain 1s at all. Let i be the index of a row where exactly one column j is set to one. Then we can compute the maximum hops from v_i^S to any other node in S . Then we determine all nodes in the graph N , whose hops distance to v_j^N is larger than that distance. Those columns can then be set to zero. This is a viable approach if $|V^N| \gg |V^S|$ and N is sparse. For efficiency reasons, it is recommended to pick the first row i in a way so that v_i^S lies in a *central* position in S , e.g. minimizing the maximum hops distance. As temporal aspects are not a pruning criterion for this filter, it can generally be applied to non-temporal subgraph isomorphism queries as well.

In our experiments, we will take a deeper look at the effectiveness and performance of the basic and our extended filters. We will also evaluate the processing order, in which these filters are applied.

5 AN INDEX STRUCTURE FOR TEMPORAL GRAPHS

In this section we will give an in depth description of how to build an index for temporal social graphs and how to perform pattern queries on this index.

The construction of an index structure that supports subgraph pattern search on temporal graphs can be summarized in four steps: (1) Select one or more simple subgraph structures (SSGs) and do the following steps for each of them. (2) Find each occurrence of the SSG in the graph G without consideration of the temporal aspect. (3) Transform each occurrence into a string reflecting its unique behaviour over time considering the functions f of the edges. (4) Index the obtained strings using an index structure for substring search. In the following we will consider each of these steps in detail.

Simple Subgraph Structure Selection: The selection of suitable SSGs ($SSG = (V^{SSG}, E^{SSG})$) is crucial for the performance of the index, since the index can later on only answer queries that contain at least one of the selected SSG. A good set of SSGs should thus contain even the simplest possible query structures. Let us note that a temporal pattern query on a TSG must involve at least a relationship (edge) of two entities (nodes). The most simple SSGs involving 2 and 3 nodes, illustrated in Figure 3, should thus always be indexed in order to allow index support for all possible queries. When challenging the trade off between simplicity and ubiquitousness of SSGs, multiple different SSGs may be indexed in parallel to suit a wider array of queries. In the following we will showcase the construction of the index based on the triangle structure.

Finding SSG Occurrences: To find all occurrences of the SSG in the graph, the temporal aspect of G will be neglected thus using “flattened” version of G^\perp of G as used in Section 4. Within G^\perp , we search for all occurrences of the SSG using a traditional subgraph isomorphism algorithm such as [21]. An SSG occurs at a set of nodes $V^O \subset V^G$ iff $(v_i^O, v_j^O) \in E^N \Leftrightarrow (v_i^{SSG}, v_j^{SSG}) \in E^{SSG}$. Please note that due to possible symmetries, several occurrence

Figure 3: Simple Subgraph Structures (SSGs) with 2 and 3 nodes

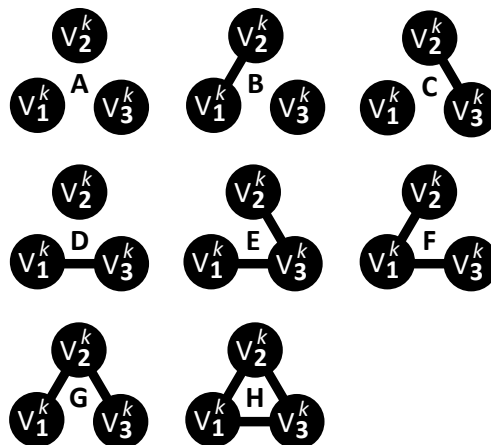

Figure 4: Encoding the edges of a graph. Each possible graph topology is encoded by an uppercase Latin character A-H.

can happen for the same set of V^O , depending on how V^O is mapped to V^{SSG} .

Example 5.1. The triangle SSG occurs within the graph of Figure 2(a) at the positions marked with \heartsuit , \clubsuit , and \diamond . If there would be an edge (v_6^G, v_{10}^G) at time 1, the set of nodes v_6^G, v_9^G, v_{10}^G would also form an occurrence, even though at no point of time an actual triangle is formed between the nodes.

The identification of those SSG occurrences does not come free of cost: In particular, finding all subgraphs of G that are an occurrence of the SSG has a runtime complexity of $O(n^{\frac{\omega k}{3}})$, where k is the size of query graph q and ω is the exponent of fast matrix multiplication [7]. However, this task can be performed offline and will not affect the query performance. Furthermore, the actual runtime is in general low enough due to two reasons: First, the SSGs are usually very small (in our example not more than 3 nodes) and second, the graph G is not fully connected in a real-world setting.

String Transformation: At every discrete point of time, a set of nodes in the graph that belong to an SSG can form a certain constellation via their edges. Figure 4 shows all possible combinations for a triangle SSG consisting of three, distinguishable nodes (v_1^{SSG}, v_2^{SSG} , and v_3^{SSG}) and assigns each constellation a unique symbol; here we are using uppercase Latin characters. To encode an SSG’s temporal behaviour over time, at each time frame the currently present edges have to be figured out and be mapped via a pre-defined assignment table (such like Figure 4) to a unique symbol or character. In general, the alphabet to encode all constellations of an SSG having k edges consists of 2^k

characters. Concatenating these characters along the chronological time-series will yield in a string representing the temporal behaviour.

Example 5.2. The graph q denoted in Figure 2(b) shall be represented by a string using the triangle SSG. When each node v_i^q is mapped to v_i^{SSG} , the symbol representing the graph constellation at each time frame t_j ($0 \leq j \leq t^q$) can be looked up in Figure 4 ($t_0: B, t_1: F, t_2: H$), thus yielding the string BFH . For other possible mappings of v^q to v^{SSG} the string representations $BGH, CEH, CGH, DEH,$ and DFH are valid as well.

This schema can be applied to all substructure occurrences found in the graph, so that each occurrence's temporal behaviour can be described through a string. It is then feasible to index those strings in a way to efficiently support substring search. We propose to employ a suffix-tree to index these substrings concisely.

Example 5.3. Consider the triangle SSG. It occurs three times in our example graph G (Figure 2(a)), namely at $\heartsuit, \clubsuit,$ and \diamond . For every occurrence, there exist six possible permutations of how the substructure can occur at this position, due to the ways v_i^G may be mapped to v_i^{SSG} . We depict all of these occurrences and permutations in Figure 5.

6 QUERY PROCESSING

Next, we describe how our string-index can find all occurrences of a given temporal query pattern q . As described in Section 5, in the following, we assume that an index has been build for a specific simple subgraph structures SSG.

- (1) Identify occurrences of the SSG in the "flattened" temporal graph query q^\perp .
- (2) For each such occurrence, perform the same string transformation than performed for the index (i.e., use the same character map).
- (3) Index-supported search for the transformed string to find candidates for verification.
- (4) Refine the candidates through verifying that the part of q which is not contained in the SSG is isomorph to the surrounding of a candidate.

In more detail, to answer queries according to Definition 2.2 using the index support of the suffix-tree, we first have to isolate those SSG occurrences in the graph topology of the query graph of the SSG that was used for the string transformation process before. An SSG may occur not at all, once, or multiple times in the graph. If no SSG occurrence can be found, the index is of no help and the search has to default to a full scan, which is why there is a motivation to keep SSGs small and simple. In case of one or several occurrences of the SSG in q , we isolate the temporal behaviour of that part of the query graph and transform it using the same string encoding method used for the index construction.

Since the queried time frame is usually smaller than the indexed time span, the length of the string derived from the SSG occurrence in q is shorter than the length of string belonging to the occurrence in the graph which is stored in the index. To answer the query, we now must find all those strings in the index that contain the substring belonging to the query.

Example 6.1. Identification and String Transformation of SSG in query q . In our example query q' (Figure 6), the triangle SSG occurs at the \clubsuit marker. Since there are six possible permutations of the occurrence, valid string transformations are $EHH, EHH, FHH, FHH, GHH,$ and GHH . With each of these unique query strings, we can search our encoding index (suffix tree) for entries that contain the query string. The substring positions are indicated through bold and underlined text in Figure 5. Entries which do not contain one of the substrings can be pruned.

Since practical SSGs consist of more than one node, there is usually always more than one way it can be mapped to either the nodes of the occurrence in the query graph or the occurrence in the main. I.e., there are also several string transformations of the occurrence. There are in general several ways to approach these permutations:

- Account for permutations at index creation and query processing. This means that every permutation is indexed, thus resulting in a larger index, and that index is queried multiple times (once for each permutation of the query)
- Consider the permutations in the index, but not for the query
- Consider the permutations only within the query
- Neglect the permutations in the query graph and at index creation.

Neglecting all permutations may result in correct results not being found, as there is no guarantee that an 'identical' permutation has been used for the index and the query. On the other hand, if permutations are considered both times, the result will also show how the query 'fits' into the graph, i.e. the direct mapping from the nodes can be deducted. However, multiple queries have to be performed on an increased index, thus increasing query cost. As a trade-off, it is possible to only consider all permutations on one side (either the index *or* the query), and then find out the mapping in a refinement step. We recommend to consider all permutations within the index and not for the query, as submitting multiple queries increases the overall query cost linearly, while linearly enlarging the index results in a sublinear increase in query performance. Compared to the approach where permutations are considered on both sides, a refinement step is now necessary to deduct the exact mapping of the query to the substructure (one mapping per possible permutation). This is likely to be done faster after the query than it is to do multiple queries (one for each permutation).

Example 6.2. Index-supported Search for Transformed String Representation of the SSG. If following our advice to only consider permutations within the index, querying our example query q' (Figure 6) with a triangle SSG, the search string will either be EHH **or** FHH **or** GHH . The exemplary index in Figure 5 will then yield the set of nodes $\{v_3^G, v_5^G, v_6^G\}$ for the \diamond , and the set $\{v_8^G, v_9^G, v_{11}^G\}$ for the \heartsuit occurrence. However, the mapping of $v_i^{q'}$ to v_j^G **cannot** be deducted from the index and has to be refined computationally.

Searching for a substring in the index then retrieves two important facts for every match: (1) a subset of V^G that corresponds to an SSG occurrence, and (2) the temporal offset Δ_t at which it occurred (calculated by the offset position of the substring from the beginning of the indexed string). Both are crucial for

efficiently refining the candidates. A refinement is necessary, as the query may be more restrictive than the SSG itself, i.e. through additional edges attached to the SSG, the retrieved candidates are a superset of the results. Therefore, this set has to be refined, i.e. it has to be checked whether the found SSG is part of a larger subgraph structure that can fulfill the query constraints with regards to graph structure as well as temporal behaviour. To refine the candidates, we return to the concept of Section 4.1. Before evaluating the substring candidates, we can still apply the degree filter for q' and G to M^0 , as it is a quick way to eliminate some impossible assignments.

Example 6.3. Figure 7 shows M^0 for our sample query q' after applying the degree and neighbour filters. It shows that for example $v_1^{q'}$ can only be mapped to nodes with a degree of at least 4, thus leaving only cells $M_{1,4}^0$ and $M_{1,9}^0$ in the first row with a 1. On the other hand, $M_{2,3}^0$ is set to 0, as $v_2^{q'}$ cannot be mapped to v_4^G , as v_4^G (unlike $v_2^{q'}$) does not have a neighbour of degree 4.

After optimizing M^0 , for each found SSG x , we initialize a copy of M^0 denoted as M^x and thereby set $M_{i,j}^x := M_{i,j}^0$. Each found SSG instance x gives us a 'hint', where an occurrence of q' in G may occur as well as the temporal offset Δ_t at which the temporal pattern of the subgraph structure matched. This hint will either lead to a correct result or may be false – but

M^0	v_1^G	v_2^G	v_3^G	v_4^G	v_5^G	v_6^G	v_7^G	v_8^G	v_9^G	v_{10}^G	v_{11}^G

$v_5^{q'}$	1	1	0	0	0	0	1	1	0	1	1

Figure 8: Assignment matrix M^{q_4} after applying the assignment from the index candidate. This means that the bold cells should be set to 1. However, cells depicted with '?!' already contain a 0 (ref. Figure 7) and cannot be set to 1 in a valid way.

its correctness will not have any effect on other SSG instances, which is why we can process them individually and in parallel. Since the index found a matching SSG which implicitly matches

the vertices of the structure to vertices of the graph (after considering the permutations of the mapping), we can assign $|V^{SSG}|$ fix assignments, thus nullifying all other cells in those rows (since M^X is usually much wider than tall, this drastically increases the number of cells containing a 0). Since Δ_t is known at this point of time, we can now apply the more sophisticated time offset and network distance filters (Section 4.2) to M^X .

Example 6.4. Let us return to our running example, where we search for occurrences of the more complex query q' (Figure 6) in the running social network G (Figure 2(a)). Let's consider the fourth permutation of the \diamond substructure, which is returned as a candidate through the query permutation EHH ($v_1^{q'} \rightarrow v_1^{SSG}$, $v_2^{q'} \rightarrow v_3^{SSG}$, $v_3^{q'} \rightarrow v_2^{SSG}$) (see Figure 5). Mapping this SSG to G yields the mappings $v_1^{q'} \rightarrow v_1^{SSG} \rightarrow v_5^G$; $v_2^{q'} \rightarrow v_3^{SSG} \rightarrow v_3^G$; and $v_3^{q'} \rightarrow v_2^{SSG} \rightarrow v_6^G$ also shown in Figure 5. We attempt to make this assignment in the corresponding matrix $M^{\diamond 4}$ depicted in Figure 8. Therefore, we have to set the values in $M_{1,5}^{\diamond 4}$, $M_{2,3}^{\diamond 4}$ and $M_{3,6}^{\diamond 4}$ to 1, but we see that the first two entries already contain a zero in the global assignment matrix M^0 , such that this assignment does not yield a valid matching. Therefore we can stop here and prune this candidate. In fact, in our example we can prune all permutations of \diamond in the same way, as well as permutations 1, 3, 5, and 6 of \heartsuit ; with \clubsuit not even providing candidates. In summary, this just leaves $M^{\heartsuit 2}$ and $M^{\heartsuit 4}$ for further refinement.

We are now left with a set of matrices that we need to derive final assignment candidates from. A naive way would be to iterate over all possible assignments and verify them; one would do that by choosing a single $M_{i,j}^X = 1$ and using it as an assignment, thus nullifying other values row i and column j , and then proceeding to row $i + 1$, re-applying the same concept. This needs to be done iteratively for all $M_{i,j}^X = 1$ of a row. We aim to improve this exponentially expensive approach by using heuristics. Therefore, we first take effort in finding a clever order of which we process the rows. We process rows in breadth-first-order starting at the corresponding SSG occurrence, skipping lines having a "1" assigned by the SSG occurrence. For any other line b , we look at any previous row a such that $(v_a^{q'}, v_b^{q'}) \in E^{q'}$, i.e., a neighbour of $v_b^{q'}$ that we have already assigned. Since we always start with a pre-assigned row and proceed in a breadth-first-manner, such a row must exist. That row a contains a single assignment $h(v_a^{q'}) = v_c^G$. Assuming this assignment is correct, we only need to look at columns d where v_d^G is a neighbour of v_c^G , thus having $(v_c^G, v_d^G) \in E^G$. This can be deduced from the following:

$$\begin{aligned} h(v_a^{q'}) = v_c^G \wedge h(v_b^{q'}) = v_d^G &= v_c^G \wedge (v_a^q, v_b^q) \in E^q \\ &\Rightarrow (v_c^G, v_d^G) \in E^G \end{aligned}$$

because $E^q \subseteq E^G$.

For every neighbour v_d^G where $M_{b,d}^X = 1$ and the temporal patterns match, we create a copy of the current M^X , nullify all other cells in row b and proceed to the next row in M^X . When the last row is reached, every vertex in v^q has been assigned exactly one partner in v^G , thus being a result.

Example 6.5. For our running example, we retrieve the following assignments from $M^{\heartsuit 2}$ and $M^{\heartsuit 4}$:

$$M^{\heartsuit 2} : h(v_1^{q'}, v_2^{q'}, v_3^{q'}) = (v_9^G, v_8^G, v_6^G)$$

$$M^{\heartsuit 4} : h(v_1^{q'}, v_2^{q'}, v_3^{q'}) = (v_{11}^G, v_8^G, v_9^G)$$

The later one is invalid, as $M_{1,11}^0$ is already 0 and $v_1^{q'}$ can therefore not be mapped to v_{11}^G . Following the first assignment, we now retrieve two final candidates for the complete occurrence of q' :

$$C_1 : h(v_1^{q'}, v_2^{q'}, v_3^{q'}, v_4^{q'}, v_5^{q'}) = (v_9^G, v_8^G, v_{11}^G, v_6^G, v_{10}^G)$$

$$C_2 : h(v_1^{q'}, v_2^{q'}, v_3^{q'}, v_4^{q'}, v_5^{q'}) = (v_{11}^G, v_8^G, v_9^G, v_{10}^G, v_6^G)$$

of which the first one C_1 is invalid, as the time-dependant-function on edges $(v_1^{q'}, v_4^{q'})$ and (v_9^G, v_6^G) do not match. C_2 is a valid result to the query.

7 EXPERIMENTS

In this section we show experimental results of our proposed methods. As a baseline approach, we resort to Ullmann's algorithm as described in Section 4.1. This represents the expansion of traditional solutions to the temporal domain. We further evaluate the included filters as well as our proposed additional filters individually and in combination to distinguish the naive baseline approach from a more advanced setup. We then compare this baseline approach, which has been extended to temporal graphs, to our advanced query processing approach proposed in Section 6 supported by the index structured introduced in Section 5. Additionally, we introduce the evaluated queries and the employed datasets. All experiments were performed on a 3Ghz workstation having 32 GB of RAM. The experiments were run on a single core.

7.1 Datasets

As a datasource for our real data evaluation we use a snapshot of the ACM Digital Library² taken on Dec 15, 2014 consisting of 582,150 publications with author information. Using only the co-author relationship for each calendar year, we build a temporal social graph $G = \{V^G, E^G, F^G\}$, reflecting the collaboration network over time, in the following way:

- Each researcher present in the dataset is represented by a node v^G .
- Two researcher nodes v_i^G and v_j^G are connected by an edge (v_i^G, v_j^G) if they have at least co-authored one publication at any time $t \in \mathcal{T}$.
- The time dependent function for an edge (v_i^G, v_j^G) indicates collaboration over time and is set the following way:

$$f_{v_i^G, v_j^G}^G(t) = \begin{cases} 1 & \text{if } v_i^G \text{ and } v_j^G \text{ co-authored a publication in year } t \\ 0 & \text{if } v_i^G \text{ and } v_j^G \text{ did not co-author a publication in year } t \end{cases}$$

The resulting temporal social graph is called *PUBS* in the remainder of this section. In order to evaluate naive approaches of the proposed algorithms we also use small subgraphs of *PUBS*

called *MiniPUBS* and *MicroPUBS*, with 10000 nodes and 3792 nodes, respectively. These subgraphs were generated from PUBS by performing a breadth-first search rooted at the first two (anonymous) authors of this work.

Table 2 summarizes the characteristics of the three datasets. In addition to the number of nodes, the number of edges and the duration of the network in years Table 2 contains the number of the subgraph structures illustrated in Figure 9.

Figure 11: Querying with a triangle and a crossbox structure of constant edges and variable length t^q .

7.2 Queries

Figure 10 shows a set of standard query subgraphs that we used in our experimental evaluation. In the first set of experiments, the query time domain t^q is set to relatively small values of $3 \leq t^q \leq 5$, to all the baseline approaches to terminate in reasonable time. The temporal pattern on these subgraphs is chosen uniformly random, such that at each point of time $t \in \mathcal{T}^q$ of the query graph, any edge has a chance of 50% to be part of the query pattern. To avoid degenerated cases, we ensure that each edge of a standard query is required to exist at at least one time t .

7.3 Baseline vs. Index

In a first experiment we compare the performance of our proposed index structure (cf Section 5) with the baseline approach as discussed in Section 4. Since the baseline approach is very time consuming we did this experiment on the *MicroPUBS* dataset. As a basic subgraph structure for our index we used the triangle and as queries we evaluated the triangle-query and the quad-clique-query with increasing temporal query length t^q . The results are shown in Figure 11. The baseline approach has to build a projection of the original TSG for each possible start time t over the duration of the query. With increasing duration of the query, this projection becomes more and more dense, which results in increasing runtime. The index based query processing on the other hand performs much faster in this setting. Note that, although the triangle query is beneficial to the index (since the index is built on the triangle structure), the quad-clique query can also be answered efficiently. With increasing query duration, the results quickly decrease, yielding a lower number of candidates, which leads to even lower runtime.

Figure 12 shows the query time for various query patterns. As most of the 4-year-long queries have a highly specific temporal pattern, the index-based approach profits from early pruning of large parts of the data, while the baseline approach is first looking for the general graph structure and can only prune at a second step where the temporal behaviour is considered. We see that the *Triangle* query for $t^q = 3$ has the highest run-time using our index, while having the lowest run-time of the baseline. The reason is that this query yields the largest number of (verified) results which, trivially, cannot be pruned. When changing the query time t^q for the more complex *T-Two-Legs* query, we can

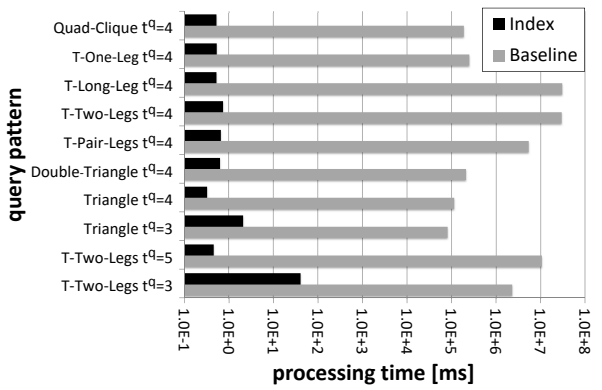

Figure 12: Querying with a distinct queries.

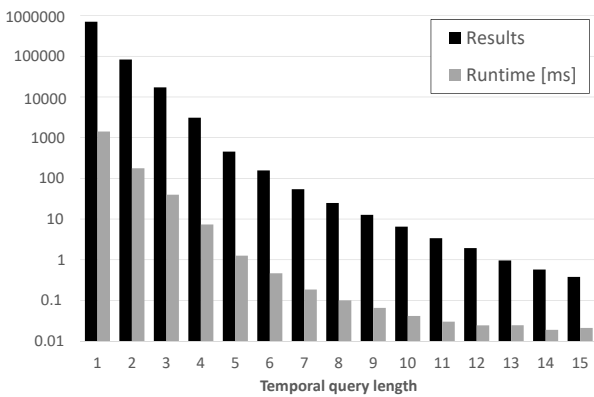

Figure 13: no. of results and runtime with increasing query length

again observe that our index supported approach can benefit from early pruning. Note that the time needed to build the index for this microPUBS dataset was less than a second.

7.4 Evaluating query parameters

Figure 14: query time for harder queries

In the next set of experiments we demonstrate the effect of the query duration t^q on the large PUBS dataset. The *Baseline* approach was not evaluated on this dataset due to its excessive run-time. In the first experiment, shown in Figure 13, we use the

Figure 15: Testing different indexed subgraph structures: number of candidates

Figure 16: Testing different indexed subgraph structures: processing time

Triangle structure for query and indexing. Index construction on this large dataset took less than 30 minutes. Results using this index are averaged over 1K runs for random temporal patterns of the PUBS dataset. We observe that the run-time is directly proportional to the number of results. This behaviour is expected, since less refinement is needed.

The previous experiment show-cased a best-case scenario, where the structure used for indexing is identical to the query structure. In this case, candidates returning by the index need only to be verified for temporally matching the query pattern.

To show the behaviour in more realistic scenarios, we made the topological structure of the query more complex by adding additional edges, while still using triangle SSGs for indexing. Thus, those added edges are not covered by the index and need to be accounted for in the refinement step. Figure 14 shows that adding additional edges and nodes to the query increases the processing time: Adding two edges to the triangle produces a more complex query than just adding one (than adding none), and a Quad-triangle is more specific than a Double-Triangle than a simple triangle.

Thus, in the next set of experiments shown in Figures 15 and 16, we test the efficiency of different SSGs on the MiniPUBS dataset. Here, we compare different structures used to build the index (specifically, the SSGs *Triangle*, *Arrow* and *String*), and different query structures for different time lengths t^q .

Figure 17: Comparing the number of candidates left after applying filters to M^0 .

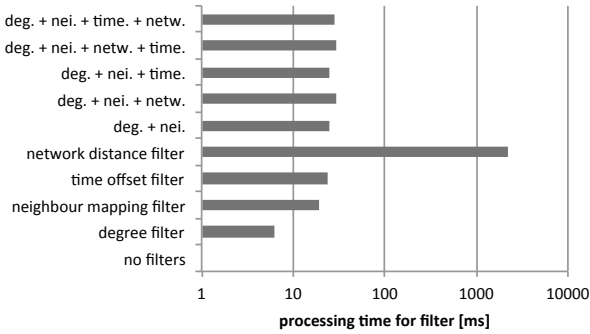

Figure 18: Measuring the computational cost of applying filters to M^0 .

Comparing these results to Table 2, we notice that simpler subgraph structures appear more often in graphs, whereas more complex structures appear less and are thus generally more selective when used as the basis for an index. This also reflects in the number of candidates produced by our index-based approach for different basic query structures. We note that in these queries, using triangle structure for indexing yields much less candidates for refinement. This is because many *Arrow* and *String* structures may not be part of a triangle, thus creating additional candidates to be pruned. However, it should be noted that the triangle index is only applicable if the query structures contains at least one triangle, which is the case for query structures featured in this experiment.

7.5 Evaluating Pruning Filters

In Section 4.2 we introduced additional pruning filters applicable to temporal graphs. We evaluated the various filters on the candidates retrieved after querying the index with a simple subgraph structure (SSG) for our running query example q' on the MiniPUBS graph. Therefore, we measure the performance of different pruning strategies (and their combinations) in their number of candidates generated from M^0 that need to be refined. Figure 17 shows that the degree filter has no effect, because the only nodes not matched in the initial assignment M^0 are the two legs not part of the SSG which just have a degree of 1. The network distance filter and the neighbour mapping filter reduce the number of candidates by a factor of about 10, 000 and 30, 000, respectively. The time offset filter has the highest pruning power, reducing the number of candidates to less than

Figure 19: Measuring the computational cost of applying filters to M^0 with highlight of individual cost.

two hundred. Furthermore, variations of sequential filter combinations are depicted as well: A combination allows to narrow down the candidate size even more. Figure 18 shows the corresponding computational time of the filters: the network distance filter is by far the most expensive one, even though it cannot outperform the time filter. We contribute the bad performance of the network distance filter to the dataset, in which network distances are generally very short, as the dataset was generated by a breadth-first search of a larger network. A more detailed look into the combination of filters is shown in 19, where it becomes clear that an expensive, but selective filter like the time offset filter, becomes cheap if applied after another more generic filter and in combination gives great results and a very small candidate set. We summarize that the time-offset filter is the most powerful pruning step in our setting. This is because most candidates do not match the specific temporal patterns exhibited by the temporal query graph, such that temporal pruning is very powerful. This also shows how traditional pruning methods only, which do not consider temporal patterns, are not sufficient to efficiently find patterns on temporal graphs.

8 CONCLUSIONS

We proposed first solutions for the problem of searching patterns on temporal social networks. For this problem, existing solutions for graph isomorphism can not be applied directly, since temporal conditions need to be handled. As a baseline approach, we define a temporal pruning heuristic to augment an existing subgraph isomorphism search algorithm. Due to the high run-time of such approach on real social networks, we proposed a data structure to index all occurrences of basic graph structures, to find a candidate set of isomorphic subgraphs quickly at query time. This data structure transforms temporal graphs and temporal graph queries in strings and employs a suffix tree to organize these strings efficiently. Our experimental evaluation shows that this index structure can reduce the run-time of searching small temporal query patterns by orders of magnitude. Still challenges remain open: since the problem of isomorphic subgraph search is exponentially hard in the size of the query graph, we cannot hope to scale to large query graphs. Thus, approximate solutions are required for larger and more complex query patterns. Further, we can relax the problem to estimation of the number of isomorphic subgraphs, rather than returning all occurrences and their location in the graph. This relaxation may allow more efficient

approximations. Another important future aspect of this work is the diversification of patterns as studied in [25, 26] for dense subgraphs only. Applying such diversification to arbitrary subgraphs is a non-trivial task, as the notion of social and temporal overlap has to be redefined.

As you have seen in our running examples, temporal subgraph queries need to be defined very detailed, i.e., each configuration at every point of time needs to be stated. In cases where such level of detail is unneeded (for example when a certain link may or not exist as well at a specific point of time) our algorithm cannot specifically account for this fact. While intuitively, allowing more configurations makes queries less hard to verify, it actually increases the query complexity as the program must now consider several possible configurations instead of one. A future version could benefit in these scenarios.

ABSTRACT

A core requirement of database engine testing is the ability to create synthetic versions of the customer’s data warehouse at the vendor site. A rich body of work exists on synthetic database regeneration, but suffers critical limitations with regard to: (a) maintaining statistical fidelity to the client’s query processing, and/or (b) scaling to large data volumes. In this paper, we present **HYDRA**, a workload-dependent database regenerator that leverages a declarative approach to data regeneration to assure volumetric similarity, a crucial aspect of statistical fidelity, and materially improves on the prior art by adding scale, dynamism and functionality. Specifically, Hydra uses an optimized linear programming (LP) formulation based on a novel *region-partitioning* approach. This spatial strategy drastically reduces the LP complexity, enabling it to handle query workloads on which contemporary techniques fail. Second, Hydra incorporates deterministic post-LP processing algorithms that provide high efficiency and improved accuracy. Third, Hydra introduces the concept of *dynamic regeneration* by constructing a minuscule *database summary* that can on-the-fly regenerate databases of arbitrary size during query execution, while obeying volumetric specifications derived from the query workload. A detailed experimental evaluation on standard OLAP benchmarks demonstrates that Hydra can efficiently and dynamically regenerate large warehouses that accurately mimic the desired statistical characteristics.

1 INTRODUCTION

In industrial practice, a common requirement for database vendors is to adequately test their database engines with representative data and workloads that accurately mimic the data processing environments at customer deployments. This need can arise either in the analysis of problems currently being faced by clients, or in proactively assessing the performance impacts of planned engine upgrades on client applications. While, in principle, clients could transfer their original data and workloads to the vendor for the intended evaluation purposes, this is often infeasible due to privacy and liability concerns. Moreover, even if a client is willing to share the data, transferring and storing the data at the vendor’s site may prove to have impractical space and time overheads, especially in the anticipated Big Data era. For instance, if a customer faces a problem on exabyte (10^{18}) sized relational tables, transferring and storing such data is likely to be infeasible even on the best of systems. Therefore, an important requirement, looking into the future, is to be able to *dynamically* regenerate representative databases, at query execution time that accurately mimic the behavior of the client’s data processing environment.

A rich body of literature exists on data regeneration, beginning with *workload-independent* techniques (e.g [12, 15]), which provide scalable and efficient solutions, but fail to retain complex statistical characteristics such as the sizes of intermediate relations created during execution of a query plan. To address this problem, a particularly potent approach of *workload-dependent* database regeneration was introduced in QAGen [11], and has served as the foundation for many of the practicable systems proposed over the last decade [6, 18]. Workload-dependent techniques aim to generate synthetic data whose behavior is *volumetrically similar* to the client database on the pre-specified query workload. That is, assuming a common choice of query execution plans at the client and vendor sites (ensured through “plan forcing” [3] or “metadata matching” [8]), the output row cardinalities of individual operators in these plans are very similar in the original and synthetic databases. This similarity helps to preserve the multi-dimensional layout and flow of the data, a pre-requisite for achieving similar performance on the client’s workload. As a case in point, the DataSynth [6, 7] tool from Microsoft expresses such volumetric constraints as a Linear Program (LP) whose solution is used to construct the synthetic database.

A common limitation of contemporary techniques (reviewed in detail in Section 8), is that they run into issues of *scale* and *efficiency* at one stage or the other in the regeneration pipeline. This is partly due to their focus on *materialized* static solutions, making them impractical at large volumes. Further, the ability to scale to large query workloads and data volumes has not been clearly established, and validations have been typically restricted to relatively simple and small benchmarks such as TPC-H [2]. These limitations become especially problematic from a futuristic “Big Data” perspective, where we have to contend with enormous data volumes and complex query workloads.

To materially address this challenge, we present **HYDRA**, a data regeneration tool, which ensures that scale and efficiency are addressed through *the entire regeneration pipeline*. As a concrete example, Hydra was able to accurately regenerate the data processing environment of a 100 GB TPC-DS client database with a workload of 131 distinct representative queries, by generating a *database summary* in less than 2 minutes on a vanilla machine. This summary can be used to statically generate a materialized database, or more potently, to *dynamically* regenerate the desired database during query execution. When the former option is chosen, the static database was successfully created in less than 11 minutes. It is important to note here that the summary construction time is *independent* of the data scale – therefore, even the exabyte-sized data scenario alluded to earlier could be modeled in just a few minutes using Hydra!

The key contributions of Hydra are the following:

Extended Workload Coverage: Hydra incorporates a novel LP formulation technique, *region-partitioning*, that can encode volumetric constraints with an LP of low complexity. When compared with the *grid-partitioning* approach used in DataSynth, region-partitioning reduces the LP complexity by many orders of magnitude. For instance, an LP with

Published in Proceedings of the 21st International Conference on Extending Database Technology (EDBT), March 26-29, 2018, ISBN 978-3-89318-078-3 on OpenProceedings.org. Distribution of this paper is permitted under the terms of the Creative Commons license CC-by-nc-nd 4.0.

more than a *billion* variables in DataSynth is reduced to an LP with a few *thousand* variables in Hydra – in fact, in this case, the LP solver crashes on the DataSynth formulation, but runs to completion in less than a minute on the Hydra formulation. The beneficial outcome of the low LP complexity is that it facilitates the efficient handling of much richer query workloads.

Apart from enhancing the workload scale, Hydra also expands the database scope to include relational schemas that have DAG-structured dependency graphs, and the query scope to include DNF filter predicates.

Database Summary and Dynamic Regeneration: A unique feature of our data regeneration approach is that it delivers a *database summary* as the output, rather than the static data itself. This summary is of negligible size, depending only on the query workload and *not* on the database scale. It can be used for *dynamically* generating data during query execution, or for materializing static relations if so desired. This summary-based approach eliminates the enormous time and space overheads incurred by prior techniques in generating and storing data before initiating analysis.

Accuracy with Efficiency: Hydra replaces the *sampling-based* approach to data regeneration in DataSynth by a *deterministic alignment* strategy. The alignment operates directly on the database summary, and is therefore extremely efficient. Further, it does not suffer the probabilistic errors that affect the sampling approach, and therefore delivers better fidelity with regard to volumetric similarity.

Enhanced Evaluation: We evaluate Hydra on a diverse workload of 100-plus queries constructed from the complex TPC-DS benchmark, and the results show that it can efficiently regenerate databases for such workloads at various data scales. Further, our evaluation is more comprehensive than prior techniques, which have largely been evaluated on simpler and small-sized query workloads operating on modest databases. For instance, DataSynth has been evaluated on simple TPC-H database environments that resulted, with their formulation, in LPs with only a few thousand variables.

Integration with CODD: CODD [8] is a graphical tool through which database environments with desired meta-data characteristics can be efficiently simulated without persistently generating and/or storing their contents – i.e. a “dataless” approach. We have integrated Hydra with CODD, thus providing an end-to-end system that fully replicates the client data processing environment at the vendor’s site, and is compliant with the CODD’s “dataless” philosophy.

Organization. The remainder of this paper is organized as follows: A brief background on the key underlying concepts is outlined in Section 2. The Hydra architecture is presented in Section 3, and our new region-based LP formulation in Section 4. The database summary generator and the tuple generator are described in Sections 5 and 6, respectively. Our experimental results are analyzed in Section 7. Related work is reviewed in Section 8, and our conclusions are summarized in Section 9.

2 PRELIMINARIES

In this section, we provide background information on the key foundations – Annotated Query Plans [11] and Cardinality Constraints [6] – that lie under this data regeneration framework.

2.1 Annotated Query Plans

Consider a toy scenario (for ease of presentation) where the client has the database schema shown in Figure 1a, where pk and fk refer to primary-key and foreign-key attributes, respectively.

A sample client query on this schema is shown in Figure 1b, with the corresponding query execution plan in Figure 1c. Note that this execution plan has the output edge of each operator annotated with the associated row cardinality (as evaluated during the client’s execution) – for instance, there are 50000 rows resulting from the join of R and (filtered) S. Such a plan is referred to as an “Annotated Query Plan” (AQP) in [11]. The goal now is to generate synthetic data at the vendor site such that when the above query is executed on this data, we obtain an identical, or very similar, AQP.

R (<u>R_pk</u> , S_fk, T_fk)	S (<u>S_pk</u> , A, B)	T (<u>T_pk</u> , C)
-------------------------------	-------------------------	----------------------

(a) Database Schema

select * from R, S, T where R.S_fk = S.S_pk and R.T_fk = T.T_pk and S.A >= 20 and S.A < 60 and T.C >= 2 and T.C < 3

(b) Example Query

(c) Annotated Query Plan (AQP)

$ R = 80000$	$ S = 700$	$ T = 1500$
$ \sigma_{S.A \in [20,60]}(S) = 400$	$ \sigma_{T.C \in [2,3]}(T) = 900$	
$ \sigma_{S.A \in [20,60]}(R \bowtie S) = 50000$		
$ \sigma_{S.A \in [20,60]} \wedge T.C \in [2,3]}(R \bowtie S \bowtie T) = 30000$		

(d) Cardinality Constraints (CCs)

Figure 1: Example Database Scenario

2.2 Cardinality Constraints

A unified and declarative mechanism for representing AQP data characteristics, called *cardinality constraints* (CCs), was proposed in [6]. For instance, the CCs expressing the AQP of Figure 1c are shown in Figure 1d. The data regeneration technique takes the schematic information and the set of CCs from the client site and produces synthetic data that closely meets these CCs. To make the problem tractable, it is assumed that CCs consist of filters on only *non-key* attributes, and that all joins are between primary keys and foreign keys, typically the case in data warehouses.

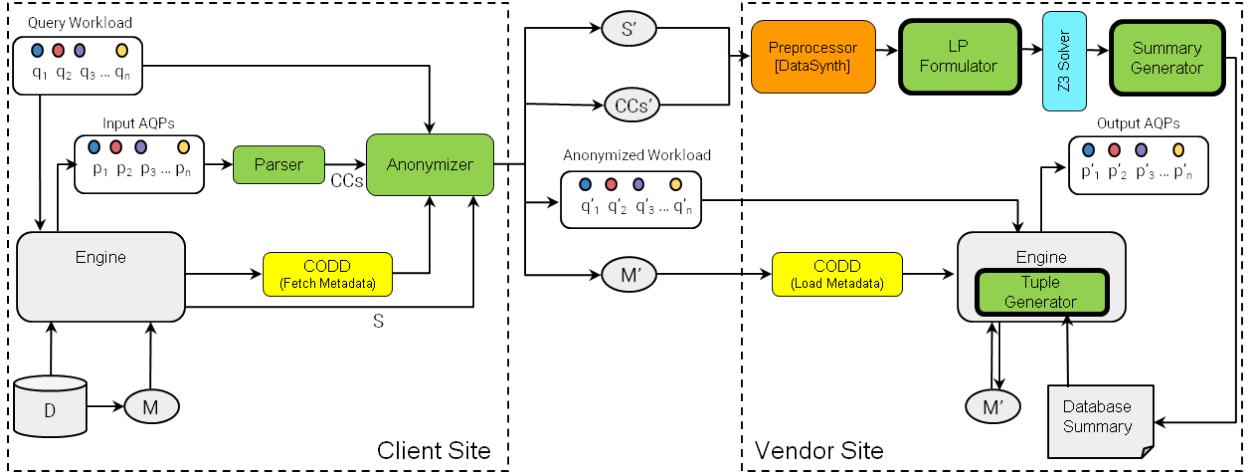

Figure 2: Hydra Architecture

3 THE HYDRA ARCHITECTURE

In this section, we present an overview of Hydra’s architecture, along with a summary of its various components and their interactions with the database engine. A pictorial view of the architecture is presented in Figure 2 – in this picture, the green boxes represent the new components designed specifically for Hydra. Among these, the primary components are the LP Formulator, the Summary Generator, and the Tuple Generator, all shown with thick borders. The other modules have been sourced from the literature, including the preprocessor (orange) from DataSynth [7], the Codd metadata processor (yellow) [8], and the Z3 solver (blue) [14]. (Refer [21] for complete details.)

3.1 Client Site

The information flow from the client to the vendor is as follows: At the client site, Hydra fetches the schema information (S), and the query workload ($q_1, q_2, q_3, \dots, q_n$) with its corresponding AQPs ($p_1, p_2, p_3, \dots, p_n$) obtained from the database engine. The AQPs are converted to equivalent cardinality constraints (CCs) using a Parser. The metadata (M) from the database catalogs is captured with the help of Codd. In order to address client security concerns, all this information (schema, metadata, queries and CCs) is passed through an Anonymizer that suitably masks the information before shipping it to the vendor. Also in this process, non-numeric constants appearing in the queries and plans are mapped to numbers to facilitate LP formulation at the vendor site. Due to this mapping, the final database summary generated at the vendor site also consists of only numeric datatypes. It is possible to reverse this mapping to get back the original datatypes, but is not a relevant consideration with regard to satisfying CCs .

3.2 Vendor Site

The main modules at the vendor site are as follows:

Preprocessor [7]: In this module, sourced from DataSynth, the schema information and CCs obtained from the client are processed to create the input for the LP Formulator. Each relation is solved independently, and this process is initiated by first creating a *view* comprised of its own non-key attributes, augmented with the non-key attributes of the relations on which it depends through referential constraints (both directly or transitively). This transformation results in replacing the join-expression present in

a CC with a view that covers all the attributes (non-key) featured in the relations participating in the join-expression. As a case in point, following views are generated for the example in Figure 1:

$$R_view(A, B, C) \quad S_view(A, B) \quad T_view(C)$$

Further, the last two constraints in Figure 1d can be rewritten as:

$$\begin{aligned} |\sigma_{A \in [20, 60]}(R_view)| &= 50000 \\ |\sigma_{A \in [20, 60] \wedge C \in [2, 3]}(R_view)| &= 30000 \end{aligned}$$

An LP is independently formulated for each view created by the above process. Since the LP complexity is adversely affected by the number of attributes in the view, the view is first decomposed into a set of *sub-views* to reduce the effective complexity. This is achieved as follows: Construct a “view-graph” by first creating a node for each attribute, and then inserting an edge between a pair of nodes if the corresponding attributes appear together in one or more CCs . Further, additional edges are added (if required) to make the view-graph to be *chordal*, a property required to ensure acyclicity in the subsequent processing. Now, the sub-views are identified as the *maximal cliques* in the view-graph.

LP Formulator and Solver: For each view, the LP Formulator takes as input the corresponding set of subviews and applicable CCs , and then constructs the LP. The domain corresponding to each sub-view is partitioned into regions using a novel *region-partitioning* algorithm that takes as input the different cardinality constraints. There is one variable for each region, corresponding to the number of tuples chosen from the region. Each cardinality constraint is encoded as an LP constraint on these variables, and the solution of the LP is used in deciding which tuples to include in the sub-view. The complete details of this algorithm are enumerated in Section 4.

Our region-partitioning strategy is in marked contrast to the *grid-partitioning* strategy used in DataSynth. Grid-Partitioning first intervalizes the domain of each attribute based on the constants appearing in the CCs , and divides the domain into a grid aligned with the interval boundaries for each attribute. If a sub-view has n attributes, and each attribute gets divided into ℓ intervals, then the domain of the sub-view is partitioned into a grid of ℓ^n cells. For each cell in the grid, a variable is created that represents the number of data rows present in that cell. In contrast, our region-partitioning strategy divides the domain into only the number of regions required to precisely write out each

cardinality constraint, and assigns one variable to each region – this typically leads to far fewer variables than grid-partitioning.

To make the above concrete, consider a single view “Person” with the following three selection CCs:

$$\begin{aligned} |\text{age} < 40 \wedge \text{salary} < 40\text{K}(\text{Person})| &= 1000 \\ |20 \leq \text{age} < 60 \wedge 20\text{K} \leq \text{salary} < 60\text{K}(\text{Person})| &= 2000 \\ |\text{Person}| &= 8000 \end{aligned}$$

Grid-partitioning divides the domain of the view as shown in Figure 3a. With a variable assigned to each grid cell, there is a total of 16 variables. In contrast, the region-partitioning strategy partitions the space into 4 regions as shown in Figure 3b, resulting in a tally of only 4 variables.

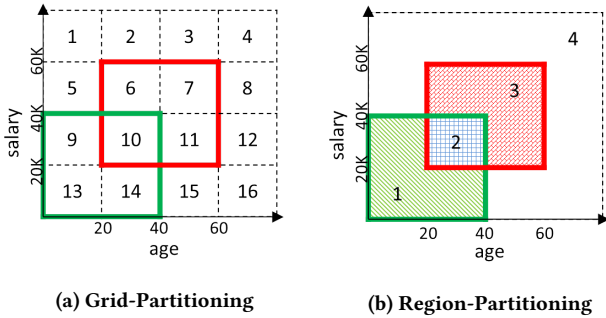

Figure 3: Grid-Partitioning vs Region-Partitioning

The CCs of Person, expressed in terms of LP constraints, are shown below in Figure 4a and 4b for grid-partitioning and region-partitioning, respectively.

$$\begin{aligned} x_9 + x_{10} + x_{13} + x_{14} &= 1000 & y_1 + y_2 &= 1000 \\ x_6 + x_7 + x_{10} + x_{11} &= 2000 & y_2 + y_3 &= 2000 \\ x_1 + x_2 + \dots + x_{16} &= 8000 & y_1 + y_2 + y_3 + y_4 &= 8000 \end{aligned}$$

(a) Grid-Partitioning (b) Region-Partitioning

Figure 4: LP Constraints

The LPs are passed on to the solver, which provides one of the feasible solutions as the output – we have used Z3 [14], a popular SMT solver, to implement this functionality. With region-partitioning, the LP is usually much simpler due to the smaller number of variables. Further, as the cardinality constraints get more complex, the differences in complexity of the LPs produced by region-partitioning and grid-partitioning become more pronounced. This effect is quantified in Section 7.

Summary Generator: This module generates the database summary from the LP solutions obtained on the views. Since partitioning is carried out at a sub-view level, the LP solution, which is expressed in terms of sub-view variables, needs to be mapped to equivalents in the original view space. A sampling-based approach was proposed in [6] for this purpose – for example, say a view (A, B, C) is split into a pair of sub-views (A, B) and (B, C) , the algorithm computes the distributions $Prob(A, B)$ and $Prob(C|B)$. Then, each tuple is generated by first sampling a point from the former distribution, and then sampling a point from the latter conditioned on this outcome.

However, we have chosen not to take this approach since the computational overheads incurred are enormous, and the sampling process introduces errors in volumetric fidelity. Instead, we have designed and implemented an alternative data-scale free, deterministic alignment algorithm (details in Section 5), which produces an intermediate database summary in the output. This component is also responsible for ensuring that the generated summary obeys referential integrity. Finally, summarized relations from corresponding view summary are obtained. An example database summary finally obtained from the AQP shown in Figure 1c, along with additional two AQPs, is shown in Figure 5. Here, entries of the type $a - b$ in the primary key columns (e.g. 101-250 for S_pk in table S), mean that the relation has $b - a + 1$ tuples with values $(a, a + 1, a + 2, \dots, b)$ for that column, keeping the other columns unchanged.

R			S			T	
R_pk	S_fk	T_fk	S_pk	A	B	T_pk	C
1 - 30K	321	1	1-100	0	15	1-600	0
30001 - 50K	621	601	101-250	20	15	601-1500	2
50001 - 60K	71	601	251-500	20	10		
60001 - 70K	121	1	501-700	0	5		
70001 - 80K	1	1					

Figure 5: Example Database Summary

Tuple Generator: The Tuple Generator resides in the database engine. It ensures that whenever a query is fired, data is not fetched from the disk but instead gets generated *on-demand*, using the database summary. The details of this component and its implementation in PostgreSQL are presented in Section 6.

We note in closing that in order to ensure the execution plan chosen at the vendor site is the same as that in the client site, metadata matching is implemented in Hydra using CODD’s metadata transfer feature.

4 LP FORMULATION

An LP for a view V is constructed as follows: For each sub-view s in V , every CC that is within its scope is formulated as an LP constraint. Since sub-views may share common attributes, additional *consistency constraints* are added to the LP to ensure that the marginal distributions along the common set of attributes are identical in the solutions for the sub-views.

In this section, we first present the mathematical basis underlying our formulation of LP constraints for a set of CCs applicable on a sub-view. We then present an algorithm that partitions the domain into the minimum number of regions required to capture each CC precisely, resulting in an LP with the optimal number of variables. Finally, we discuss the formulation of additional consistency constraints to ensure consistency across multiple sub-views belonging to V .

4.1 Mathematical Basis for LP Formulation

Let n denote the number of attributes in the given sub-view s , \mathcal{D}_i the domain of the i th attribute, and \mathcal{D} the data universe $\mathcal{D}_1 \times \mathcal{D}_2 \times \dots \times \mathcal{D}_n$.

We are given a set of m CCs that are applicable on s . For $1 \leq j \leq m$, each constraint C_j is a pair $\langle \sigma_j, k_j \rangle$ where σ_j is a selection predicate and k_j is a non-negative integer equal to the number of rows satisfying predicate σ_j . We assume that each predicate is in disjunctive normal form (DNF).

Simple LP Formulation. Let us first consider a simple way of formulating an LP that encodes all CCs. For each tuple $t \in \mathcal{D}$, assign a variable x_t that denotes the number of copies of t in the sub-view s . Then, the LP formulation shown in Figure 6 ensures that a feasible solution satisfies all CCs, including a constraint on the total size of s .

The problem with this formulation is that the number of variables in the resulting LP is as large as the size of the universe \mathcal{D} . Hence, it is infeasible to work directly with this formulation.

$$\begin{aligned}
(1) & \text{ For each } t \in \mathcal{D}, x_t \geq 0 \\
(2) & \left[\sum_{t \in \mathcal{D}} x_t \right] = k \\
(3) & \text{ For each } j, 1 \leq j \leq m, \left[\sum_{t: \sigma_j(t)=\text{true}} x_t \right] = k_j
\end{aligned}$$

Figure 6: Simple LP formulation

Reduced LP Formulation. We can derive an LP with far fewer variables as follows: We first note that in the simple formulation, variables corresponding to a pair of points $t_1, t_2 \in \mathcal{D}$ that behave identically with respect to a constraint C_j (i.e. $\sigma_j(t_1) = \sigma_j(t_2)$) can be combined together as $(x_{t_1} + x_{t_2})$, for the purposes of satisfying constraint C_j . If this is true that with respect to every constraint C_j for $j = 1 \dots m$, $\sigma_j(t_1) = \sigma_j(t_2)$, then there is no need to treat t_1 and t_2 separately – instead, they can be combined into a single region, and the variables x_{t_1} and x_{t_2} can be merged into a single variable $(x_{t_1} + x_{t_2})$ in every equation, leading to fewer variables in the LP. By repeating this variable merging process recursively until it is no further possible, we arrive at a vastly reduced LP.

We hasten to add that the above LP construction process based on merging variables is only for illustrating the concept – the actual algorithm employed in our system *directly* derives the regions, as described in Section 4.2.

For constraint C and $t \in \mathcal{D}$, let $C(t)$ be an indicator variable:

$$C(t) = \begin{cases} \text{true} & \text{if } t \text{ satisfies } C \\ \text{false} & \text{otherwise} \end{cases}$$

Definition 4.1. For a pair of points $p, q \in \mathcal{D}$ and a set of constraints \mathbb{C} , we say $pR^{\mathbb{C}}q$ if for each $C \in \mathbb{C}$, $C(p) = C(q)$.

OBSERVATION 1. $R^{\mathbb{C}}$ is an equivalence relation on \mathcal{D} .

PROOF. It can be easily seen that $R^{\mathbb{C}}$ is reflexive and symmetric. For transitivity, suppose that for $p, q, r \in \mathcal{D}$, $pR^{\mathbb{C}}q$ and $qR^{\mathbb{C}}r$. Note that for each $C \in \mathbb{C}$, it must be true that $C(p) = C(q)$ and $C(q) = C(r)$. Therefore, it must be true that $C(p) = C(r)$ for each $C \in \mathbb{C}$, showing that the relation is transitive. \square

A partition of \mathcal{D} is a set of subsets of \mathcal{D} such that every element $x \in \mathcal{D}$ is in exactly one of these subsets. The individual sets in a partition are called *blocks*.

Definition 4.2. A set of points b is said to be valid with respect to a set of constraints \mathbb{C} if for any two points $p, q \in b$, $pR^{\mathbb{C}}q$. Given a set of constraints \mathbb{C} , a partition \mathbb{P} of \mathcal{D} is said to be a *valid partition* if for each block $b \in \mathbb{P}$, b is valid with respect to \mathbb{C} .

In a valid partition of \mathcal{D} with respect to \mathbb{C} , any pair of points within the same block satisfy the same set of CCs. Once we

obtain a valid partition \mathbb{P} , the LP can be re-formulated as shown in Figure 7. Instead of a variable for each point $t \in \mathcal{D}$, there is now a single variable x_b for each block $b \in \mathbb{P}$ representing the number of tuples of the sub-view that are contained in this block. Note that the tuples in a sub-view need not be unique, therefore x_b may include duplicates in its count.

$$\begin{aligned}
(1) & \text{ For each } b \in \mathbb{P}, x_b \geq 0 \\
(2) & \left[\sum_{b \in \mathbb{P}} x_b \right] = k \\
(3) & \text{ For each } j, 1 \leq j \leq m, \left[\sum_{b: \sigma_j(b)=\text{true}} x_b \right] = k_j
\end{aligned}$$

Figure 7: Reduced LP formulation

The total number of variables in the reduced LP shown in Figure 7 is equal to the number of blocks in the partition \mathbb{P} and is potentially much smaller than the number of variables in the original LP, shown in Figure 6. Since we desire an LP with the smallest number of variables, we look for a valid partition of \mathcal{D} with the minimum number of blocks. A valid partition with respect to \mathbb{C} is an *optimal partition* if it has the smallest number of blocks from among all valid partitions of \mathcal{D} with respect to \mathbb{C} .

LEMMA 4.3. *The quotient set of \mathcal{D} by $R^{\mathbb{C}}$ is the (unique) optimal partition of \mathcal{D} with respect to \mathbb{C} .*

PROOF. Let \mathbb{P}_1 denote the quotient set¹ of \mathcal{D} by $R^{\mathbb{C}}$. By the definition of an equivalence relation, for any block $b \in \mathbb{P}_1$, all points in b are related to each other by $R^{\mathbb{C}}$, and hence \mathbb{P}_1 is a valid partition.

Suppose that \mathbb{P}_1 is not the unique optimal partition. Then, there must exist another valid partition \mathbb{P}_2 such that $\mathbb{P}_2 \neq \mathbb{P}_1$ and $|\mathbb{P}_2| \leq |\mathbb{P}_1|$. This implies that there exist two points $p, q \in \mathcal{D}$ such that p and q are in different blocks in \mathbb{P}_1 , but in the same block in \mathbb{P}_2 . Since p and q belong to different blocks in \mathbb{P}_1 , it must be true that p and q are not related by $R^{\mathbb{C}}$. But, in \mathbb{P}_2 points p and q belong to the same block, which implies that \mathbb{P}_2 cannot be a valid partition, a contradiction. \square

4.2 Deriving the Optimal Partition

We now present an algorithm to derive the optimal partition of \mathcal{D} with respect to \mathbb{C} . Each constraint $C \in \mathbb{C}$ is in DNF, and is expressed as the union of many smaller “sub-constraints”. Each sub-constraint is the conjunction of many per-attribute constraints, and each per-attribute constraint is a constraint on the values that the attribute is permitted to take. For example, the following constraint on attributes A_1 and A_2 :

$$((A_1 \leq 20) \wedge (A_2 > 30)) \vee (A_1 > 50)$$

is divided into the basic sub-constraints:

$$(A_1 \leq 20) \wedge (A_2 > 30) \text{ and } (A_1 > 50)$$

Algorithm 1 (Optimal Partition) takes a set of DNF constraints as input, and returns a partition with the smallest number of regions with respect to this set. Internally, it invokes Algorithm 2 (Valid Partition) that takes a set of sub-constraints as input and returns a valid partition of the domain with respect to this set.

¹The quotient set is the set of equivalence classes resulting from $R^{\mathbb{C}}$ on \mathcal{D} .

Algorithm 1: Optimal Partition(\mathcal{D}, \mathbb{C})

Input: Universe \mathcal{D} , set of DNF constraints \mathbb{C} **Output:** An optimal partition \mathbb{P}^* of \mathcal{D} subject to \mathbb{C}

- 1 Generate the set of sub-constraints \mathbb{C}' resulting from the constraints in \mathbb{C} ;
 - 2 Construct a valid partition \mathbb{P}' of \mathcal{D} subject to \mathbb{C}' using Valid-Partition(\mathcal{D}, \mathbb{C}') (Algorithm 2);
 - 3 For each block $b \in \mathbb{P}'$, compute the label $\ell(b)$, equal to the set of all constraints in \mathbb{C} that b satisfies. Let L denote the set of all distinct labels from $\{\ell(b) | b \in \mathbb{P}'\}$;
 - 4 Coarsen partition \mathbb{P}' into \mathbb{P}^* as follows: For each label $l \in L$, merge all blocks in \mathbb{P}' whose labels equal l into a single block;
 - 5 Return \mathbb{P}^* ;
-

LEMMA 4.4. Given a set of DNF constraints \mathbb{C} , Algorithm 1 returns an optimal partition of \mathcal{D} with respect to \mathbb{C} .

PROOF. As in the algorithm, let \mathbb{C}' denote the set of sub-constraints resulting from constraints in \mathbb{C} . From Lemma 4.7, we know that \mathbb{P}' is a valid partition with respect to \mathbb{C}' . Consider any block $b \in \mathbb{P}'$. Since b is valid with respect to \mathbb{C}' , and each constraint in \mathbb{C}' is stricter than a corresponding constraint in \mathbb{C} , b is valid with respect to \mathbb{C} . Hence, \mathbb{P}' is a valid partition with respect to \mathbb{C} .

Next, consider that each block b^* in \mathbb{P}^* was obtained by merging blocks in \mathbb{P}' that have the same label. For any pair of points p, q in b^* , it is true they satisfy the same set of constraints in \mathbb{C} , showing that \mathbb{P}^* is a valid partition wrt \mathbb{C} . Also, any two blocks in \mathbb{P}^* have distinct labels (if they had the same label, they would have been merged). Therefore, we conclude using arguments similar to Lemma 4.3 that \mathbb{P}^* is an optimal partition of \mathcal{D} with respect to \mathbb{C} . \square

Deriving a Valid Partition for a Set of Sub-Constraints: We now present an algorithm for deriving a valid partition with a small number of blocks, for a set of sub-constraints \mathbb{C} .

Definition 4.5. For a sub-constraint C and dimension i , let C^i denote the restriction (projection) of C to dimension i . Further, let $C_1^i = \bigwedge_{k=1 \dots i} C^k$ denote the restriction of C to dimensions $1, 2, \dots, i$. For instance, if $C = (A_1 \geq 1) \wedge (A_2 \geq 4) \wedge (A_2 \leq 5) \wedge (A_3 > 6)$, then $C^2 = (A_2 \geq 4) \wedge (A_2 \leq 5)$, and $C_1^2 = (A_1 \geq 1) \wedge (A_2 \geq 4) \wedge (A_2 \leq 5)$. For convenience, if C does not have a constraint along dimension i , then C^i is defined to be “true”.

Our algorithm, described in Algorithm 2, proceeds iteratively, one dimension at a time. Before processing dimension i , it has a partition of \mathcal{D} that is a valid partition subject to constraints along dimensions 1 till $(i-1)$. In processing dimension i , it refines the current partition as follows: For each block b in the current partition, it appropriately divides the block along dimension i if there is a constraint $C \in \mathbb{C}$ such that there are some points in b that satisfy constraint C^i , and some that do not.

Definition 4.6. A constraint C is said to split a block $b \subseteq \mathcal{D}$ if there exist a pair of points $p_1, p_2 \in b$ such that $C(p_1) = \text{true}$ and $C(p_2) = \text{false}$. If C splits b , then refining b by C partitions b into two subsets $b^+(C) = \{x \in b | C(x) = \text{true}\}$ and $b^-(C) = \{x \in b | C(x) = \text{false}\}$.

LEMMA 4.7. Given a set of sub-constraints \mathbb{C} , Algorithm 2 returns a valid partition of \mathcal{D} with respect to \mathbb{C} .

Algorithm 2: Valid-Partition(\mathcal{D}, \mathbb{C})

Input: Universe \mathcal{D} , set of sub-constraints \mathbb{C} **Output:** A valid partition \mathbb{P} of \mathcal{D} subject to set of sub-constraints \mathbb{C}

- 1 $\mathbb{P}^0 = \{\mathcal{D}\}$ // A partition with one set, \mathcal{D} .
 - 2 **for** i from 1 to n **do**
 - 3 $M \leftarrow \mathbb{P}^{i-1}$;
 - 4 **foreach** $C \in \mathbb{C}$ **do**
 - 5 $M' \leftarrow \emptyset$;
 - 6 **foreach** block $b \in M$ **do**
 - 7 **if** C^i splits b **then**
 - 8 Let b^+ and b^- result from refining b with C^i ;
 - 9 Add b^+ and b^- to M' ;
 - 10 **else**
 - 11 Add b to M' ;
 - 12 $M \leftarrow M'$;
 - 13 $\mathbb{P}^i \leftarrow M$;
 - 14 **Return** \mathbb{P}^n ;
-

PROOF. For $1 \leq i \leq n$, let $\mathbb{C}_1^i = \{C_1^i | C \in \mathbb{C}\}$. We show by induction on i that after the i th iteration of the outermost for loop in the algorithm, \mathbb{P}^i contains a valid partition of \mathcal{D} with respect to \mathbb{C}_1^i . Since $\mathbb{C}_1^n = \mathbb{C}$, it follows that after n iterations, \mathbb{P}^n contains a valid partition of \mathcal{D} with respect to \mathbb{C} . We consider $i = 0$ as the base case, and the set \mathbb{C}_1^0 as a set of “always true” constraints. Hence, \mathbb{P}^0 , which consists of only one element, \mathcal{D} , is a valid partition with respect to \mathbb{C}_1^0 .

For the inductive step, suppose that for $i > 0$, \mathbb{P}^{i-1} is a valid partition of \mathcal{D} with respect to \mathbb{C}_1^{i-1} . For each block $b \in \mathbb{P}^{i-1}$, two cases are possible: (1) b is not split by C^i , for any $C \in \mathbb{C}$. Then b is valid with respect to \mathbb{C}_1^i , and will be retained in \mathbb{P}^i . (2) b is split by one more constraints C^i . The algorithm iterates through all such constraints that split b , and partitions block b such that every resulting block is valid with respect to each C^i , $C \in \mathbb{C}$.

We next note that \mathbb{P}^i is indeed a partition of \mathcal{D} (i.e. the union of all blocks equals \mathcal{D}). To see this observe that each block $b \in \mathbb{P}^{i-1}$ is either present in \mathbb{P}^i or has been refined and all its constituent blocks (whose union equals b) are in \mathbb{P}^i . Thus, \mathbb{P}^i is a valid partition with respect to \mathbb{C}_1^i . This proves the inductive step. \square

Consistency Constraints. Since different sub-views can have common attribute(s), additional constraints need to be added to ensure that their distributions for the common attribute(s) are the same. In order to do so, we may need to further refine the partition generated from the above procedure. Specifically, consider a pair of sub-views s_1 and s_2 with attribute sets \mathbb{A}_1 and \mathbb{A}_2 respectively, such that $\mathbb{A}_1 \cap \mathbb{A}_2 \neq \emptyset$. Let $\mathcal{D}^1 = \prod_{i \in \mathbb{A}_1} \mathcal{D}_i$, and $\mathcal{D}^2 = \prod_{j \in \mathbb{A}_2} \mathcal{D}_j$ be the corresponding domains for s_1 and s_2 respectively, and $\mathcal{D}^{1,2} = \prod_{i \in \mathbb{A}_1 \cap \mathbb{A}_2} \mathcal{D}_i$. Let the partitions obtained on \mathcal{D}^1 and \mathcal{D}^2 be \mathbb{P}_1 and \mathbb{P}_2 , respectively. In order to keep \mathbb{P}_1 and \mathbb{P}_2 consistent with each other, we need to ensure that their region boundaries are aligned with each other, and this is achieved by refining \mathbb{P}_1 and \mathbb{P}_2 so that they have common boundaries along dimensions $\mathbb{A}_1 \cap \mathbb{A}_2$. We consider the union of the “split points” of \mathbb{P}_1 and \mathbb{P}_2 along dimensions $\mathbb{A}_1 \cap \mathbb{A}_2$ and further for each block in \mathbb{P}_1 (and \mathbb{P}_2), we refine this block until it no longer crosses such a split point. Finally, we add LP constraints that equate distributions of the common attributes in \mathbb{P}_1 and \mathbb{P}_2 .

5 DATABASE SUMMARY GENERATOR

This component takes the LP solution for each view as the input and generates the database summary, which as mentioned previously, can be used for dynamically generating data for query execution, or can optionally be used to generate the materialized database.

Recall that a variable in the LP (for a view) represents an underlying block in a sub-view’s partition, and its assigned value is the number of rows present in that block – this value is hereafter referred to generically as NUMTUPLES. The collection of NUMTUPLES values represent the sub-view solutions, and these solutions are integrated to obtain the solution for the complete view. However, since each view is solved independently, the referential constraints that exist between the corresponding relations may be lost in these view solutions. Therefore, they may have to be modified to ensure global consistency. Finally, it is necessary to extract relations from the views in order to populate the database. Accordingly, the summary generator component in Hydra is responsible for the following sequence of tasks:

- (1) Constructing a solution for complete views
- (2) Instantiating view summaries
- (3) Making view summaries consistent wrt each other
- (4) Extracting relation summaries from view summaries

5.1 Constructing Solution for the View
